This relatively high incidence of macrosomia is important to recognize because of the complications associated with this condition. These include increased maternal and fetal trauma, shoulder dystocia with resulting Erb's palsy, perinatal asphyxia, meconium aspiration, increased rate of labor disorders, and postpartum hemorrhage.[10-13] We chose to evaluate the incidence of cesarean section in response to arrest and protraction disorders because of its relatively common occurrence and because such disorders are defined by standard and generally accepted criteria.[7] In our study the incidence of cesarean section because of arrest and protraction disorders in the postdate pregnancies with macrosomic infants was 22.2% and was significantly greater than the 10.1% observed for postdate pregnancies with nonmacrosomic infants ($p < 0.01$). Others[9, 13] have also demonstrated that there is an increased incidence of cesarean section because of arrest and protraction disorders in this population. Parks and Ziel[13] have advocated primary cesarean section for fetuses with an estimated fetal weight >5000 gm to avoid the potential complications of vaginal delivery of an infant believed to be ≥4500 gm.

Present protocols with regard to the conservative management of the postdate pregnancy have emphasized the detection of fetal asphyxia but have neglected to account for increasing fetal size. The rationale that is often given for prolongation beyond term of a pregnancy with good dates is the avoidance of cesarean section thought to result from induction of labor with an unfavorable cervix. It may not be appropriate, however, to screen a postdate pregnancy solely for asphyxia while allowing the fetus to continue to grow, thereby also increasing the chances for cesarean section on the basis of fetal size. Clinical suspicion based on a symphyseal-fundal height >40 cm or maternal risk factors such as maternal age, parity, prepregnant obesity, maternal diabetes, or previous birth of a large infant has been shown to be inadequate, leaving >50% of macrosomic infants undetected.[9] Whereas routine ultrasonographic screening is advocated in the diabetic pregnancy in which the incidence of macrosomatia ranges from 10% to 28%,[14, 15] it is rarely, if at all, used in the postdate pregnancy where the absolute incidence of large infants may be higher.

The third purpose of this study was to evaluate the accuracy of an ultrasonographically determined estimated fetal weight obtained at ≥41 weeks' gestation. In our study, 87% of the estimated fetal weights were within 15% of the actual birth weights and 68% were within 10% of the actual weights. The sensitivity and specificity of an estimated fetal weight >4000 gm to predict an actual birth weight >4000 gm were 61% and 91%, respectively. The positive predictive value of 70% indicates that the ultrasonographic diagnosis of macrosomia was associated with actual macrosomia in 7 of every 10 cases. The negative predictive value of 87% indicates that when ultrasonography excluded macrosomia, it was present in only 1.3 of 10 cases. These findings occurred despite the fact that the estimates were determined by multiple operators. We chose an estimation of fetal weight based on a standard equation determined from measurements of the abdominal cir-

cumference and femur length because these measurements could be easily obtained in all patients, whereas a BPD could not be adequately measured in 66 (20.8%) of the 317 patients. Various methods for the ultrasonographic detection of the macrosomic infant have been suggested. These have included evaluation of estimates of fetal weight as determined by the equation of Shephard based on measurements of the BPD and abdominal circumference, and that of Hadlock based on measurements of the abdominal circumference and femur length. Others have used various indices such as the BPD or abdominal circumference alone, or the head circumference or femur length/abdominal circumference ratios.[16, 17] The latter two are based on the premise that the abdominal circumference should be relatively increased in the macrosomic infant. The majority of these studies have focused on the infant of the diabetic mother or on the large-for-gestational-age infant, delivered at a wide variety of gestational ages. It has been suggested that the body proportions of the postdate infant may be different from that of the diabetic infant and thus it is uncertain whether the above studies can be applied to the postdate population.[16]

A study by Guzick et al.[18] that evaluated the use of standard equations to estimate fetal weight in the postdate population concluded that the predictive value of these equations was not related to gestational age. He did not, however, determine the ability to predict macrosomia. We found the sensitivity and specificity of our ultrasonographic prediction of macrosomia in the postdate population to be similar to those reported by other studies of infants at <40 weeks' gestation or in diabetic pregnancies.[17, 19] The fact that they did not vary greatly from other studies may be a reflection of the error of the technique.

The addition of the determination of an estimated fetal weight at the first visit at ≥41 weeks' gestation can be easily accomplished and may be a valuable adjunct in the management of these pregnancies. We plan further studies that will incorporate this determination into a prospective management scheme for this population. This is needed to determine whether induction of labor would, in fact, result in a lower incidence of cesarean deliveries or birth trauma when compared with expectant management.

In conclusion, this study has demonstrated that the incidence of macrosomia in postdate pregnancies is considerable, that this condition is associated with an increased rate of cesarean section because of arrest and protraction disorders, and that real-time ultrasonography can be used with reasonable accuracy to predict this condition in the postdate pregnancy.

Discordant twins—A prospective study of the diagnostic value of real-time ultrasonography combined with umbilical artery velocimetry

Michael Y. Divon, MD, Barbara A. Girz, DO, Avi Sklar, MD, Denise A. Guidetti, MD, and Oded Langer, MD

Bronx, New York

This study was undertaken to evaluate the role of Doppler velocimetry combined with intertwin differences in ultrasonographically derived estimated fetal weight, biparietal diameter, abdominal circumference, and femur length as a comprehensive test for the prediction of discordancy. The following cutoff values were used to indicate abnormal test results: Δ biparietal diameter > 6 mm, Δ abdominal circumference > 20 mm, Δ femur length > 5 mm, Δ estimated fetal weight > 15%, and Δ systolic/diastolic ratio > 15%. Discordancy was identified when the birth weight difference exceeded 15%. The study population consisted of 58 consecutively evaluated third-trimester twin gestations. Eighteen sets of twins were discordant. None of these tests was uniformally successful in identifying twin discordancy; in three instances, all test results were normal. The diagnostic accuracy provided by ultrasonography was not significantly different from that provided by Doppler velocimetry. Overall the best predictor appeared to be the presence of either Δ systolic/diastolic ratio > 15% or Δ estimated fetal weights > 15%, which correctly identified 14 of the 18 discordant twins and misclassified only five of the 40 concordant pairs. This combination also had the highest positive and negative predictive values (73% and 90%, respectively). (Am J Obstet Gynecol 1989;161:757-60.)

Key words: Twin gestation, discordancy, ultrasonography, Doppler

Discordant growth in twin gestation can result from placental crowding, twin-to-twin transfusion, a poor placental implantation site, or chromosomal anomalies.[1] This high-risk condition is associated with a significant increase in perinatal morbidity and mortality.[1,2] Use of discordancy as an outcome variable has its pitfalls (i.e., discordant twins who are both normal or a growth-retarded pair, which may not be discordant).

The clinical diagnosis of discordant growth in twin gestation is almost impossible.[1] With the use of real-time ultrasonography, various indices have been suggested for identification of discordant growth. These include intrapair differences in biparietal diameters, abdominal circumferences, and femur lengths.[3-6] Since the definition of growth discordancy is based on birth weight differences, ultrasonographic estimates of fetal weight have also been useful in making this diagnosis.

Recent studies have suggested that twin discordancy is associated with unequal fetoplacental blood flows. Thus umbilical artery flow velocimetry has been advocated for prediction of this condition.[7,8] These studies, however, did not compare the diagnostic value of umbilical artery flow velocimetry in relation to other established ultrasonographic criteria for diagnosis of discordant growth in twin gestation.

The purpose of this study was to examine the diagnostic value of various ultrasonographic indices combined with Doppler assessment of umbilical artery velocity waveforms as a comprehensive test for detection of twin discordancy.

Material and methods

The study population consisted of patients evaluated at the Maternal-Fetal Assessment Center at the Albert Einstein College of Medicine. The following were criteria for inclusion in the study: (1) third-trimester twin gestation with both fetuses alive at the time of the examination, (2) well-documented dates (by reliable menstrual history in agreement with an ultrasonographic examination before 22 weeks' gestation), (3) intact membranes and mother not in labor, (4) delivery occurred within 2 weeks of ultrasonographic-Doppler evaluation. Morphometric measurements were made with real-time scanning (either ATL-Ultramark IV or an Aloka 633) equipment, and included intrapair dif-

Table I. Coefficients of correlation between percent difference in birth weight and percent difference in ultrasonographic-Doppler indices

	R	*p*
% ΔBW vs. % ΔBPD	0.33	NS
% ΔBW vs. % ΔAC	0.49	NS
% ΔBW vs. % ΔFL	0.55	NS
% ΔBW vs. % ΔS/D	0.57	NS
% ΔBW vs. % ΔEFW	0.70	<0.05

ferences in (1) biparietal diameters—ΔBPD, (2) abdominal circumferences—ΔAC, (3) femur length—ΔFL. These measurements were performed by means of standard techniques and also allowed the calculation of the estimated fetal weights (EFW) (based on AC-FL[9]) and the intrapair difference in EFWs (ΔEFW).

Umbilical artery velocity waveforms were analyzed with a continuous-wave Doppler device (Fetal-Flo, Medasonics, Inc., Mountain View, Calif.). The locations of the umbilical cords were determined by real-time ultrasonography, and the Doppler transducer was then aimed in the direction of each umbilical cord. Thus umbilical cords were identified by their location and by the differing fetal heart rates.[10] We accepted recordings for analysis only after obtaining a steady state of at least five consecutive pulsatile arterial waveforms simultaneously displaying the nonpulsatile signal generated by umbilical venous flow (flowing in the opposite direction). No waveforms were obtained during periods of fetal breathing movements, body movements, or cardiac arrhythmias. The umbilical artery flow velocity waveform was characterized by the ratio of peak systolic/end-diastolic frequencies (S/D ratio). Three separately obtained S/D ratios were derived per fetus, and the results were averaged. The intrapair S/D ratio difference was expressed as a percentage of the larger twin's S/D ratio (ΔS/D).

The following cutoff levels were used prospectively to indicate abnormal test results: (1) ΔBPD > 6 mm, (2) ΔAC > 20 mm, (3) ΔFL > 5 mm, (4) ΔS/D > 15%, (5) ΔEFW > 15%.[4, 5, 11] Bed rest at home was recommended when ΔEFW > 15%.

The intrapair birth weight (BW) difference was expressed as a percentage of the larger twin's birth weight (ΔBW). Discordancy was defined as ΔBW > 15%.[1, 12] The coefficients of correlation (R) between %ΔBW and the percent difference in each of the ultrasonographic-Doppler variables were calculated. To evalute the usefulness of the various indices for predicting twin discordancy, we calculated the specificity, sensitivity, and positive and negative predictive values for single and combined test results.

Results

Fifty-eight sets of twins fulfilled the study criteria and formed the population for this study. Of the 58 women, 40 (69%) were delivered of concordant twins and 18 (31%) were delivered of discordant twins. There was a statistically significant difference in the mean birth weight between the concordant twins (2627 ± 526 gm; range, 1680 to 3700) and the discordant twins (2192 ± 315 gm; range, 1170 to 3050; $p < 0.01$). The mean gestational age at delivery was 37.4 ± 1.2 weeks (range, 30 to 42); there was no difference between the concordant and the discordant pairs.

Table I presents the coefficients of correlation between the percent difference in birth weight and the percent difference in each of the ultrasonographic-Doppler indices used in this study. Only the %ΔEFW was significantly correlated with the %ΔBW ($R = 0.7$, $p < 0.05$).

Table II presents the sensitivity, specificity, and positive and negative predictive values of single and combined test results. None of these five tests was uniformally successful in identification of growth discordancy in twins. Overall, the best predictor appeared to be the presence of either ΔEFW > 15% or ΔS/D > 15%, which correctly identified 14 of the 18 growth-discordant twins (sensitivity of 78% and specificity 87%). This combination of tests also had the highest positive and negative predictive values (73% and 90%, respectively). In three instances with mild birth weight discordancy, results of all tests had been normal (Table III). The diagnostic accuracy provided by Doppler velocimetry was not significantly different from that provided by real-time ultrasonography.

Comment

This study assessed the diagnostic value of real-time ultrasonography combined with umbilical artery velocimetry as a comprehensive test for prediction of twin discordancy. The results indicate that none of the tests evaluated in this study was consistently successful in identifying growth discordancy. Overall, the best predictor seemed to be the presence of either ΔEFW > 15% or ΔS/D > 15%. This combination correctly identified 14 of the 18 discordant sets of twins.

The most common definitions of growth discordancy are based on intertwin birth weight difference expressed as a percentage of the larger twin's weight.[1] A wide range of cutoff values for %ΔBW has been discussed in the literature. These values range from ΔBW > 15% to ΔBW > 40%.[1, 13] Although most clinical problems occur when the ΔBW exceeds 25%, the lower end of this spectrum was chosen for this study because we wanted to screen and include all possible pairs of discordant growth despite the obvious possibility of an increased incidence of false-positive test results. The incidence of growth discordancy in our study population was 31%. Other studies have reported a somewhat lower incidence of 19% to 23% with the same definition for discordancy.[1, 13] This difference may be explained

Table II. Sensitivity, specificity, and positive and negative predictive values for single and combinations of test results

	Sensitivity (%)	*Specificity (%)*	*Positive predictive value (%)*	*Negative predictive value (%)*
ΔS/D > 15%	66	64	55	75
ΔEFW > 15%	47	81	56	74

by differences in sample size and by the fact that our study population was comprised of high-risk referrals.

Real-time ultrasonography is essential for the diagnosis of discordancy in twins. Initially, discordancy was diagnosed by evaluation of the BPD. Crane et al.[3] compared the growth of the BPD between concordant twins and appropriate-for-gestational-age singleton gestations and detected no significant differences. They also showed that the mean difference in BPD among concordant twins was 1.8 mm (range, 0 to 5 mm). However, the mean difference in BPD among discordant twins was 12.3 mm (range, 5 to 31 mm). A study by Leveno et al.[11] suggested that a cutoff value of ΔBPD ≥ 6 mm is associated with discordancy and poor fetal outcome. In our study, the sensitivity and specificity of ΔBPD > 6 mm for predicting discordancy were 30% and 88%, respectively. These results imply that most discordant twins do not demonstrate significant intrapair differences in BPD and are in agreement with other studies that reported disappointing results with this variable.[2, 3, 5]

Grumbach et al.[14] evaluated the abdominal circumference in twin and singleton gestations. Their results indicated a significant decrease in the growth rate of the abdominal circumference in twins starting at approximately 32 weeks of gestation. Large intertwin differences in abdominal circumferences were reported to be associated with neonatal birth weight discordancy by Barnea et al.[4] In the present study the positive and negative predictive values for ΔAC > 20 mm were 53% and 77%, respectively. These results indicate that a substantial difference between the abdominal circumferences will correctly predict approximately one half of the discordant pairs. Several investigators evaluated this index and reported its sensitivity to range from 66% to 80% and its specificity to range from 74% to 85%.[13] The slightly lower sensitivity obtained in our study may be related to the prospective nature of the study and to the fact that we used measurements obtained by multiple perinatologists.

During the third trimester, growth of the fetal femur in twins is not significantly different from that in singleton gestations.[14] Storlazzi et al.[5] evaluated several ultrasonographic indices as predictors of discordant fetal growth and showed that ΔFL ≥ 5 mm had a positive predictive value of 75%. A slightly lower positive predictive value of 63% was calculated in our patient population.

The neonatal diagnosis of discordant growth in twin gestation is based on birth weight criteria. Therefore it is reasonable to evaluate the value of intrapair differences in EFW for making this diagnosis. In our study, %ΔEFW was the only ultrasonographic-Doppler variable that had a statistically significant correlation with %ΔBW ($R = 0.7, p < 0.05$). The sensitivity of 47% and specificity of 77% for ΔEFW > 15% are not markedly different from those obtained for ΔAC > 20 mm. This is not surprising since the various formulas available for calculating EFW emphasize the abdominal circumference much more than any other variable. As the ΔEFW increases, the likelihood of one fetus being small for gestational age is also increased. This fact was noted by O'Brien et al.,[12] who reported that ΔEFW ≥ 30% is associated with a small-for-gestational-age newborn in 66% of cases.

Abnormal umbilical artery velocity waveforms have been detected in approximately 50% of growth-retarded singleton pregnancies.[15] Such waveforms probably reflect increased placental impedance to blood flow and are consistent with histologic evidence of a

placental vascular lesion.[16] Several investigators have reported the use of umbilical artery velocimetry for surveillance of twin pregnancies.[7, 8, 10, 17, 18] Farmakides et al.[7] used an absolute cutoff value of $\Delta S/D > 0.4$ and found this test useful for identification of discordant growth. Their sensitivity and specificity values were the same as those detected by us with a relative cutoff level of $\Delta S/D > 15\%$ (i.e., 73% and 82%, respectively). However, no comparison was made between umbilical artery velocimetry and real-time ultrasonography. Saldana et al.,[10] who compared $\Delta S/D$ to ultrasonographically derived ΔEFW, concluded that Doppler velocimetry was a better predictor of discordancy. The difference between their results and ours could partially be a result of different definitions of discordancy. Whereas Saldana et al. used an absolute value of $\Delta BW > 350$ gm, we chose a relative birth weight difference of 15%. Nimrod et al.[17] evaluated a combination of ΔAC, ΔBPD, and $\Delta S/D$ in either the fetal aorta or the umbilical artery and found that 9 of their 11 discordant pairs had at least two abnormal variables. However, these combinations were associated with a high false-positive rate. Although discordant S/D ratios may reflect unequal fetoplacental circulations, the neonatal definition of discordancy is not related to umbilical arterial flow. A significant birth weight discordancy was identified in one of our patients who demonstrated concordant S/D ratios associated with twin-to-twin transfusion.

In conclusion, the results of our study indicate that Doppler velocimetry complements real-time ultrasonography for the diagnosis of discordant fetal growth in twin pregnancies. The presence of either $\Delta S/D > 15\%$ or $\Delta EFW > 15\%$ correctly identified 14 of the 18 discordant twins and misclassified only 5 of the 40 concordant pairs. Ideally, an accurate ultrasonographic estimate of fetal weights should suffice for making this diagnosis. However, ultrasonographic estimates of fetal weight have inherent inaccuracies[19] that are amplified in this situation by head compression, unfavorable fetal lie, and the fact that an overlying fetus may cover parts of the other fetus. Abnormal umbilical artery velocity waveforms are not as directly related to the definition of discordancy as is an increased ΔEFW, but they do reflect unequal fetal-placental circulations, which is probably a major contributor to growth discordancy in twin pregnancies.

Doppler umbilical artery waveform indices—Normal values from fourteen to forty-two weeks

Susan K. Hendricks, MD, Tanya K. Sorensen, MD, Keith Y. Wang, MD, PhD, Jeanette M. Bushnell, MSN, Elaine M. Seguin, RNC, and Rosalee W. Zingheim, BSN
Seattle, Washington

Normal values for Doppler waveform indices of the umbilical artery have been reported for gestational ages of 20 to 40 weeks in small numbers of normal patients. We evaluated 590 patient studies performed at 2-week intervals from 14 to 42 weeks' gestation on patients without medical or pregnancy complications. Readings were obtained during fetal quiet times (no fetal breathing or movements). Values for A (systolic) and B (diastolic) pressures were plotted as Pourcelot (A − B/A) and A/B ratios. Mean, SD, and 95% confidence limits were derived, and the skewness, kurtosis, and regression correlations were calculated. No diastolic flow was found in any pregnancy >15 weeks' gestation (n = 25) or in 50% of the gestations between 15 to 17 weeks (n = 25). When diastolic pressure equals zero, the Pourcelot ratio value equals one and the A/B ratio approaches infinity and loses meaning. Recent work by Thompson et al. suggests that the Pourcelot ratio fits a normal distribution from 20 to 40 weeks' gestation and that the A/B ratio (which does not fit a normal curve) may be transformed to a normal distribution by conversion of the A/B ratio to 1/1 − Pourcelot ratio. Our data supports the normality of both indices from 18 to 42 weeks' gestation, but these assumptions are not applicable as the Pourcelot ratio approaches one or as the A/B ratio approaches infinity. Knowledge of normal umbilical flow ratios at gestational ages from 18 weeks may allow early detection and directed management of high-risk pregnancies. (Am J Obstet Gynecol 1989;161:761-5.)

Key words: Doppler velocimetry, normality, Pourcelot ratio, A/B ratio

The utility of fetal velocimetry in antepartum assessment continues to be controversial. Although a plethora of research has attempted to support and clarify the use of Doppler ultrasonography for high-risk assessment, the majority of clinical practitioners remain uncertain about the position of Doppler ultrasonography in the schemata of antenatal testing. The classic methods of assessment (nonstress tests, contraction stress tests, and biophysical profile tests) are similarly inconsistent at gestational ages <28 weeks. The physiologic variability of system development in the fetus is responsible for the lack of reliability and predictability in the second trimester. The genesis and development of uterine and umbilical blood flow is phylogenically earlier than that of respiratory rhythmicity and fetal heart rate variability, and thus provokes the hypotheses that Doppler ultrasonography might be an appropriate modality for the selection and management of high-risk pregnancies at younger gestational ages than current techniques allow. To date, normal curve development has been limited by the small numbers of patients tested between 20 and 40 weeks' gestation.[1-3] Furthermore, most Doppler ultrasonographic studies have used parametric statistics to evaluate the A/B ratio. This ratio, which approaches infinity as B values approach zero, has been shown by statistical analysis to be non-normal. Our study calculates the distributions of the Pourcelot and A/B ratios (after mathematical transformation to a normal distribution by the conversion of A/B to 1/1 − Pourcelot ratio) in a large low-risk population and offers a suggestion for the future use and direction of fetal velocimetry.

Material and methods

Fetal velocimetry of the umbilical arteries was performed on 590 patients with low-risk pregnancies. Patients with medical complications during or preceding pregnancy were excluded, as were all tests on patients with complications of pregnancy. Fetal anomalies were excluded by ultrasonography.

Tests were performed at 2-week intervals from 14 to 42 weeks' gestation. Readings of the umbilical artery were obtained by continuous-wave Doppler ultra-

sonography (4 MHz) (MedaSonics Vasculab D-10, Mountain View, Calif.) in the manner originally described by Trudinger et al.[1] Patients were placed in the left lateral recumbent position during times of examination. Measurements were taken during periods of fetal inactivity and apnea, which have been shown to affect the accuracy of measurement. Real-time spectral analysis was used to identify the maximum amplitude of the umbilical arterial waveform concomitantly visualized with the umbilical venous signal. The signal was recorded for a minimum of 10 waveforms and measurements were performed by hand. An average was calculated for a minimum of five signals to obtain each separate value for A and B. Only low-risk singleton gestations were evaluated. Patients were not initially included in the study if there were antecedent maternal or fetal abnormalities or complications (hypertension, diabetes, endocrine disorders, fetal anomalies) and were removed from the study if a pregnancy-related complication arose (intrauterine growth retardation, pregnancy-induced hypertension, oligohydramnios).

Values for A (systolic) and B (diastolic) pressures were obtained and plotted as Pourcelot ratio. To decrease the potential effect of extremely high A/B ratios, which may approach infinity as values of B approach zero, values for A/B were calculated from its relationship to the Pourcelot ratio (A/B = 1/1 − Pourcelot ratio) as previously described by Thompson et al.[4] This relationship has been shown to translate the A/B curve into a normal distribution. Mean, SD, and 95% confidence intervals were calculated and fitted to regression curves. Distribution curves were developed for Pourcelot and A/B ratios at each gestational age and for the total distribution, and the skewness and kurtosis (graphic measures of symmetry and distribution) of these curves were analyzed.

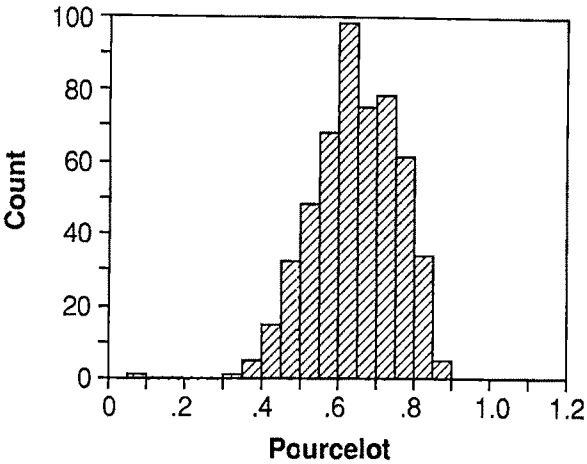

Fig. 1. Frequency distribution, Pourcelot ratio.

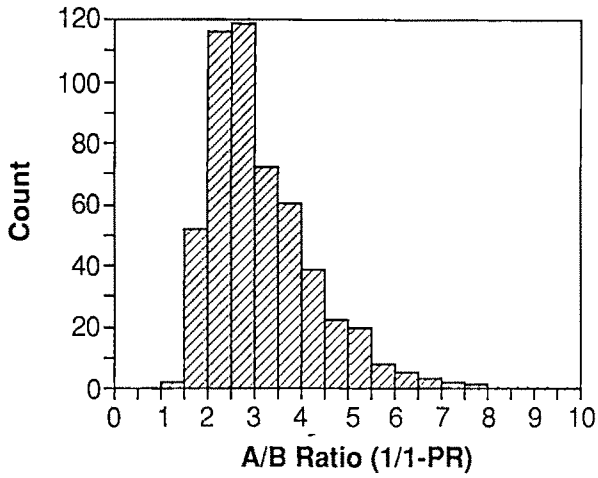

Fig. 2. Frequency of distribution, A/B ratio.

Results

The n for each gestational age and the calculated values of mean, SD, and 95% confidence intervals for Pourcelot and A/B ratios are listed in Tables I and II. Pourcelot ratio has been shown to be normal at all gestational ages in previous studies by Thompson et al.[5] This assumption of normality holds for the A/B ratio only when converted directly from the Pourcelot ratio for each gestational age group, which has little significance at gestational ages <18 weeks (when B = O and Pourcelot ratio = 1). For each gestational age ranking, skewness and kurtosis were calculated to graphically estimate the normality of the distribution for each ratio. Skewness and kurtosis were measured for the entire population set, excluding 14 and 16 weeks' gestation (Tables I and II). All values of B at 14 weeks' gestation were zero (n = 25), and 13 of 25 values at 16 weeks' were zero, which makes statistical manipulation of these subsets meaningless (Pourcelot ratio = 1 and A/B = infinity). The skew of these data was immense, which rendered the use of parametric statistics invalid. Skewness, a measure of symmetry, was calculated at 0.258 for Pourcelot ratio and at 0.439 for the A/B ratio for the data from 18 to 42 weeks' gestation, which strengthened the argument of normality (showing a nonsignificant positive, or right-handed, skew). Kurtosis, a graphic measure of distribution shape, was calculated at 1.043 for Pourcelot ratio and at 1.002 for the A/B ratio (demonstrating a nonsignificant leptokurtosis). The distribution curves for the total data set of Pourcelot and A/B (1/1 − Pourcelot ratio) ratios are shown in Figs. 1 and 2.

The gestational progression of Pourcelot ratio is represented in Fig. 3. The mean and 95% confidence intervals are plotted. Regression lines were fitted to the curve with a correlation coefficient of r = 0.95. The mean and 95% confidence intervals of the A/B ratio are plotted in Fig. 4 with the fitted regression curves (r = 0.89). These calculations were obtained by a direct conversion of A/B from the Pourcelot ratio by the formula (1/1 − Pourcelot ratio) as previously described.

Comment

Doppler waveform indices have been studied by multiple investigators as a possible measure of fetal well-being since original reports by Fitzgerald and Drumm (1977)[6] and McCallum et al. (1978)[7] reported the technical ability to measure the blood flow velocity waveforms in the umbilical artery of the fetus. Normal studies have been reported by some investigators but in relatively small numbers and generally encompassing the gestational ages between 28 and 40 weeks.[1-3] Thompson et al. have reported normal values for 35 patients between 20 and 40 weeks' gestation with the n at each gestational age ranging from 15 studies at 20 weeks to 34 studies at 36 weeks.[4] In this study we report a series of 590 normal low-risk patient studies from 14 to 42 weeks' gestation. The assumption of normality for Pourcelot ratio as proved by Thompson et al.[4] is reconfirmed by our data for gestations of 18 to 42 weeks. Similarly, calculation of the mean and 95% confidence intervals of the A/B ratio by direct conversion from the normal distribution of the Pourcelot ratio (A/B = 1/1 − Pourcelot ratio) transforms the A/B ratio into a normal distribution and allows the valid use of parametric statistical methods. This statistical treatment does not appear valid for gestations <18 weeks because of the high percentage of fetuses without diastolic flow.

Early studies of fetal well-being as predicted by fetal velocimetry were encouraging. Various investigators have found a good correlation between an increased

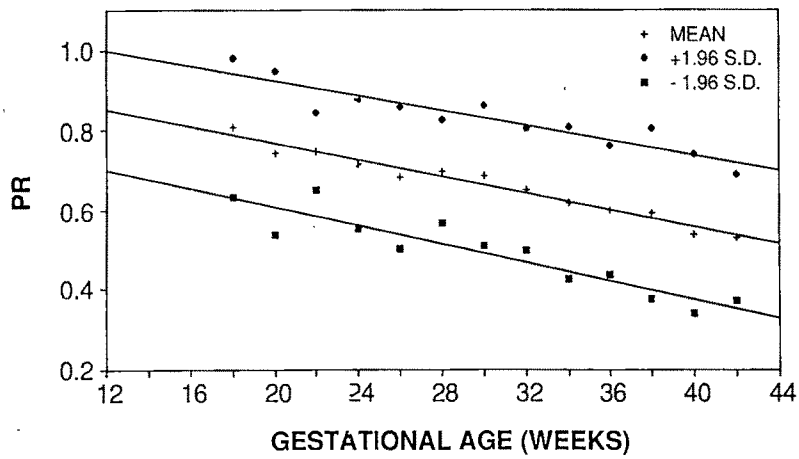

Fig. 3. Normal values for Pourcelot ratio.

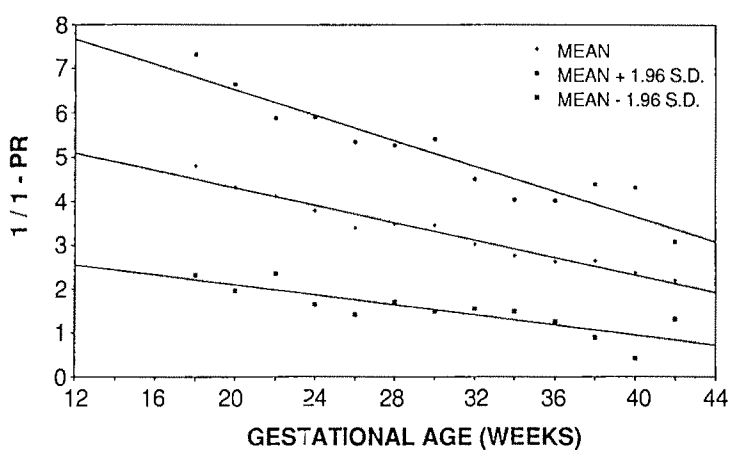

Fig. 4. Normal values for A/B ratio (1/1 − Pourcelot ratio).

A/B ratio and the presence of intrauterine growth retardation, which is currently the only Food and Drug Administration-sanctioned use of fetal Doppler ultrasonography in the United States.[8-10] Trudinger et al.[11] noted that the sensitivity of fetal Doppler ultrasonography was greater than that of traditional means of antepartum tests (the nonstress test) while maintaining equivalent specificity and predictive values. However, the place of fetal velocimetry in the spectrum of routine antepartum tests for the majority of high-risk pregnancy conditions remains unclear. If a uniqueness exists in the comparison of Doppler ultrasonography with other fetal testing methods, it may be that this modality offers the ability to screen high-risk pregnancies early in gestation with a reproducible testing mechanism. Knowledge of normal values for the Pourcelot and A/B ratios at early gestational ages may permit identification and assessment of high-risk pregnancies at earlier gestational ages than that allowed by the limitations of current antepartum test modalities, which creates the possibility of earlier intervention and therapy.

We thank Kathleen Nelson for her invaluable contributions to this work.

Screening with Doppler velocimetry in labor

Leonard Feinkind, MD, Ovadia Abulafia, MD, Isaac Delke, MD, Joseph Feldman, MD, and Howard Minkoff, MD

Brooklyn, New York

Doppler flow velocimetry was performed on 273 nonselected patients in labor. All patients were at least 2 cm dilated and 80% effaced (58% > 4 cm) and were delivered of infants within 24 hours. Fetal heart rate tracing performed at the same time was read by another observer and compared with Doppler flow velocity measurements (systolic/diastolic ratio, pulsatility index). A significant correlation was noted ($r = 0.234$, $p < 0.001$) between the two modalities. Both fetal heart rate tracings and umbilical flow velocity measurements were correlated with fetal outcome. Significant associations were noted between the umbilical systolic/diastolic ratio and fetal distress, 5-minute Apgar scores, the need for intubation independent of gestational age, and umbilical arterial cord pH and base excess. It appears that the information obtained from flow velocimetry had additional benefits compared with that of fetal heart rate tracings alone. (Am J Obstet Gynecol 1989;161:765-70.)

Key words: Doppler ultrasonography, flow velocimetry, labor

Traditionally, the nonstress test (NST) has been used in the antepartum period to monitor fetal well-being.[1,2] More recently in the intrapartum period it has become routine in many institutions to obtain an initial "triage" NST when the patient is first seen. This initial NST is said to have predictive value for the occurrence of fetal distress.[2,3] Other modalities have been used in conjunction with the screening NST to increase its predictive value. We report on the use of Doppler flow velocimetry to identify patients at increased risk for poor perinatal outcome. Doppler velocimetry was chosen for this study because it has previously been used to identify the fetus in jeopardy.[4] The fetus subjected to a chronic decrease in uterine blood flow or umbilical blood flow may be diagnosed with Doppler flow velocimetry and is more susceptible to episodes of decreased Po_2 levels that normally occur during labor. Neonatal asphyxia may occur more rapidly in these patients. The purpose of this study is to examine in labor the relationship between the NST, umbilical artery flow velocity, and perinatal outcome.

Methods

A total of 273 random patients in labor underwent a 20-minute Doppler flow velocimetry examination during the period from April 1987 to November 1987. All patients were ≥2 cm dilated and 80% effaced (58% > 4 cm) and were delivered of infants within 24 hours. The systolic/diastolic (S/D) ratio and pulsatility index (PI) (maximum velocity − minimum velocity/mean velocity) were recorded. Continuous-wave Doppler ultrasonography with a 4 mHz transducer and

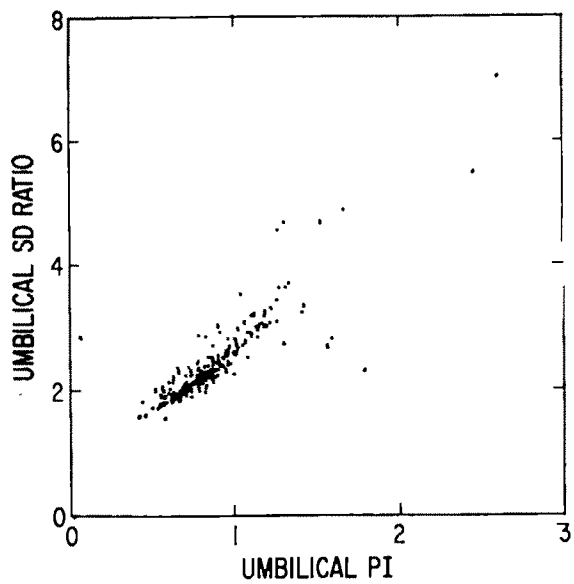

Fig. 1. Relationship between umbilical S/D ratio and umbilical PI.

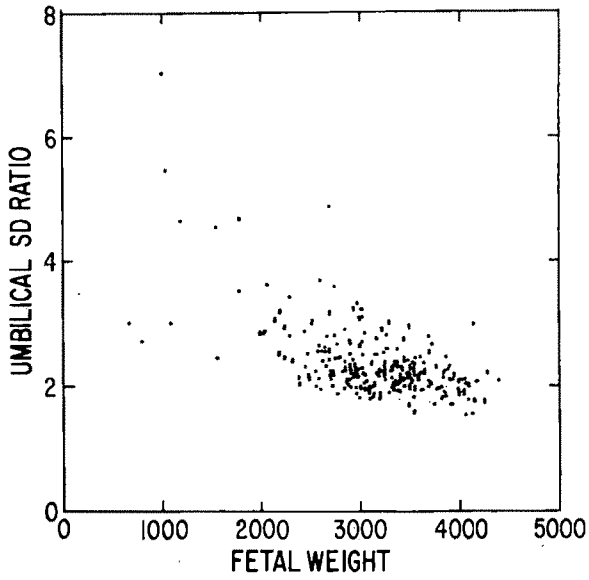

Fig. 2. Relationship between umbilical S/D ratio and fetal weight.

a power density of 6.5 mw/cm^2 (Multigon Industries, North Yonkers, N.Y.) was used to obtain readings on the umbilical and uterine arteries. The S/D ratio and PI of these vessels were computed. The uterine artery signals were obtained transabdominally in the right and left lower quadrants. While the patient was in the left lateral position, the hand-held transducer was adjusted until the best signal was obtained. Two recordings from the right uterine artery and two recordings from the left uterine artery were averaged. The values of three umbilical recordings were also averaged. Care was taken to note the occurrence of umbilical vein fluctuations and irregular arterial waveforms. All measurements were taken in the absence of fetal breathing with at least 10 consistent waveforms present. All patients were simultaneously monitored by internal or external means with a Corometrics (Wallingford, Conn.) model 111 or 115 fetal monitor. During the Doppler examination the corresponding fetal tracing was analyzed for the same 20-minute period by another investigator. In addition, the last 30 minutes of fetal tracing immediately before delivery was also analyzed.

The Lyons scoring system was used to evaluate the fetal tracings on a score of 1 to 10.[5] This was done by a separate observer who was unaware of the results of the Doppler velocimetry and the fetal outcome. The initial tracing (tracing 1) when the Doppler flow velocimetry was performed and the last 30-minute tracing before delivery (tracing 2) were scored. Intraobserver variation was also analyzed by repeat readings taken on 50 random patients. The information gathered from the Doppler flow velocimetry was not used in the clinical management of the patient. Attending staff not involved in the study made all clinical decisions without knowledge of the Doppler flow velocity measurements. Furthermore, all cases of fetal distress were reviewed separately by an independent observer. The gestational age was calculated by last menstrual period or ultrasonogram, with confirmation of gestational age by the Dubowitz[6] examination performed by a pediatrician.

Various dependent variables that were analyzed included fetal heart rate tracing, meconium-stained amniotic fluid, oxytocin administration, gestational age, sex, and fetal weight at the time of delivery, 1- and 5-minute Apgar scores, delivery mode, fetal distress (persistent late decelerations, fetal bradycardia to 60 beats/min, or a scalp pH <7.2 that required operative delivery), and the need for neonatal resuscitation (intubation or oxygen by Ambu bag).

Another of the outcome variables analyzed was arterial umbilical cord blood gases. Because of the practical constraints of running a busy delivery unit only 198 samples were obtained. Blood gas samples that were not analyzed by the laboratory within 15 minutes were discarded. Blood samples that had not arrived in the laboratory by this time were noted to have prolonged delays in transport and were considered unreliable. This left 135 arterial blood gas samples available for analysis. No bias could be detected in those cases in which blood was sent for analysis.

Statistics. Multiple regression analysis was used to account for the possible interrelations of several variables. However, the results indicate little improvement in predictive value when several variables were considered simultaneously or individually. Thus the results are presented in terms of Pearson product moment

Table I. Pearson product moment correlation coefficients between Doppler flow velocimetry, fetal heart rate tracings, and various selected outcome variables ($n = 273$)

correlation coefficients between pairs of variables. In the use of these correlation coefficients it is helpful to think in terms of r^2. This product would then express the proportion of the variation in the outcome variable that can be explained by its relationship with the independent variables.

The Student t test, computed with both pooled and separate variances, was used to compare means. In the evaluation of fetal distress, the Student t test and the Kolmogorov-Smirnov two-sample test were used. The latter test was chosen because it evaluates the discrepancy in the entire distribution of two populations rather than focusing solely on the means. Calculations were performed on an IBM XT computer with a statistical program (Systat, Evanston, Illinois); $p < 0.05$ was considered significant.

Results

The population at Kings County Hospital primarily comprises low socioeconomic black and Hispanic patients. The average maternal age was 25.9 years (SD = 6.3, minimum = 15, maximum = 45). A total of 16% (44:273) of the patients acknowledged smoking tobacco and 5% acknowledged taking "street" drugs (12 took crack, one patient took methadone, one took methadone and crack, and one took alcohol and crack). The average gestational age was 39 weeks (6.5% < 35 weeks, 9.1% < 37 weeks).

There were three patients with an antepartum diagnosis of intrauterine growth retardation (1%), three with sickle cell disease (1%), 14 with diabetes (5%), and 17 with hypertension or preeclampsia (6%).

Intraobserver correlation was judged to be good when 50 tracings were scored by the same observer over two separate time periods ($n = 50$, $r = 0.877$, $p < 0.001$, coefficient of variation = 10.1%). A similar correlation was noted for Doppler flow velocity measurements taken on 50 patients ($n = 50$, $r = 0.95$, $p < 0.001$, coefficient of variation = 9%).

In addition, a good correlation ($r = 0.86, p < 0.0001$) was noted between the umbilical S/D ratio and the umbilical PI (Fig. 1). In view of this, the S/D ratio will be used primarily in this article . However, the umbilical S/D ratio was slightly more skewed (skewness = 3.52, mean = 2.36 ± 0.59, median = 2.22) than was the umbilical PI (skewness = 2.69, mean = 0.85 ± 0.25, median = 0.81).

As visualized in Fig. 2, a strong negative correlation between the umbilical S/D ratio and fetal weight can be seen ($r = -0.60$, $p < 0.0001$). This remains true even when controlling for gestational age with multiple regression analysis (multiple $r = 0.69$; umbilical S/D ratio: $t = -9.8$; $p < 0.0001$; gestational age, $t = 7.5$; $p < 0.0001$). In addition, a negative correlation could be seen for gestational age and umbilical S/D ratios. There was no correlation between gestational age, fetal weight, and the initial tracing (tracing 1) or the final 30-minute tracing (tracing 2).

The initial fetal heart rate tracing and the last 30-minute tracing were correlated ($r = 0.27$, $p < 0.001$). In addition, both tracings were negatively associated with the umbilical S/D ratio ($r = -0.24$, $p < 0.001$).

Fetal compromise. Various factors were considered in the evaluation of fetal compromise. These included 5-minute Apgar score, occurrence of fetal distress, fetal heart rate tracings 1 and 2, and arterial umbilical blood gas values. Umbilical S/D ratio analysis proved to be negatively correlated with 5-minute Apgar scores (Table I). This remained true even when controlling for gestational age and fetal weight (multiple regression, 0.44; umbilical S/D ratio, $t = 6.3$, $p < 0.0001$; fetal weight, $t = 5.3$, $p < 0.0001$; gestational age, $t = 2.12$, $p < 0.04$). In addition, a higher umbilical S/D ratio was associated with fetal distress. This approached significance with the two-tailed Student t test (pooled variances, $t = 4.22$, $p < 0.0001$; separate variances, $t = 1.83$, $p < 0.08$) and achieved significance with the one-tailed Student t test ($p < 0.05$). Overall, the distribution of the umbilical S/D ratio in fetal distress was also significant with the Kolmogorov-Smirnov

Negative predictive value	93	92	94

two-sample test ($p < 0.05$). Finally, low scores on fetal heart rate tracing 1 were associated with fetal distress and low 5-minute Apgar scores (5-minute Apgar scores were believed to reflect fetal status more than did 1-minute Apgar scores).

Umbilical artery cord blood gases showed more variable results. Low scores on fetal tracing 1 were associated with lower umbilical arterial pH and higher base excess ($r = 0.23$, $p < 0.01$ and $r = -0.30$, $p < 0.001$, respectively). P_{CO_2}, P_{O_2}, and oxygen saturation were not correlated with fetal heart rate tracings (Table II). In addition, there appeared to be no benefit in examining fetal heart rate tracing 2 as opposed to tracing 1 with regard to arterial blood gas, fetal distress, and Apgar scores because the correlation coefficients were not any greater for tracing 2.

No correlation could be found between umbilical S/D ratios and the arterial umbilical cord pH, bicarbonate, base excess, P_{O_2}, P_{CO_2}, or oxygen saturation (Table II). In view of this lack of correlation, it was decided to look at a smaller group of at-risk pregnancies. A total of 16 fetuses with an umbilical S/D ratio ≥3 (equivalent to a PI ≥1.2, both approximately >2 SD of the mean), and with available umbilical arterial cord blood gases were analyzed (26 fetuses had a S/D ratio ≥3). In this high-risk population positive and negative correlations could be seen between umbilical S/D ratios, base excess and pH ($r = 0.86$, $p < 0.003$, and $r = -0.74$, $p < 0.05$, respectively). No correlation was seen for P_{CO_2}, P_{O_2}, oxygen saturation and bicarbonate. In this group of patients, low scores on the fetal heart rate monitor were associated with increased base excess ($r = -0.82$, $p < 0.007$). There were no other significant correlations when pH ($r = 0.34$, $p < 0.3$), P_{CO_2}, P_{CO_2}, bicarbonate, or oxygen saturation were analyzed.

The S/D ratios of the right and left sides of the uterus were also analyzed by Pearson correlation coefficients and compared with the umbilical S/D ratio, fetal heart rate tracings 1 and 2, resuscitation, fetal distress, fetal weight, gestational age, maternal age, Apgar scores, and arterial blood gas values. Except for a correlation with umbilical S/D ratios no other significant association was found ($r = 0.23$, $p < 0.001$).

The sensitivity, specificity, positive and negative predictive value for fetal heart rate tracing 1, umbilical S/D ratio, and both umbilical S/D ratio and fetal heart rate tracing are shown in Table III. A fetal heart rate tracing <7 and an umbilical S/D ratio ≥3 (>31 weeks' gestation) were considered abnormal. These values were chosen because they have been suggested in other studies.[7] Abnormal outcome was defined as fetal distress or a 5-minute Apgar score <7. For the population of patients with a normal outcome the S/D ratio was 2.31 ± 0.43 for a gestational age ≥31 weeks and 3.33 ± 1.0 for a gestational age <31 weeks. There were 39 fetal heart rate tracings that were scored <7. In 231 cases scores were ≥7 (in three cases the tracing could not be located). There were 26 umbilical artery velocimetry recordings ≥3 and 247 recordings that were <3. For a gestational age ≥31 weeks, 7% of the population had umbilical S/D ratios ≥3. There were no instances in which umbilical diastolic flow was absent.

For the population with an abnormal outcome the S/D ratio was 2.77 ± 1.22 for a gestational age ≥31

weeks and 3.16 ± 1.19 for those <31 weeks' gestation. The difference between the normal group and the abnormal group approached significance ($p = 0.06$) for a gestational age ≥31 weeks, with the two-tailed Student t test for separate variances.

The umbilical S/D ratio had a 30% positive predictive value for an abnormal outcome, whereas the fetal heart rate tracing had a positive predictive value of 23%. The sensitivity of the fetal heart rate tracing appeared to be slightly better than that of the umbilical S/D ratio (36% versus 29%, respectively). When the two modalities were combined the positive predictive value increased to 56%; however, the sensitivity remained unchanged (Table III).

Adjustment of the umbilical S/D ratio for gestational age did not change the sensitivity or the predicative value, inasmuch as only two fetuses <31 weeks' gestation had normal S/D ratios >3—one with fetal distress, the other with a normal outcome.

Comment

There are three major angle independent indices that evaluate the flow velocity waveform—PI, resistance index, and S/D ratio. The PI and S/D ratio were strongly correlated in this report ($r = 0.86$, $p < 0.0001$). This finding confirms earlier work by Thompson[7] and others. It appears that the exact correlation depends on the manner in which the PI is calculated. In a study by Gilbert et al.,[8] a correlation coefficient of 0.95 was noted when the PI was calculated by a manual pen method, but only a correlation of 0.68 when an automated method was used.

As can be seen in this study and in others,[8, 9] there was a strong correlation between fetal weight and flow velocimetry. Several studies have suggested that flow velocimetry may be useful in the diagnosis of intrauterine growth retardation.[4, 9, 10, 11]

Other investigators have attempted to compare flow velocimetry and the ultrasonographic estimation of fetal weight.[12] Whereas there is a good correlation between fetal weight and flow velocimetry ($r = -0.6$, $p < 0.0001$), it would be erroneous to suggest that flow velocity waveform measurements are designed to estimate fetal weight. Morphometric measurements derived ultrasonographically should not be compared with measurements obtained by velocimetry.[13] Flow velocimetry will, however, identify the small-for-gestational-age fetus at increased risk.[9, 11, 14]

Biochemical data also was previously used to identify the fetus at risk. That data was obtained with a transabdominal technique to obtain amniotic fluid[15] during amniocentesis or by cordocentesis to obtain fetal blood during the antepartum period.[16, 17] Ours is the only study that has sought to compare the role of vascular impedance in the umbilical circulation during labor with biochemical data. Increased umbilical S/D ratios, a reflection of decreased umbilical blood flow, was not significantly correlated with arterial cord blood gas values when a group of 135 laboring patients who had cord blood gas measurements available were analyzed. However, when a small subset of high-risk fetuses with umbilical S/D ratios ≥3 (which corresponded to a PI of ≥1.2) were considered independently, a significant correlation could be seen. Umbilical S/D ratios (and PI) were negatively associated with pH and positively associated with base excess ($r = -0.74$, $p < 0.05$ and $r = 0.84$, $p < 0.003$, respectively). The fetus with increased placental impedance demonstrated an increased risk for acidosis and probably for excessive lactic acid accumulation. It is not surprising that in a large normal population with the additional stress of labor any relation between biochemical indices and measurements of blood flow velocity would be obscured. This was not the case when considering a small high-risk population. In addition, there may have been a tendency to administer oxygen to laboring patients who showed signs of fetal compromise. Oxygen treatment may have altered flow velocimetry and umbilical artery cord blood gases.[18] However, inasmuch as a significant relationship was present between the fetal tracing and the flow velocity measurements that were recorded simultaneously in the larger cohort, it may indicate that a correlation does exist between placental impedance and fetal oxygenation. In a report by Ferrazzi et al.[19] a significant correlation was found between the umbilical PI and pH, Pco_2, and lactate levels from umbilical cord blood obtained by cordocentesis and after elective ce-

sarean section in a small high-risk population. It is also interesting that they found a strong association between lactate concentration and PI when measurements >1.5 were reached. Above this value lactate concentration appeared to increase sharply. A critical level of blood flow reduction has been also shown to cause fetal hypoxia and acidosis in the sheep model (unpublished observation). Other data that have been presented by Soothill[20] also found an association between venous umbilical blood gas values obtained through cordocentesis and blood flow velocity measurements. All of these correlations have been noted in a select high-risk population.

In addition to biochemical data, pregnancies with increased placental impedance had lower 5-minute Apgar scores, fetal distress occurred (Fig. 3), and intubation was required more often, independent of gestational age. The fetal heart rate tracing was also significantly correlated with these outcomes and appeared to be more closely associated with arterial blood gases than was Doppler flow velocimetry. It is understandable that fetal distress would be better correlated with fetal heart rate tracings than with flow velocimetry because tracings were used in the diagnosis of fetal distress and in the management of all patients.

A comparison of the initial fetal tracing and Doppler velocimetry is revealed in Table III. Sensitivity, specificity, and positive and negative predictive values were comparable for the two modalities. When both modalities were used in conjunction, however, the positive predictive value increased to 56% and specificity increased to 98%. Therefore it appears that decreased flow velocity measurements may provide additional information in the identification of the high-risk fetus.

In summary, it appears that Doppler flow velocimetry is as sensitive as the NST in the identification of the fetus at risk for a poor perinatal outcome. However, it should be acknowledged that the sensitivity in this nonselected population was generally low, as were the majority of the correlation coefficients. Thus, it would be unwise to make firm recommendations concerning the benefits of Doppler velocimetry compared to the NST in labor without further study. Each of these modalities, though, have their own unique benefits and may be used concurrently in the laboring patient. The patient with abnormal NST results and an abnormal umbilical S/D ratio appears to be at greatest risk for a poor outcome. In addition, in a high-risk population of growth retarded infants the umbilical S/D ratio appears to be well correlated with umbilical cord pH and base excess. However, the fetal heart rate tracing reflects the dynamic changes that can occur during labor and is better correlated with umbilical arterial blood gas values at delivery in a group of low-risk patients.

The effect of magnesium sulfate tocolysis on the fetal biophysical profile

Alan M. Peaceman, MD, Bruce A. Meyer, MD, James A. Thorp, MD, Valerie M. Parisi, MD, MPH, and Robert K. Creasy, MD

Houston, Texas

The biophysical profile has proved to be a valuable tool for the assessment of fetal well-being, independent of gestational age. Magnesium sulfate is commonly used as a tocolytic agent, yet relatively little is known about its effects on the biophysical activities of the fetus. To investigate the effects of magnesium sulfate on the biophysical profile, we performed serial studies on patients who received tocolytic therapy with this agent because of preterm labor. A total of 16 women with 22 fetuses at 26 to 34 weeks' gestation in spontaneous preterm labor were studied. An initial biophysical profile was performed at the time of admission, and a second examination was performed when maternal serum magnesium levels reached 6 to 8 mg/dl. On admission all fetuses had reactive nonstress test results and 21 of 22 (95%) demonstrated sustained fetal breathing movements. With magnesium sulfate tocolysis, 50% of fetuses had nonreactive nonstress test results, and only 4 of 22 (18%) demonstrated sustained fetal breathing movements. Fetal tone, gross body movements, and amniotic fluid volume were found to be unaffected by magnesium sulfate tocolysis. (AM J OBSTET GYNECOL 1989;161:771-4.)

Key words: Magnesium sulfate, preterm labor, biophysical profile

The biophysical profile is a valuable tool in the assessment of fetal well-being.[1, 2] Fetal tone, movements, reactivity, and breathing reflect acute central nervous system function. Amniotic fluid volume is a marker for fetal urine production, which may be diminished with chronic intrauterine compromise.[3] This test has proven validity in fetal assessment throughout the third trimester[4] and in twin gestations.[5] The five biophysical parameters involved can be influenced by other factors in addition to fetal distress. These include premature rupture of the membranes, normal sleep-wake cycles,[3] infection,[6] and pharmacologic intervention.[5] Interpretation of the biophysical profile results should take these other factors into account.

Magnesium sulfate is a commonly used agent for tocolysis in the management of pretern labor. It can cause maternal lethargy and depression of deep tendon reflexes when administered in doses often used for tocolysis.[7] Magnesium readily crosses the placenta, and fetal blood magnesium levels correlate well with maternal levels.[8] The higher doses of magnesium sulfate used for tocolysis may cause central nervous system depression in the fetus as well and thereby alter the biophysical profile. The purpose of this prospective study was to assess the effect of magnesium sulfate, in doses used to arrest preterm labor, on the parameters of the biophysical profile.

Material and methods

All women who were seen at the Hermann Hospital labor and delivery suite at 26 to 34 weeks' gestation with an initial episode of spontaneous preterm labor, as evidenced by regular uterine contractions and documented cervical change, were eligible for participation. Patients who had underlying hypertension or diabetes were excluded from this study. Other exclusion criteria included cervical dilation >4 cm, treatment in the preceding week with any tocolytic agent or sedative, and the presence of any significant abnormalities of the fetal heart rate tracing on admission (as judged by the managing physician). A total of 16 patients were recruited for the study, six of whom were carrying twin gestations. An initial biophysical profile was performed by the chief resident or attending physician before the initiation of tocolytic therapy. Fetal nonstress tests (NSTs) were evaluated from heart rate monitoring in the hour preceding the initial ultrasonographic examination. This recording was obtained with the patient in the semi-Fowler position with Doppler ultrasonography to record the fetal heart rate (Hewlett-Packard 8040A Cardiotocograph, Palo Alto, Calif.). The NST was considered reactive if, in any 20-minute period, there were two or more heart rate accelerations

6/6/13718

Table I. Fetal biophysical profile

Reactive nonstress test	At least two episodes of fetal heart rate acceleration >15 beats/min and ≥15 seconds' duration associated with fetal movement in 20 minutes
Fetal breathing movements	At least one episode of sustained fetal breathing movements ≥30 seconds' duration in 30 minutes of observation
Fetal tone	At least one episode of active extension with return to flexion of fetal limbs or trunk in 30 minutes of observation
Fetal movement	At least three discrete limb or body movements in 30 minutes of observation
Amniotic fluid volume	At least one pocket of amniotic fluid that measured 3 cm in two perpendicular planes

Two points were awarded for each parameter when the above criteria were fulfilled. No points were given if the criteria were not met.

Modified from Manning et al. Fetal assessment based on fetal biophysical profile scoring: experience in 12,620 referred high-risk pregnancies. I. Perinatal mortality by frequency and etiology. AM J OBSTET GYNECOL 1985;151:345.

≥15 beats/min that lasted ≥15 seconds and that were associated with fetal movement. The test was considered nonreactive if no 20-minute interval of the 60-minute observation period contained two or more accelerations with fetal movements. Linear array real-time ultrasonographic scanning was performed with a 3.5 mHz transducer (General Electric RT 2800, Milwaukee, Wisc.). Fetal movements, tone, breathing movements, and amniotic fluid volume were assessed. Each parameter was assigned either 0 points or 2 points on the basis of a protocol modified from Manning et al.[1] (Table I). Two points were awarded for (1) reactive NST results, (2) an amniotic fluid pocket that measured ≥3.0 cm in two perpendicular planes, (3) at least three discrete body or limb movements, (4) at least one episode of limb or trunk extension with return to flexion, and (5) at least one episode of sustained fetal breathing >30 seconds. A total of 30 minutes of real-time ultrasonographic scanning was allowed for the evaluation of these parameters. The results of this initial biophysical profile were then recorded, in addition to maternal age, gestational age, and cervical dilation data.

After completion of the initial biophysical profile, the fetuses were continuously monitored, and each patient was administered an intravenous loading dose of magnesium sulfate. This preceded continuous intravenous infusion of a more concentrated solution. A total of 10 gm of magnesium sulfate (American Reagent Laboratories, Shirley, N.Y.) was diluted in 250 ml of 5% dextrose, which resulted in a 4% solution. A loading dose of 4 to 6 gm was then infused through an IMED 960 volumetric infusion pump (IMED Corporation, San Diego, Calif.) over 20 to 30 minutes. For continuous infusion, an 8% solution of magnesium sulfate in 5% dextrose was administered at 1.5 to 3.5 gm/hr. The doses used for loading and continuous infusion were determined by the attending physician to attain maternal serum magnesium concentrations in the therapeutic range of 6 to 8 mg/dl (5.0 to 6.7 mEq/l). Serum magnesium levels were measured every 4 to 6 hours, and the infusion rate was adjusted until the serum level was in the desired range. After a therapeutic level was documented, a repeat biophysical profile was performed and the results were recorded. The 60-minute interval after the magnesium level reached the therapeutic range was used for evaluation of fetal heart rate reactivity. Fetal heart rate baselines from the two NST recordings were also compared. All data are expressed as the mean ± 1 SD. Statistical analysis was performed by the Wilcoxon signed rank test and the McNemar exact test for correlated proportions. A paired Student *t* test was used for evaluation of fetal heart rate baseline changes. A p value of 0.05 was chosen to represent statistical significance. This study was approved by the institutional review board of the University of Texas Medical School at Houston.

Results

The mean maternal age was 23.4 ± 4.5 years, with mean gestational age 30.7 ± 2.2 weeks. Mean cervical dilation on initiation of tocolysis was 2.8 ± 1.5 cm. None of the study participants was delivered of infants before the second biophysical profile, and there were no maternal complications of therapy. The mean serum magnesium level at the time of the second biophysical profile was 6.6 ± 0.6 mg/dl, and the mean length of time between the two examinations was 14.1 ± 5.4 hours. Examination of the cardiotocograph recordings at the time of the second biophysical profile revealed that preterm labor had been arrested in all cases and that there were no instances of suspected fetal distress. The results of the biophysical tests are displayed in Fig. 1. All 22 fetuses were found to have reactive fetal heart rate patterns on admission, but only 11 of 22 (50%) were found to be reactive during therapeutic magnesium tocolysis ($p < 0.001$). All but one fetus demonstrated sustained breathing movements at the time of the initial biophysical profile. After a therapeutic magnesium level was achieved, however, only four fetuses demonstrated sustained breathing movements ($p < 0.0001$). All fetuses demonstrated normal tone,

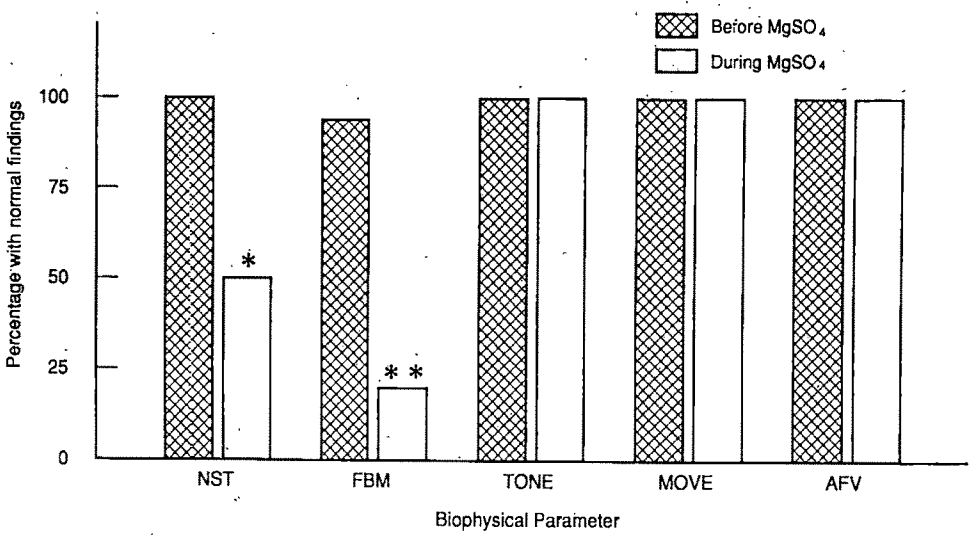

Fig. 1. Fetal biophysical profile results before and during magnesium sulfate tocolysis. Percentages of patients who fulfill criteria for each parameter of biophysical profile before and during therapy are compared (*$p < 0.001$, **$p < 0.0001$). *NST*, Nonstress test, *FBM*, fetal breathing movements, *TONE*, fetal tone, *MOVE*, fetal movement, *AFV*, amniotic fluid volume.

gross movements, and amniotic fluid volume at both the initial and follow-up biophysical profile examinations. Magnesium sulfate tocolysis resulted in a statistically significant decrease in overall biophysical profile scores ($p = 0.0002$), with a decrease of 2 or 4 points observed in 18 of 22 fetuses.

Examination of baseline fetal heart rates revealed a decrease ≥10 beats/min in 16 of 22 (73%) fetuses. The mean baseline fetal heart rate during the first biophysical profile was 144 beats/min and decreased to 131 beats/min at the time of the second biophysical profile. This decrease was statistically significant ($p < 0.0001$).

Comment

The biophysical profile has been shown to be a valuable tool for the assessment of the well-being of the fetus.[1-3] The test results reflect central nervous system function, and are independent of gestational age and fetal number.[4,5] Biophysical parameters can be altered by hypoxemia, drugs, rupture of the membranes, infection, and periodic rest cycles.[3,6] Most clinical protocols for tocolysis of preterm labor involve some form of monitoring of fetal well-being. The biophysical profile may be a useful tool in this setting, but the effects of pharmacologic intervention on this test must be taken into account before interpretation of the test results are used clinically.

Magnesium sulfate first achieved widespread use in obstetrics for the prevention of eclamptic seizures because of both its efficacy and safety.[9] Maternal complications have been seen with the use of this agent, but they are relatively infrequent when magnesium sulfate is administered by controlled infusion systems and the appropriate safeguards of monitoring urine output and deep tendon reflexes are observed. Respiratory paralysis and general anesthesia can occur at serum levels of 18 mg/dl, but are easily reversed with calcium gluconate.[10] Although clinical neurologic depression has been reported in neonates of women treated with magnesium sulfate because of preeclampsia,[11] most reports fail to identify any adverse effect on Apgar scores,[12,13] neonatal mortality rate,[14] or neonatal neurologic assessment examinations.[12] In a study of the sheep fetus, Bolan et al.[15] found that magnesium readily crossed the placenta but caused no alteration in baseline heart rate, hemodynamic parameters, or arterial blood gas parameters. Evaluation of the effects of magnesium sulfate on the human fetus to this point have included observations of changes in heart rate variability and baseline. In a study of patients with preeclampsia, Stallworth et al.[16] failed to demonstrate any significant change in fetal heart rate variability in the first 75 minutes of therapy, whereas Zuspan,[10] Lin et al.,[8] and Babaknia and Niebyl[17] all observed some decrease in fetal heart rate variability without evidence of compromise in the infant after delivery. Mean maternal and neonatal magnesium levels obtained in the above studies ranged from 3.6 to 5.7 mg/dl. The therapeutic range of magnesium in the prevention of eclamptic seizures has been reported to be 4.2 to 7.2 mg/dl.[18]

When magnesium sulfate is used as a tocolytic agent,

higher doses than are normally used in protocols for eclamptic seizure prophylaxis are often required to arrest preterm labor. Elliott[19] suggested that a maternal serum magnesium level of 5.5 to 7.5 mg/dl is necessary to inhibit uterine contractions. Only two studies have investigated the effects of magnesium sulfate therapy on the human fetus in patients treated because of preterm labor. Thiagarajah et al.[20] found a decrease in baseline fetal heart rate, whereas Brar et al.[21] did not observe such change. Neither of these studies evaluated parameters of the biophysical profile. Because magnesium passes readily to the fetus and fetal levels correlate with maternal levels, the use of magnesium sulfate for tocolysis may have more pronounced effects on the fetus than those seen with its use in seizure prophylaxis. Magnesium sulfate therapy for tocolysis is usually discontinued long before the birth of the infant. Because of placental transfer and rapid maternal excretion, neonatal magnesium levels may not be significantly elevated if maternal administration has been discontinued. Thus when magnesium sulfate is used as a tocolytic agent, evaluation of the newborn may not reflect the drug's effects on the fetus. Therefore, tests that directly assess the fetus are necessary for the evaluation of intrauterine effects of this therapy. To our knowledge, no previous studies have evaluated the effects of magnesium sulfate tocolysis on the biophysical profile.

It has been reported that breathing movements may be absent from fetuses during term[22] and preterm[23] labor. This finding was not observed in our study, as all but one fetus demonstrated breathing movements on admission. The diagnosis of preterm labor followed strict criteria of both regular uterine contractions and documented cervical change. Because arrest of preterm labor had occurred at the time of all follow-up examinations, yet breathing movements were not observed in most fetuses at that time, we must conclude that the significant reduction of fetal breathing movements seen is a pharmacologic effect rather than a result of labor.

We conclude that magnesium sulfate tocolysis (1) results in nonreactive nonstress test results and cessation of fetal breathing movements in a significant proportion of fetuses; (2) has no significant effect on fetal tone, gross body movements or amniotic fluid volume as assessed by the biophysical profile during our period of observation; (3) results in a decrease in baseline fetal heart rate in a significant number of fetuses; and (4) significantly reduces the overall biophysical profile score in the majority of fetuses. Most likely these changes do not reflect compromise of fetal well-being but rather central nervous system depression on a pharmacologic basis. These effects should be taken into account when the biophysical profile is used to assess fetal well-being in a patient who receives magnesium sulfate in high doses for tocolysis.

Controlled trial of hydration and bed rest versus bed rest alone in the evaluation of preterm uterine contractions

Richard A. Pircon, MD, Howard T. Strassner, MD, Donna S. Kirz, MD, and Craig V. Towers, MD

Orange and Long Beach, California, and Chicago, Illinois

Patients who are seen with uterine contractions but without documented change in cervical dilation or effacement are often treated with intravenous hydration before the initiation of intravenous tocolytic therapy. This is done with the intention of stopping uterine activity in patients with false preterm labor. A prospective randomized study was conducted to evaluate the effect of hydration on preterm uterine contractions in patients without proved preterm labor. A total of 28 patients were treated with bed rest and an intravenous bolus and subsequent continuous infusion of 5% dextrose in lactated Ringer's solution. A control group of 20 patients were treated with bed rest alone. Uterine activity and arrest of uterine contractions were compared between the two groups. Contractions stopped in 54% of the patients treated with hydration, whereas contractions stopped in 40% of the patients in the control group. This difference was not statistically significant. As a crossover study, those in the control group with contractions that continued after the initial observation period were subsequently treated with intravenous fluids. Only one patient in this group stopped contracting. Of all patients whose contractions stopped with either therapy, 18% eventually were delivered of preterm infants. This included 20% of the hydration group and 14% of the control group. The use of hydration as a pretherapy indicator to differentiate true preterm labor from false preterm labor could not be supported by this study. In addition, patients whose contractions stopped with either hydration or bed rest are at increased risk of subsequent preterm delivery. (Am J Obstet Gynecol 1989;161:775-9.)

Key words: Premature labor, premature contractions, tocolysis

Preterm delivery is a problem that affects approximately 8% of the obstetric population and is responsible for 75% of perinatal mortality,[1] thus there has been a great deal of interest in the development and use of effective tocolytic agents. Although early intervention is desired to prevent preterm delivery, the use of these agents should be limited to patients with true preterm labor (i.e., patients with uterine contractions that result in progressive cervical dilation and effacement). Many patients are first seen with uterine contractions and after observation do not demonstrate cervical change. Therefore it is difficult, based on the presence of contractions alone, to differentiate true preterm labor from frequent preterm (Braxton Hicks) contractions.

Various clinical parameters have been used to help separate these two groups. Some have used the character and frequency of uterine contractions to differentiate true labor from false labor. Perhaps the most commonly used method to distinguish true labor from false preterm labor is the response to hydration and bed rest. Although this practice is thought to be effective, no one has studied its usefulness in a prospective randomized fashion. Because of this we prospectively sought to determine the effect of hydration on the arrest of preterm uterine contractions in patients seen for evaluation of preterm labor. These patients were compared to a control group that received only bed rest and observation.

Material and methods

Patients seen with preterm uterine contractions at the labor and delivery unit at Rush Presbyterian–St. Lukes Medical Center were evaluated for enrollment in the study. Only those with a singleton pregnancy between 20 to 36 weeks' gestation and no identifiable cause of preterm contractions were included. On initial evaluation, patients who met criteria for true preterm labor as outlined by Creasy et al.[2] were excluded and treated with a tocolytic agent. Therefore only those patients who were <2 cm dilated, <80% effaced, and had intact amniotic membranes were considered for further study.

All patients who fulfilled these criteria were then continuously monitored for uterine activity and fetal heart

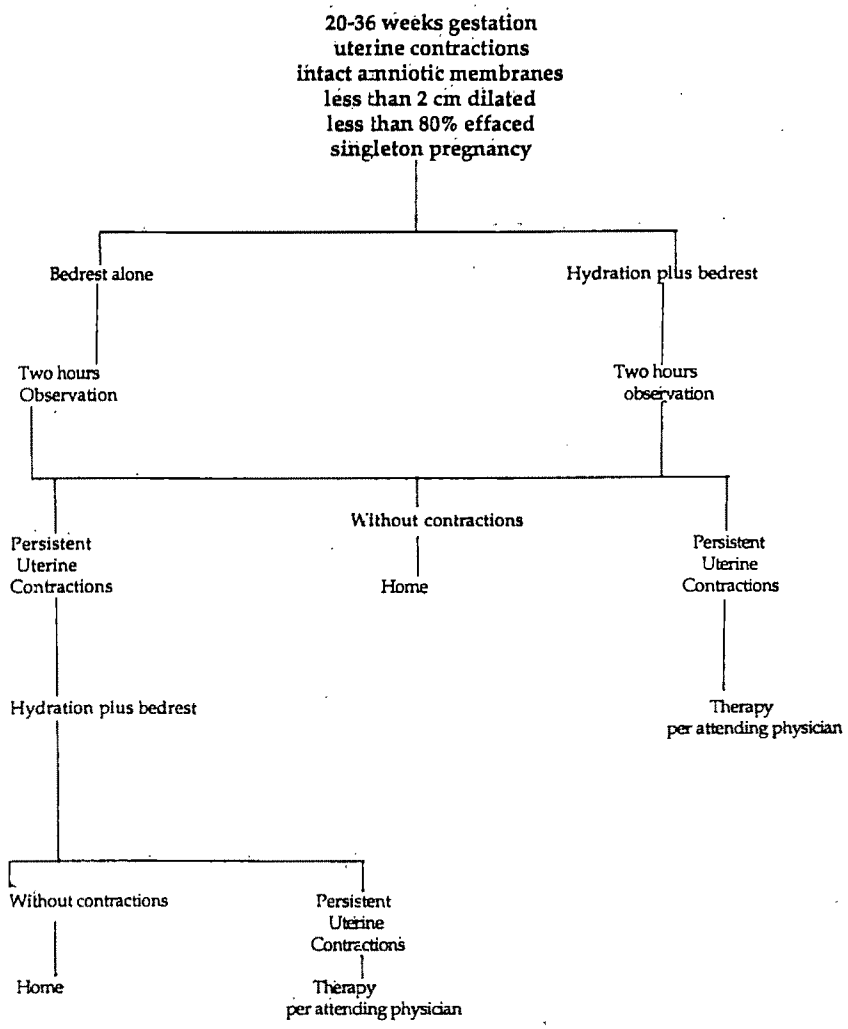

Fig. 1. Study protocol.

tones. Any patient with evidence of fetal distress was excluded from the study and treated in an appropriate fashion. At the end of 30 minutes uterine contractions were quantitated. Patients with uterine contractions more frequent than every 10 minutes or three contractions in 30 minutes were eligible for the study (Fig. 1).

These patients were randomly treated with hydration and bed rest or with bed rest only (control group). Allocation of patients to study groups was based on the day they were examined. Those treated with hydration were given an intravenous bolus of 500 ml of 5% dextrose in lactated Ringer's solution, and then 200 ml/hr continuous infusion. Patients in the control group were given ice chips only, and this was restricted to <200 ml total oral intake.

Both groups were then observed for 2 hours All patients were placed in the left lateral position during observation. Fetal heart tones and uterine contractions were continuously monitored. Sterile vaginal examinations were repeated after 1 hour of observation. If cervical change was noted by the same examiner, the patient was considered to be in preterm labor, removed from the study, and treated with intravenous tocolytic agents. After the 2-hour study period, uterine contractions were quantitated, and the patient was again examined. As before, those with cervical change were treated with intravenous tocolytic agents. After the 2 hours of observation the study was concluded for all patients who received hydration and those whose contractions stopped with bed rest. Patients in the hydration group without cervical change but with persistent contractions were treated on an individual basis by their attending physician. Patients whose contractions abated were discharged home. Each patient's disposition was recorded and outcome of therapy was noted.

Study participants who were treated with bed rest alone and who continued to contract after the initial 2-hour study period were then treated with intravenous hydration. The patients were given a 500 ml bolus of

5% dextrose in lactated Ringer's solution and then 200 ml/hr continuous infusion. These patients were observed for an additional 2 hours. The outcome of this additional therapy in this group of patients was recorded. Patients who continuted to contract were treated individually by their attending physician.

The charts of all study participants were reviewed after they were delivered of infants. Subsequent returns to the hospital and admissions because of preterm contractions were recorded. The difference between the hydration group and the control group in the abatement of uterine contractions were statistically evaluted by χ^2 with Yates correction. The two study populations were evaluated with regard to differences in age, gravidity, parity, previous preterm deliveries, estimated gestational age, uterine contraction frequency and duration, and cervical status when first seen. This comparison was done with the Mann-Whitney U test. For those patients whose contractions stopped during the study period, we reviewed any subsequent admissions because of preterm labor and compared these differences.

Results

A total of 48 patients were enrolled in the study; 28 were treated with hydration and 20 were treated with bed rest only. During the observation period, five patients had cervical change; two were in the control group and three were in the hydration group. No patient had evidence of fetal distress during the observation period.

There was no significant difference between groups with respect to age, gravidity, parity, previous preterm deliveries, or estimated gestational age when first seen. In addition, there was no difference between groups with regard to cervical dilation, effacement, station, and uterine contraction frequency and duration when first seen.

Of the 28 patients who received hydration, 15 (53.6%) stopped contracting during the observation period, whereas 7 (35%) of the 20 control patients stopped contracting. By χ^2 analysis, there was no significant difference between the two therapies of the abatement of preterm uterine contractions ($p \leq 0.33$).

Of the 13 patients in the control group who did not stop contracting during the study period, 12 were then treated with intravenous hydration. Only one patient stopped contracting with hydration; the other 11 required use of a tocolytic agent. One patient was not treated with hydration as per protocol. She was treated with further observation and no additional therapies and contractions stopped with this management.

There were three patients who were seen at the hospital more than once with preterm contractions without cervical dilation or effacement and an intact amniotic membrane. They were placed in different study groups on each visit. Both hydration and bed rest were effective in stopping contractions in two of the patients. The third patient did not stop contracting during the observation period with either treatment regimen. When she was first seen she was randomized to the control group. During that admission the contractions became less frequent during the 2-hour observation period. This is the patient who was not subsequently treated according to protocol, but was observed further without additional therapy. The contractions eventually stopped, and she was discharged. On a subsequent admission the same patient was randomized to the hydration group and again continued to contract after the 2-hour study period. She was then treated with a β-sympathomimetic tocolytic agent with subsequent tocolysis.

Of the 22 patients who stopped contracting during the initial study period, seven were seen again with uterine contractions before 36 completed weeks' gestation. Two of these patients were originally treated with bed rest alone. Five were treated with hydration and bed rest. This difference was not significant. As previously noted, three of these patients were reenrolled in the study. The other four patients had cervical dilation or effacement and could not be reenrolled.

Seventeen (35%) of the patients were delivered of preterm infants. Of these, six were in the control group and 11 were in the hydration group. The difference was not statistically significant. Of the 22 patients who stopped contracting during the study period, four (18%) eventually were delivered of preterm infants. This included three (20%) of the 15 patients in the hydration group and one (14%) of the seven patients in the control group. Of those who did not stop contracting during the study period, 13 patients (50%) were delivered of preterm infants. Eight of these patients were in the study group and five were in the control group. These differences were also not significant.

Comment

Preterm labor is defined as the onset of uterine contractions with resultant dilation and effacement of the cervix >20 and <37 weeks' gestation. Without change in the dilation or effacement of the cervix it is difficult to decide whether a patient is having true labor or preterm uterine irritability. This clinical problem is evident by the various definitions of preterm labor used by investigators who study various tocolytic agents. All agree that the patient must have regular painful uterine contractions. Some insist on documented cervical dilation or effacement.[3, 4] In our study, we found this accounted for only 10% of those patients first seen with persistent painful uterine contractions. Other investi-

gators only require uterine contractions to be of a certain frequency. Beall et al.[5] in their study that compared ritodrine, terbutaline, and magnesium sulfate required contractions to be more frequent than every 10 minutes. Elliott,[6] while studying magnesium sulfate, required a uterine contraction frequency twice that of Beall's criteria. Neither study required documented cervical change or minimal cervical dilation or effacement before entry into their studies.

Creasy et al.[2] used cervical status along with uterine contraction frequency as an indicator of preterm labor. For the diagnosis he required documented cervical change in those patients with intact membranes and a cervix <2 cm dilated or <80% effaced. However, patients contracting with ruptured membranes or a cervix >80% effaced or 2 cm dilated are considered to be in preterm labor. With the use of these criteria, one limits the use of tocolytic agents to patients with contractions who show the true sign of labor—cervical change. However, use of these criteria does not delay the use of tocolytic agents in patients first seen with an abnormally dilated or effaced cervix. For these reasons, we have adopted these criteria at our institution.

A problem, however, arises in patients who are regularly contracting without evidence of cervical change. Castle and Turnbull[7] have advocated the use of ultrasonography to demonstrate the presence or absence of fetal breathing movements. They found that the presence of fetal breathing predicted patients whose contractions would spontaneously subside. Others have not found this technique to be helpful.[8]

Ingermarsson[9] used sedation and bed rest in an effort to discriminate true preterm labor from preterm uterine irritability. The patients were given 10 mg of valium intramuscularly and were observed for abatement of the uterine contractions. Cotton et al.[10] hydrated patients by giving 1 L of 5% dextrose in lactated Ringer's solution. Valenzuela[11] used a combination of hydration and 8 to 12 mg of intramuscular morphine sulfate. Although many of these regimens are now commonly used, no one has studied their effects in a prospective randomized fashion.

The tocolytic effect of hydration is attributed to inhibition of antidiuretic hormone through the Henry-Gauer reflex.[12] This reflex, however, has only been described in dogs. Goodlin et al.[13] studied plasma volumes in patients with preterm labor. They found patients with preterm labor were hypovolemic and their plasma volumes were ≥45 ml/kg below normal. They also found significant delays in delivery in patients with preterm contractions whose plasma volumes were expanded with albumin. They noted that β-sympathomimetics, tranquilizers, and bed rest expanded plasma volume.

We studied the effect of hydration and bed rest versus bed rest alone in the abatement of preterm uterine contractions. Of patients in the control group, 40% stopped contracting with observation alone (seven during the 2-hour observation period and one who was treated with continued observation beyond the completion of the study), whereas 54% of the study participants who received hydration stopped contracting. The difference did not reach statistical significance. Although there is a trend, the efficacy of hydration in the differentiation of true labor from false labor is doubted further when patients who did not stop contracting after treatment with bed rest alone are followed up. All except one of these patients were subsequently treated with hydration. Only one patient stopped contracting, whereas the other 10 patients had persistent uterine activity. Furthermore, no difference was seen between therapies in patients who were seen more than once and who were treated with different therapies with each visit.

One other study that evaluated the efficacy of treating threatened preterm labor is that of Valenzuela et al.[8] As previously noted, they used hydration in combination with sedation. This was a prospective study; however, it was not randomized with a control group. They found that 55% of the patients responded to this therapy. This was similar to our data in which 54% responded to hydration and 40% responded to bed rest alone.

The data of Valenzuela et al.[8] is similar to ours with regard to preterm delivery rates. Their study revealed an overall preterm delivery rate of 26% with a 15% rate in patients who stopped contracting with hydration and sedation. Our study had an overall preterm delivery rate of 35%. Of the patients who stopped contracting during the study period, 14% of the control group and 20% of the hydration group were delivered of preterm infants. Finally, of those who did not stop contracting during the study period, 50% of our patients were delivered of preterm infants, as compared to 37% in the study of Valenzuela et al.[8]

The benefit of hydration was not demonstrated by this study. The potential risks, however, have been documented in previous articles. Of those who continue to contract and are subsequently treated with intravenous tocolytic agents, the risk of pulmonary edema is increased by the use of large amounts of fluid. This has been demonstrated with use of both β-sympathomimetics and magnesium sulfate.[6, 14] The use of sedatives such as valium or morphine sulfate in the treatment of patients who could potentially be delivered of preterm infants is also questioned. The depressive effects of these drugs on the preterm neonate can be seen at delivery and up to 2 to 4 days after their use.[15] Therefore we cannot advocate the use of either hydration or other agents until their benefit can be proved through prospective randomized studies.

Fetal heart rate patterns in the small-for-gestational-age human fetus

Robert Gagnon, MD, Cora Hunse, RN, and Alan D. Bocking, MD

London, Ontario, Canada

A total of 24 pregnant women with growth-retarded fetuses were studied to examine the distribution of fetal heart rate accelerations between 30 and 40 weeks' gestation, as compared with those of fetuses of normal growth that were matched for gestational age and length of fetal heart rate tracings. Growth-retarded fetuses had significantly lower Po_2 levels in the umbilical artery at birth (3 mm Hg less) than did healthy fetuses ($p < 0.05$), but without metabolic acidosis. There was a larger proportion of small amplitude (<10 beats/min) and a smaller proportion of large amplitude (>20 beats/min) fetal heart rate accelerations in the small-for-gestational-age fetuses than in the fetuses of normal growth. Although the number of accelerations was significantly reduced (50% less) in growth-retarded fetuses compared with healthy fetuses, there was no significant difference in the mean basal fetal heart rate and the mean number of decelerations between the two groups. Currently used definition of an acceleration as ≥15 beats/min for ≥15 seconds was applicable only in fetuses of normal growth. We hypothesized that a decrease in absolute acceleration frequency might be a useful index to detect the chronically hypoxemic fetus before severe metabolic acidosis and irreversible damage occurred. (AM J OBSTET GYNECOL 1989;161:779-84.)

The association between the presence of fetal heart rate (FHR) accelerations and fetal health[1] has led to the development and clinical use of antepartum FHR tests.[2] Currently used criteria for nonstress tests (NST) are based on the detection of FHR accelerations above the baseline of a predefined amplitude and duration.[3] To provide a better understanding of antepartum FHR tests in high-risk pregnancies, the aims of this study were to analyze the distribution of FHR accelerations

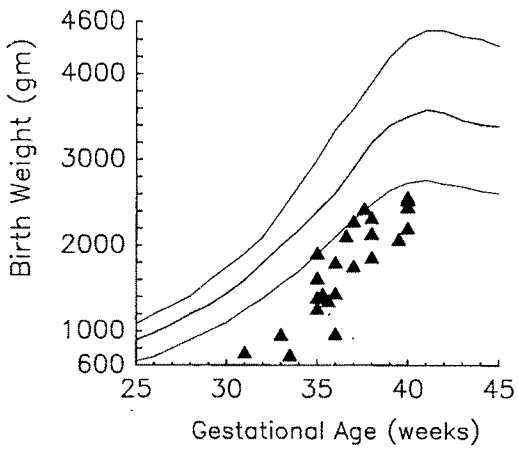

Fig. 1. Birth weight distribution of neonates. Normal range (mean ± 2 SD) is shown.

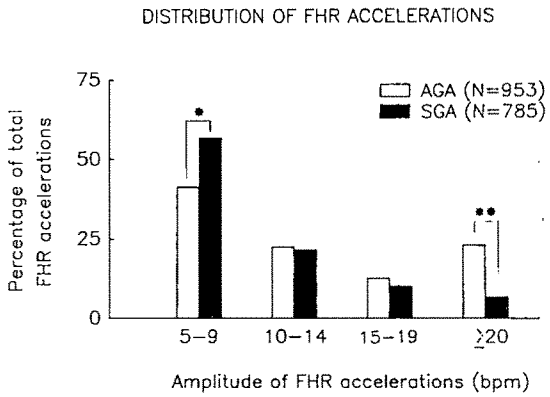

Fig. 2. Frequency histogram of 1738 FHR accelerations ≥15 seconds duration was plotted in successive increments of 5 beats/min to define distribution of acceleration amplitudes in SGA and AGA fetuses. (* $p < 0.05$; ** $p < 0.01$.)

in small-for-gestational-age (SGA) fetuses from 30 weeks' gestation to term and to determine whether current criteria used for nonstress tests are applicable in SGA fetuses.

Material and methods

Experimental design. The study participants received a standardized 800 kcal breakfast or lunch at 8 AM or at noon. All studies began 1 hour later and were conducted in a quiet room with patients either sitting upright in bed or resting in a lateral recumbent position. Participants were asked not to smoke ≥4 hours before the studies. Smoking or food intake by patients or observers was not permitted during the studies. This protocol, although not done for routine NSTs, was designed to minimize the potential effect of maternal glycemia on FHR.[4] In the SGA group, participants were studied continuously for 30 minutes (n = 10) or 1 hour (n = 30) and were matched for length of observation and gestational age with patients with appropriate for-gestational-age (AGA) fetuses. Seven patients in the SGA group and two in the AGA group participated in more than one study, separated by ≥7 days. Six studies were done at 30 to 32 weeks' gestation, 19 at 33 to 35 weeks' gestation, and 15 at 36 to 40 weeks' gestation in each group for a total observation time of 70 hours.

FHR measurements. FHR was recorded with a Hewlett-Packard 8040A (Hewlett-Packard GMBH, Boeblinger, Federal Republic of Germany) external monitor by use of a compact transducer and was analyzed on-line by a Sage II microprocessor (Sage Computer Technology, Reno, Nevada) as previously described.[5,6] The FHR intervals were examined by means of an artifact detection algorithm, and valid pulse intervals were averaged over 3.75 seconds. During on-line analysis a baseline was fitted to the heart rate record.[7] FHR accelerations ≥10 beats/min for ≥15 seconds above the baseline and FHR decelerations of ≥10 beats/min for ≥60 seconds below the baseline were recognized automatically.

For each 10-minute interval the basal FHR (beats/min), the number of FHR accelerations, and the number of FHR decelerations were calculated. Fetal breathing movements and gross fetal body movements were measured with a real-time ultrasound scanner (Model 2130, Advanced Diagnostic Research Corp., Tempe, Arizona) and will be reported elsewhere.

Data analysis. The basal FHR, the number of FHR accelerations ≥10 beats/min for ≥15 seconds above the baseline, the number of FHR decelerations ≥10 beats/min for ≥60 seconds below the baseline, and amplitude of individual FHR accelerations were determined on-line in successive 10-minute intervals. The number of FHR accelerations ≥15 seconds and FHR decelerations ≥60 seconds were also automatically determined off-line for acceleration and deceleration amplitudes of 5 beats/min and in successive increments of 5 beats/min to a maximum amplitude of 60 beats/min.

Portions of records that could not be analyzed because of FHR signal loss of >30% or patient interruption were not included and made up 1.2% of total study time. The average signal loss of the remaining 69.2 hours included in this analysis was 3.3% ± 0.5% in the SGA group and 4.5% ± 0.5% in the AGA group.

Results are presented as grouped mean and SEM. The significance of difference in the means was examined by unpaired Student t test and χ^2 for proportions. Standard regression analysis with Pearson product-moment correlations (r) were determined.

Results

Patients. Informed consent was obtained from 46 pregnant women with singleton pregnancies between 30 and 40 weeks' gestation with clinical or ultrasono-

Table I. Patient characteristics

graphic findings suspicious for intrauterine growth retardation (IUGR) (SGA fetus) and in 36 low-risk pregnant women (AGA fetus) matched for gestational age. All AGA infants subsequently had normal neonatal outcomes. All patients either had reliable menstrual dates or underwent ultrasonographic examination during the second trimester. Usher and McLean[8] charts were used to classify the birth weights at sea level of the fetuses studied. Growth retardation was diagnosed when birth weight was less than the 3rd percentile for gestational age. A total of 22 (48%) of the 46 participants with fetuses thought to be SGA had normal term deliveries with normal birth weights and were excluded from subsequent analysis. All other participants were delivered of infants with a birth weight less than the 3rd percentile (Fig. 1). The 3rd percentile at sea level is similar to the 10th percentile for birth weights of the Denver standards.[9]

Patients who subsequently were delivered of SGA infants ($n = 24$) were matched for gestational age and length of heart rate tracings with healthy pregnant women (AGA; $n = 36$). Table I illustrates the characteristics of the fetuses studied. Umbilical arterial and venous blood gas values were determined in all SGA fetuses and in 26 AGA fetuses. The mean umbilical artery P_{O_2} level at birth was 15.1 ± 1.0 mm Hg in SGA neonates, which was significantly lower than 18.0 ± 0.8 mm Hg in AGA neonates ($p < 0.05$; Table II), which suggests the presence of chronic hypoxemia in SGA fetuses. There was no significant difference in the umbilical artery P_{CO_2} level and pH at birth between SGA and AGA neonates (Table II). One neonatal death of a 40-week SGA infant occurred because of bilateral diaphragmatic hernia (umbilical arterial cord blood pH of 7.30 and P_{O_2} level of 14.8 mm Hg). There was no other congenital anomaly or neonatal death. Twelve (50%) patients in the SGA group were delivered of infants by cesarean section: two because of intrapartum fetal distress; two because of prolonged nonreactive NSTs; two because of footling breech presentation at the onset of labor; two because of severe pregnancy-induced hypertension; one because of prolapsed cord; and three were repeat cesarean sections.

Distribution of FHR accelerations. Fig. 2 is a histogram plot of 1738 FHR accelerations ≥15 seconds above the baseline in the 60 fetuses studied. The percentage of total FHR accelerations was calculated in successive increments of 5 beats/min to define the distribution of acceleration amplitudes. In SGA fetuses, 56.8% of FHR accelerations were <10 beats/min am-

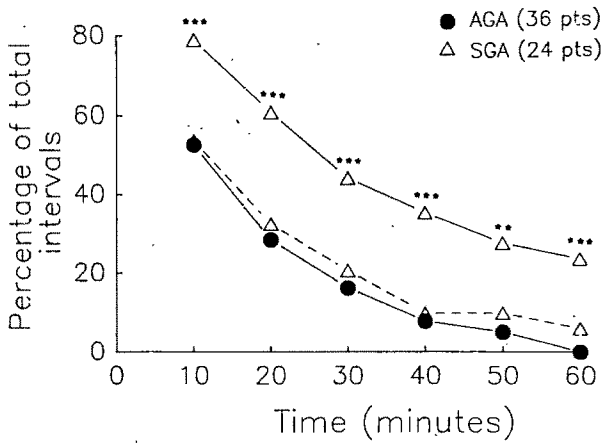

Fig. 3. Percentage of time intervals during which fewer than two FHR accelerations of ≥15 beats/min for ≥15 seconds occurred was plotted for all fetuses (——). (** $p < 0.01$ compared with AGA, *** $p < 0.001$ compared with AGA.) Percentage of time intervals during which fewer than two FHR accelerations of ≥10 beats/min for ≥15 seconds occurred was also plotted for SGA fetuses on same time scale (- - - -).

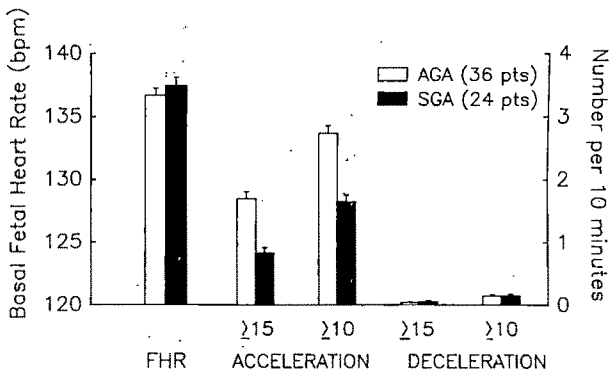

Fig. 4. Mean basal FHR, mean number of FHR accelerations per 10 minutes of ≥15 beats/min and ≥10 beats/min for ≥15 seconds, and mean number of FHR decelerations per 10 minutes of ≥15 beats/min and ≥10 beats/min for ≥60 seconds were plotted for each FHR tracing of AGA and SGA fetuses.

plitude, which was significantly higher than the 41.3% in AGA fetuses ($p < 0.05$). In contrast, SGA fetuses had fewer accelerations of large amplitude (≥20 beats/min) than did AGA fetuses (6.8% and 23%, respectively, $p < 0.01$).

The percentage of time intervals during which fewer than two FHR accelerations ≥15 beats/min for ≥15 seconds occurred is plotted in 10-minute increments (Fig. 3). In the AGA group, 52.6% of tracings had fewer than two FHR accelerations at 10 minutes and 1.3% at 60 minutes. However, in SGA fetuses 79% of the recordings had fewer than two FHR accelerations at 10 minutes, 35.2% at 40 minutes, and 24% at 60 minutes, which was significantly higher than in the AGA fetuses (all $p < 0.001$). With a minimum amplitude of 10 beats/min for ≥15 seconds to define an acceleration in SGA fetuses, the length of time from the beginning of recordings until two FHR accelerations occurred was similar to that of the AGA group (Fig. 3).

Relationship between basal FHR and amplitude of FHR accelerations. Fig. 4 summarizes characteristics of FHR accelerations and decelerations for each of the 426 10-minute intervals. The mean number of FHR accelerations per 10 minutes of ≥15 beats/min amplitude was 0.8 ± 0.1 in the SGA group, compared with 1.7 ± 0.1 in AGA fetuses ($p < 0.001$). With the use of a definition of 10 beats/min for acceleration amplitude in SGA fetuses, the mean number of FHR accelerations per 10 minutes was similar to that of the AGA group with the use of 15 beats/min for acceleration amplitude (1.6 ± 0.1 and 1.7 ± 0.1, respectively, Fig. 4). No significant difference was seen between AGA and SGA fetuses in the mean basal FHR and the mean number of FHR decelerations ≥10 beats/min for ≥15 beats/min for ≥60 seconds (Fig. 4).

There was a significant negative correlation between the mean amplitude of FHR accelerations of ≥10 beats/min for ≥15 seconds and the mean basal FHR in AGA fetuses ($r = -0.43$, $p < 0.01$), which demonstrated that in AGA fetuses at 30 to 40 weeks' gestation the higher the mean basal heart rate, the lower the height of individual FHR acceleration. No such correlation was found in SGA fetuses ($r = 0.02$, NS).

Comment

Analysis of the distribution of FHR acceleration amplitude in a highly selected population of SGA fetuses from 30 to 40 weeks' gestation demonstrated a larger proportion of small amplitude (<10 beats/min) and a smaller proportion of large amplitude (>20 beats/min) FHR accelerations than did the AGA fetuses. With 10 beats/min to define the minimum amplitude of an acceleration in SGA fetuses, the length of time necessary to have a reactive nonstress test will follow the same pattern as that in AGA fetuses with the use of 15 beats/min.

Although there was a significant negative correlation between the mean amplitude of FHR accelerations and the mean basal FHR in AGA fetuses, this relationship was not demonstrated in SGA fetuses. No significant difference in the mean basal FHR and the mean number of FHR decelerations was seen between SGA and AGA fetuses.

Creasy et al.[10] produced IUGR in the fetal lamb by reduction of the normal maternal uteroplacental blood flow. This was done by gradual embolization of the uterine vascular bed of the pregnant sheep with nonradioactive microspheres. The fetal lambs with growth retardation were chronically hypoxemic for the last 2 weeks of embolization and on average the P_{O_2} level into

the descending aorta was 3 mm Hg lower than that of fetuses of normal growth. Our data also demonstrated that SGA fetuses had, on average, Po_2 levels in the umbilical artery at birth 3 mm Hg lower than did AGA fetuses without significant metabolic acidosis (Table II), which suggests that SGA fetuses were chronically hypoxemic but not acidotic before birth.

It was previously reported[11] that human fetuses with severe but late-onset (>32 weeks' gestation) IUGR (birth weight less than the 3rd percentile) have a reduction in long-term FHR variability (25% less), incidence of gross fetal body movements (40% less), and time spent in FHR accelerations (50% less). Similar observations have been made in human fetuses with early-onset (<32 weeks' gestation) IUGR.[12] We have made use of computerized FHR analysis to define the distribution of acceleration amplitudes, which is the major component of long-term FHR variability.[5] Our data demonstrated that the decrease in FHR variability previously described in SGA fetuses[11-13] could be a result of a shift in the distribution of FHR acceleration amplitude, the small amplitude (<10 beats/min) being predominant with IUGR. A similar pattern is seen in healthy fetuses before 30 weeks' gestation[11] which suggests that severely growth-retarded (birth weight less than the 3rd percentile) human fetuses may have an "immature pattern" in the distribution of acceleration amplitude. This observation might indicate a delay in the functional maturation of the autonomic control of the FHR due to chronic nutritional deprivation and hypoxemia.

Current data, like others,[12, 13, 15] demonstrated a significant decrease in the number of FHR accelerations (50% less) in compromised SGA fetuses compared with AGA fetuses with the use of 10 or 15 beats/min as a definition for minimum FHR acceleration amplitude. With 10 beats/min as a minimum amplitude, the detection of FHR accelerations was improved in SGA fetuses at a level comparable to AGA fetuses with the use of 15 beats/min. It is therefore possible to speculate that currently used criteria for nonstress tests (FHR accelerations ≥15 beats/min for ≥15 seconds) could lead to classification of a high proportion of SGA fetuses as nonreactive (24% at 60 minutes, Fig. 3) and premature delivery.

We previously described in healthy human fetuses of >30 weeks' gestation, a significant negative correlation between the basal FHR and the mean amplitude of FHR accelerations.[14] It is believed that individual fetuses >30 weeks' gestation have a set "gain" for FHR accelerations that is related to the basal heart rate.[14] This relationship between basal heart rate and amplitude of FHR accelerations is not present <30 weeks' gestation in healthy human fetuses.[14] In SGA fetuses of >30 weeks' gestation such correlation could not be demonstrated, which suggests an impairment of the cardioacceleratory (β-sympathetic) system in the presence of chronic fetal hypoxemia. FHR decelerations ≥60 seconds did not occur more frequently in SGA fetuses than in AGA fetuses, which suggests that the parasympathetic (cardioinhibitory) system is probably not affected to the same extent as is the sympathetic tone during mild chronic fetal hypoxemia and nutritional deprivation. However, this remains to be determined.

The results indicated that in the presence of chronic hypoxemia without acidosis associated with IUGR, the earliest change in FHR patterns might be a decrease in the number of FHR accelerations rather than an increase in the number of FHR decelerations. Furthermore, the baseline heart rate was not significantly altered in the presence of IUGR. Use of an amplitude ≥10 beats/min to define an acceleration could be a strategy to increase the chance to detect FHR accelerations at >30 weeks' gestational age in SGA fetuses. The data also support the concept, as recently suggested,[16-17] that the presence of a decline in absolute acceleration frequency may be a sensitive indicator of chronic fetal hypoxemia before severe metabolic acidosis and irreversible damage occurs.

We thank Dr. J. Patrick for his interest in this work and Mrs. M. de Sousa for her technical assistance.

Impact of residual amniotic fluid volume in patients receiving parenteral tocolysis after premature rupture of the membranes

Richard K. Silver, MD, Scott N. MacGregor, DO, and Edward D. Hobart
Evanston, Illinois

The inhibition of labor subsequent to premature rupture of the membranes remains controversial. To evaluate the possibility that diminished amniotic fluid volume impacts on the latent period in patients receiving tocolytic therapy after premature rupture of the membranes, we reviewed our recent clinical experience with premature rupture of the membranes and the use of tocolytic agents. Between January 1985 and June 1988, 70 singleton pregnancies with premature rupture of the membranes between 25 and 34 weeks of gestation without prior tocolytic therapy were included. Ritodrine ($n = 22$), magnesium sulfate ($n = 37$), or both agents ($n = 11$) were administered and followed by oral terbutaline if tocolysis was achieved. Ultrasonographic examination was performed after admission and patients were grouped on the basis of estimates of residual amniotic fluid volume. Fourteen patients had adquate fluid volume; 20 had diminished fluid volume, and 36 had oligohydramnios. Patients with adequate fluid volume had a significantly longer interval between tocolytic therapy and delivery when compared with the other two categories (analysis of variance, $p < 0.001$), and proportionately more patients remained undelivered for >1 week (adequate 8 of 14 vs. diminished 3 of 20 and oligohydramnios 3 of 36; $p < 0.001$). In the 18 patients with premature rupture of the membranes before 30 weeks' gestation, adequate fluid volume was associated with the longest latent period (adequate 14.0 days; diminished 12.6 days, and oligohydramnios 2.8 days; analysis of variance, $p < 0.05$). We conclude that tocolytic therapy is of little benefit in the presence of oligohydramnios. If additional prospective studies of tocolytic efficacy in pregnancies complicated by premature rupture of the membranes are undertaken, inclusion of residual amniotic fluid volume as an independent variable before randomization should be considered. (AM J OBSTET GYNECOL 1989;161:784-7.)

Key words: Premature membrane rupture, tocolysis, amniotic fluid volume

The inhibition of labor subsequent to premature rupture of the membranes remains controversial. Although tocolytic therapy may forestall delivery in some patients,[1, 2] an improvement in perinatal outcome has not been identified.[3, 4] The inclination to use tocolytic agents is greatest when the diagnosis is made before 30 weeks' gestation because those fetuses may best benefit from pregnancy prolongation.[5] Other rationales for tocolytic therapy include delay of delivery to accomplish maternal transport or to administer antenatal steroids (the latter rationale is also controversial).

Two prospective, randomized trials evaluating the efficacy of tocolytic therapy in patients with premature rupture of the membranes were recently reported.[3, 4] Neither study identified an impact of tocolytic use on perinatal outcome, although one trial observed a sig-

nificant delay in delivery among patients diagnosed before 28 weeks' gestation.[4] Although both studies reached similar conclusions, the influence of diminished amniotic fluid volume was not considered in either study design. In patients with premature rupture of the membranes, reduced amniotic fluid is predictive of subclinical infection[6] and shorter interval to delivery.[7] Because they did not consider amniotic fluid volume before randomization, or control for its effects during analyses, both studies may have failed to identify significant differences between control and treatment groups. In clinical terms, patients with low amniotic fluid volume and preterm contractions may respond differently to tocolytic therapy when compared with quiescent patients with adequate amniotic fluid volume. To evaluate the possibility that diminished amniotic fluid volume impacts on the latent period in patients receiving tocolytic therapy after premature rupture of the membranes, we reviewed our recent clinical experience with premature rupture of the membranes and the use of tocolytic agents.

Material and methods

Between January 1985 and June 1988, all pregnancies complicated by preterm premature rupture of the membranes that were treated by tocolysis were considered for this study. Only singleton pregnancies between 25 and 34 weeks of gestation that had not received tocolytic therapy before premature rupture of the membranes were included. Of the 92 cases identified during this interval, 22 were excluded from analysis (twins, $n = 9$; prior tocolytic treatment, $n = 13$). The remaining 70 patients composed the study population.

The diagnosis of membrane rupture was made by sterile speculum examination in all cases; ferning of amniotic fluid was considered confirmatory. Reconfirmation of the diagnosis was mandatory for patients transferred from referring hospitals with the diagnosis of premature rupture of the membranes. Parenteral therapy with either ritodrine or magnesium sulfate was administered at the onset of regular contractions (or on admission, if contractions began before presentation). The decision to use tocolytics was made independently of amniotic fluid estimates. Ritodrine was administered at an initial dose of 100 μg/min, and was increased by 50 μg/min every 10 minutes until either an effective dose or 450 μg/min was reached. Magnesium sulfate was initially given as a 6 gm loading dose over 20 minutes followed by a 2 gm/hr maintenance dose (with a 4 gm/hr infusion limit). Measurements of magnesium ion blood levels were obtained when clinically indicated, and adjustment of either drug's infusion rate was predicated on achieving a uterine response of fewer than four contractions per hour. Oral terbutaline was administered to patients after intravenous treatment. The dose and frequency were adjusted to maintain maternal tachycardia (pulse≥100 beats/min). Tocolytics were withdrawn for any of the following reasons: if the diagnosis of intraamniotic infection was made (by virtue of elevated maternal temperature, fetal tachycardia, uterine tenderness, or positive Gram stain of amniotic fuid); if a mature lecithin/sphingomyelin ratio was identified; if labor progressed despite maximal therapy (cervical dilatation ≥5 cm); or if a change in fetal assessment (e.g., significant heart rate abnormality) prompted delivery.

An ultrasonographic examination was performed shortly after admission to assess fetal growth parameters and evaluate amniotic fluid volume. The largest pocket of amniotic fluid was identified and its vertical diameter was measured and recorded. Amniotic fluid assessment was repeated weekly if the patient remained undelivered.

Obstetric data were collected and coded and ultrasonographic results were also coded without knowledge of corresponding outcomes. Statistical methods included analysis of variance for continuous data, and χ^2 for categoric variables (3 × 2 contingency tables).

Results

Forty-one of the 70 patients were transported from referring hospitals and tocolytic therapy was instituted in 36 cases before transfer. Although 10 patients had a history of prior preterm birth, 40 (57.1%) were nulliparous. The mean gestational age on admission was 31.2 weeks; 18 patients were <30 weeks of gestation when premature rupture of the membranes occurred. The time from membrane rupture to hospital admission varied (range, 1 to 80 hours), with a mean interval of 13 hours. Tocolytic therapy was begun within 24 hours of membrane rupture in 59 (84.3%) patients. Magnesium sulfate was used most often (37 of 70, 52.9%) and 11 patients received simultaneous treatment with both magnesium sulfate and ritodrine. Forty-one patients (58.6%) were undelivered 48 hours after premature rupture of the membranes and 14 (20%) had a latent period >1 week. The most common indication for withdrawal of tocolysis was progressive labor despite maximum therapy ($n = 37$). Suspected intraamniotic infection prompted delivery in 16 cases. Of the 34 patients who had successful sampling by amniocentesis, positive Gram stains were identified in four cases. A mature lecithin/sphingomyelin ratio (obtained by amniocentesis) permitted withdrawal of tocolytic therapy in an additional six patients, and fetal heart rate abnormalities led to emergent delivery in six patients.

The initial ultrasonographic evaluation permitted categorization of patients on the basis of vertical measurement of the largest amniotic fluid pocket. Fourteen

Table I. Selected peripartum variables grouped acccrding to residual amniotic fluid volume after premature rupture of the membranes

	Amniotic fluid volume		
	Adequate (N = 14)	*Diminished (N = 20)*	*Oligohydramnios (N = 36)*
Gestational age at premature rupture of the membranes (wk, mean ± SD)	30.9 ± 2.0	31.2 ± 3.1	31.4 ± 2.9
Tocolysis instituted within 24 hr of premature rupture of the membranes (No. and %)	13 (92.8)	16 (80.0)	30 (83.3)
Magnesium sulfate only (No. and %)	6 (46.2)	12 (60.0)	19 (52.8)

patients had a measurement >3 cm and were considered to have adequate fluid volume; 20 had diminished fluid (vertical diameter between 1 and 3 cm), and 36 had oligohydramnios (vertical diameter <1 cm). Selected obstetric variables were compared between cases grouped according to amniotic fluid volume (Table I).

As shown in Table II, patients with adequate amniotic fluid volume had a significantly longer interval between institution of tocolytic therapy and delivery. This resulted in a greater proportion of undelivered patients at 48 hours of latency, a difference that persisted beyond 1 week of expectant management. Tocolytic failure was highest in patients with oligohydramnios (n = 22; 61.1%). This finding could not be attributed to a difference in the incidence of intraamniotic infection.

The impact of amniotic fluid volume was also examined in the subset of pregnancies admitted before 30 weeks' gestation (Table III). The presence of adequate fluid volume was again associated with the longest latent period and a significant increase in the proportion of undelivered patients beyond 48 hours from membrane rupture. In this same comparison the net increase in gestational age was highest in the adequate and diminished fluid groups (14.0 and 12.6 days; respectively) when compared with the patients with oligohydramnios (2.8 days; $p < 0.05$).

Perinatal outcome was favorable in this series with only four neonatal deaths, all occurring in patients with decreased amniotic fluid. The majority of significant morbidity also occurred in patients with decrased fluid. Ten of 11 cases of respiratory distress syndrome and 4 of the 5 cases of intraventricular hemorrhage were observed in these patients. Neonatal sepsis (e.g., bacteremia, pneumonia, or both) was observed in 3 of 14 infants in the adequate fluid group compared with 2 of 20 and 5 of 36 neonates associated with diminished fluid or oligohydramnios, respectively. Major maternal complications related to tocolytic treatment were not observed, nor were tocolytics withdrawn because of patient intolerance.

Comment

The persistence of amniotic fluid after premature rupture of the membranes appears to have a favorable impact on the latent period among patients receiving parenteral tocolytic therapy. Even patients with diminished fluid volume (maximum vertical measurement between 1 and 3 cm) experienced a significant increase in latency when compared with patients with oligohydramnios. The extent that tocolytic therapy itself influenced outcome cannot be ascertained from these data. However, one observation regarding tocolytic efficacy can be made despite the limitations of this uncontrolled study. Of the 36 patients with oligohydramnios, only 7 had a latent period >2 days. That 80% of these patients were delivered within 48 hours underscores the relative futility of tocolytic use in the absence of residual amniotic fluid. However, one potential justification would be to delay delivery long enough to complete a course of maternal steroid therapy, a controversial approach in patients with ruptured membranes.[8-10]

Many theories have been proposed to explain why patients without fluid are delivered shortly after membrane rupture. For example, a larger opening in the amniotic membrane, associated with excessive leakage, may permit a significant inoculum of genital tract bacteria to gain access to the amniotic cavity early in a patient's course.[7] Alternatively, the antibacterial properties attributed to amniotic fluid may be diminished in patients with the least residual fluid volume, leading to prompt bacterial colonization, subclinical infection and labor.[11] Oligohydramnios might result instead from increased uterine tone, which could interfere with reaccumulation and retention of fluid after membrane rupture. Although this last theory might provide a physiologic justification for tocolytic use, it is unlikely that any tocolytic treatment currently available will modify the clinical course in patients with oligohydramnios.

In conclusion, if additional prospective studies of tocolytic efficacy in pregnacies complicated by premature rupture of the membranes are undertaken, inclusion of residual amniotic fluid volume as an independent variable before randomization should be considered. A disproportionate representation of patients with oligohydramnios in either the treatment or control group might inadvertently bias the results. Finally, in those patients with oligohydramnios, tocolytic therapy is of no measurable benefit and should probably be withheld.

Cardiovascular and metabolic effects associated with nifedipine and ritodrine tocolysis

James E. Ferguson II, MD, Donald C. Dyson, MD,[a] R. Harold Holbrook, Jr, MD, Thomas Schutz, BA, and David K. Stevenson, MD[b]

Santa Clara and Stanford, California

Recent investigations have indicated that nifedipine, a calcium channel entry blocker, may be useful in the treatment of preterm labor. This prospective, randomized study compares cardiovascular and metabolic effects measured in association with sublingual and oral administration of nifedipine with those noted with the intravenous and oral administration of the β-adrenergic agent ritodrine. Serial measurements of cardiovascular parameters, hematocrit, electrolytes, glucose, blood urea nitrogen, creatinine, calcium, and serum glutamic-oxaloacetic and glutamic-pyruvic transaminase were compared between groups. Sublingual and oral nifedipine caused minimal cardiovascular alterations. At doses sufficient to achieve tocolysis, ritodrine caused more pronounced cardiovascular changes than nifedipine. Both agents had a hemodilutional effect, but nifedipine was not associated with alterations in serum electrolytes or a dramatic hyperglycemia. On the basis of this study, it appears that the use of nifedipine for preterm labor management is associated with hemodilutional changes but not the adverse cardiovascular or metabolic effects often associated with ritodrine tocolysis. (AM J OBSTET GYNECOL 1989;161:788-95.)

Key words: Nifedipine, ritodrine, premature labor, tocolysis

Currently a variety of pharmacologic agents are used to treat preterm labor, but only the β-adrenergic agent ritodrine has a Food and Drug Administration–labeled indication for such therapy.[1] The use of β-adrenergic agents, however, can be associated with undesirable cardiovascular and metabolic side effects.[1,2] These potential side effects prompted evaluation of an alternate tocolytic agent.

Because of their relaxing effects on the myometrium, calcium channel entry blockers show promise. Preliminary studies with nifedipine have suggested that it can inhibit labor while producing few apparent side effects.[3-5] However, knowledge of possible cardiovascular or metabolic effects associated with the sublingual and oral routes of administration of nifedipine in the pregnant patient is limited. We conducted this study to evaluate cardiovascular and metabolic responses to nifedipine, and to compare them with changes noted with the β-adrenergic agent ritodrine.

Material and methods

Between July 1984 and June 1986, patients with preterm labor occurring between 24 and 36 completed weeks of gestation were eligible for enrollment into the study. Informed consent as approved by the Stanford University Committee for Protection of Human Subjects in Research and the Kaiser Permanente Human Subject's Committee was obtained from each patient. Patients with the following maternal factors were excluded: tocolytic exposure during the current pregnancy, diabetes, hyperthyroidism, cardiac disease, severe preeclampsia-eclampsia, abruptio placentae, chorioamnionitis, multiple gestation, hydramnios, and cervical dilatation >4 cm. Fetal distress, severe intrauterine growth retardation, dead fetus, or fetal anomaly incompatible with life constituted fetal factors for exclusion.

Preterm labor was defined as regular uterine contractions with a documented change in cervical dilatation or effacement before 36 completed weeks' gestation. Once preterm labor was diagnosed and written consent had been obtained, the assignment group was determined by opening a sequentially numbered sealed envelope, randomized by the use of a random number table, with the patients stratified according to cervical dilatation (≤2 cm or >2 but ≤4 cm) and whether the patient had intact or ruptured membranes. An intravenous infusion of 5% dextrose in lactated Ringer's solution at 100 ml/hour was administered to all patients after an initial 200 ml fluid bolus. An electrocardiogram was obtained from each patient before and at 12 hours of treatment. Fetal heart rate and uterine activity were monitored continuously during the study. Cervical cultures for group B β-hemolytic streptococcus and *Neisseria gonorrhoeae* were obtained. The use of amniocentesis and steroid administration followed our standard

6/6/13712

practice as previously described.[6] Tocolysis was attempted in each group of patients for 48 hours in patients with ruptured membranes and through 36 completed weeks of gestation in patients whose membranes were intact.

Nifedipine tocolysis was initiated with a 10 mg capsule given sublingually. Patients were instructed to bite the capsule between their molars and, if possible, to avoid swallowing to facilitate sublingual absorption. If uterine contractions persisted after 20 minutes, a similar dose was repeated at intervals of 20 minutes, up to a maximal total dose of 40 mg during the first hour of treatment. If sublingual tocolysis stopped the uterine activity, then oral therapy with 20 mg of nifedipine was initiated 6 hours after the last sublingual capsule. This dose was repeated at 4 to 6-hour intervals, or if clinically indicated to continue tocolysis, occasionally at more frequent intervals. During treatment in the ritodrine group the infusion rate was begun at 50 μg/min and increased by 50 μg/min every 15 to 30 minutes in response to continued uterine activity until uterine contractions were inhibited, 350 μg/min was reached, or unacceptable side effects developed. Thereafter the infusion rate was decreased by 50 μg/min and was then maintained at that rate for 12 hours. After 12 hours the infusion rate was decreased by 50 μg/min every 2 hours until 100 μg/min was reached. If uterine contractions recurred, the sequence was repeated. Oral therapy (10 to 20 mg every 4 to 6 hours) was started 30 minutes before discontinuation of intravenous ritodrine. Tocolysis was considered to have been achieved when the treating physician determined that uterine contractions were stopped. At that time no further sublingual nifedipine therapy was given or the infusion rate of ritodrine was decreased to the maintenance rate.

In both study groups, fluid intake was limited to 2400 ml/24 hr, and volume of total intake and urine output was recorded. Patients were allowed no oral intake except when sips of water were permitted to swallow oral medications. Blood urea nitrogen, creatinine, calcium, serum glutamic-oxaloacetic and glutamic-pyruvic transaminase levels were measured before therapy and after 24 hours of treatment. Hematocrit, glucose, sodium, potassium, chloride, and bicarbonate levels were measured before therapy and after 8, 16, and 24 hours of treatment. The anion gap was determined for these intervals from the following formula: (sodium + potassium) − (chloride + bicarbonate). A baseline hemogram also was obtained for all patients.

Patients were positioned in left lateral recumbency for cardiovascular measurements. The superior arm was used and Korotkoff phase 4 documented the diastolic pressure. Mean arterial pressure was calculated with the standard formula. The pulse rate was determined by counting the pulse for 1 full minute. Patients in each group had a minimum of two pretreatment blood pressure and pulse rate determinations. In the patients who received nifedipine, systolic and diastolic blood pressures and pulse rate were measured 5, 10, and 20 minutes after each sublingual dose, then hourly until the first oral dose. During oral administration these parameters were measured before successive doses and at 5, 10, and 20 minutes, and 2, 4, and 6 hours after each dose during the first day. In the patients who received ritodrine, similar parameters were determined at the time of and 10 minutes, 20 minutes, 2 hours, and 4 hours after each change in the intravenous infusion rate and every hour once a stable infusion rate was determined.

Statistical analyses were performed with the use of an unpaired t test for comparison between the two treatment groups at specific time points (baseline and interval values), paired t test and assessment of difference patterns for comparison of serial interval values to baseline values within a treatment group, and χ^2 analysis with Yates correction for continuity. Additionally, a two-way analysis of variance with comparison of least-square means to identify specific differences was used to evaluate the effects of time and treatment, and the interaction of time and treatment. Linear regression was used to determine if there was any correlation between cumulative nifedipine dose over 24 hours on a milligram per kilogram basis and changes from baseline in the 24-hour metabolic parameters.

Results

Twenty-seven patients were randomly assigned to the nifedipine group and 26 to the ritodrine group. Cardiovascular data were not available for analysis from one of the nifedipine patients, and metabolic data were unavailable from one patient in the ritodrine group. During oral therapy, only patients who received 20 mg doses of nifedipine at 6-hour intervals in the initial 24 hours are reported. To evaluate possible differences between the two treatment groups at the same clinical end point (i.e., after uterine contractions had stopped), we compared cardiovascular effects at similar time intervals in both groups. Comparisons were made between cardiovascular values recorded at 20 minutes and between averaged values recorded from 2 to 4 hours after the last sublingual dose or the intravenous infusion rate necessary to stop uterine contractions in patients in the nifedipine and ritodrine groups, respectively.

Various factors that could have affected the study outcome are shown in Table I and indicate that the groups are comparable.

Pretreatment values and the cardiovascular responses to sublingual nifedipine administration for the 26 patients in whom sublingual tocolysis was evaluated are shown in Fig. 1, *A*. Twenty patients required four sublingual doses, four required three doses, and two patients required only two sublingual doses. When compared with pretreatment values, the systolic blood

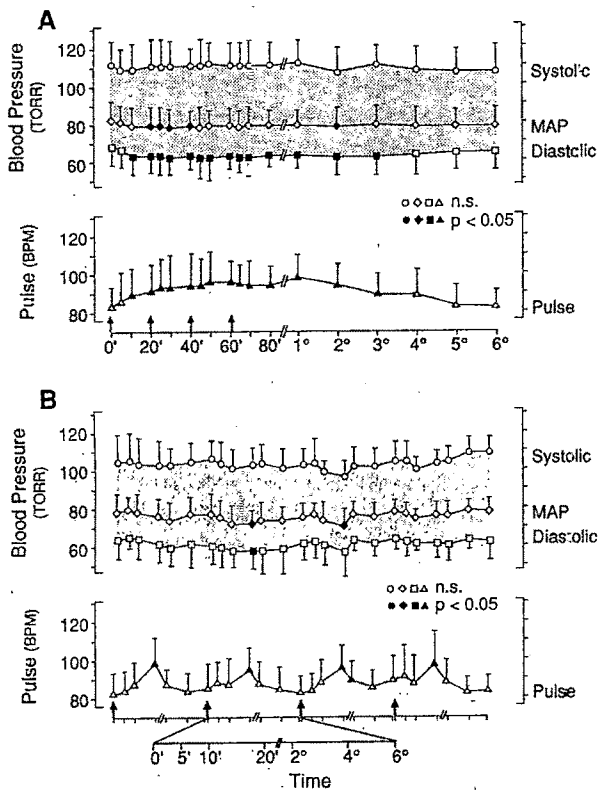

Fig. 1. A, Effects of sublingual nifedipine on systolic and diastolic blood pressure, mean arterial pressure *(MAP)*, and pulse rate. *Vertical arrows* indicate timing of administration of 10 mg of nifedipine. *Solid symbols* represent $p < 0.05$, compared with baseline values. **B,** Effects of oral nifedipine on systolic and diastolic blood pressure, mean arterial pressure *(MAP)*, and pulse rate. *Vertical arrows* indicate timing of administration of 20 mg of nifedipine. *Solid symbols* represent $p < 0.05$ compared with baseline values. Values expressed as mean ± SD.

pressure statistically did not change during sublingual dosing or during the 6-hour inteval after the last sublingual dose. However, diastolic blood pressure was decreased by 4 torr 10 minutes after the initial dose ($p = 0.018$). Additional doses caused little further decrease in diastolic blood pressure when compared with diastolic values recorded just before subsequent sublingual doses (i.e., at 20, 40, or 60 minutes after the initiation of treatment). The lowest mean diastolic pressure was 62.2 torr. The diastolic blood pressure remained decreased through 3 hours after the last sublingual dose ($p = 0.044$) and then returned toward pretreatment values. Changes in the mean arterial pressure occurred during the interval when diastolic blood pressure was decreased; however, because systolic blood pressure did not change significantly, the decreases in diastolic blood pressure were not always associated with statistically significant decreases in mean arterial pressure. The pulse rate increased 10 minutes after the initial dose ($p = 0.002$) when compared with baseline values and remained elevated through 3 hours after the last sublingual dose. When compared with pulse values recorded just before subsequent sublingual doses, only the increased value recorded 20 minutes after the third sublingual dose was statistically greater ($p = 0.018$). The maximal mean pulse rate was 98 beats/min and occurred 1 hour after the last sublingual dose.

Table I. Maternal factors of study patients randomly selected to receive nifedipine or ritodrine tocolysis

Classification	*Nifedipine*	*Ritodrine*
Age (yr)*	26.6 ± 5.2	25.9 ± 5.5
Gestational age (wk)*	30.7 ± 3.0	30.8 ± 2.3
White blood cell count*	11.1 ± 3.8	12.7 ± 3.8
Parity		
0	14/27	16/26
>0	13/27	10/26
Cervical dilatation (cm)		
≤2	22/27	20/26
>2, ≤4	5/27	6/26
Premature rupture of membranes	6/27	6/26
Betamethasone use	23/27	23/26

*Mean ± SD; none of these was significantly different by Student's t test or χ^2 analysis, where appropriate.

The cardiovascular responses of patients who received 20 mg of nifedipine orally at exactly 6-hour intervals are shown in Fig. 1, *B*. Values at 5, 10, and 20 minutes, and 2, 4, and 6 hours after each oral dose are compared with those measured just before each dose. Systolic blood pressure did not change significantly during oral therapy. Whereas diastolic blood pressure did decrease somewhat after each oral dose, when compared with predose values, only the decrease at 20 minutes after the second oral dose was statistically significant ($p = 0.03$). The mean arterial pressure demonstrated a similar pattern of change. After each oral dose, the pulse rate increased when compared with values measured before each dose. Statistically significant increases in pulse rate were consistently noted 20 minutes after each oral dose. Maximal pulse increases and diastolic blood pressure and mean arterial pressure decreases were similar in magnitude to those measured during sublingual administration.

Fig. 2 shows the cardiovascular response to stepwise increases with equal doses in the infusion rate of ritodrine in the 26 patients who were evaluated. The cardiovascular parameters depicted were obtained 15 to 30 minutes after the particular infusion rate was initiated. There was no significant change in systolic blood pressure, but diastolic and consequently mean arterial pressures decreased. Pulse rate increased significantly.

These changes were progressive until the 200 μg/min infusion rate was reached. Thereafter they changed little, but remained significantly different from baseline values.

In Table II, cardiovascular parameters measured in patients in both the nifedipine and ritodrine groups at the specified intervals after tocolysis was achieved are compared to baseline values and to each other. In the nifedipine patients, when interval values were compared with baseline values, systolic and mean arterial blood pressure did not change statistically, whereas the decreased diastolic blood pressure and the increased pulse rate were statistically significant at each interval. In the ritodrine patients in whom tocolysis was achieved, the labor-inhibiting rate was 221 ± 74 μg/min(mean ± SD), and the mean maintenance rate was 165 ± 53 μg/min. Systolic blood pressure did not change statistically when values from the ritodrine patients at each interval were compared to baseline; however, the decreased diastolic blood pressure and mean arterial pressure and the increased pulse rate were statistically significant at both intervals. When the nifedipine and ritodrine groups were compared, baseline values did not differ statistically for any of the cardiovascular parameters, nor did systolic blood pressure values differ when compared at either interval. Comparison between groups revealed that diastolic blood pressure and mean arterial pressure were statistically lower and the pulse rate statistically higher in the ritodrine group at both intervals after tocolysis.

Values for metabolic parameters that were obtained at baseline and after 24 hours of treatment are shown in Table III. In patients who received nifedipine, there was a decrease in blood urea nitrogen and serum glutamic-pyruvic transaminase values at 24 hours when compared to baseline ($p = 0.0042$ and $p = 0.004$, respectively). Although the absolute differences between baseline and 24-hour values were minimal, the decreased calcium values in both the nifedipine and ritodrine groups were statistically significant ($p = 0.0004$ and $p = 0.0058$, respectively). When values from patients in the two treatment groups were compared at baseline and 24 hours of treatment, no significant differences existed.

Glucose values after 8, 16, and 24 hours of treatment were significantly increased in both groups when compared with their respective baseline values (Fig. 3, *A*). Values in the ritodrine group also were statistically greater than values in the nifedipine group at 8 and 16 hours of therapy. Decreases in hematocrit were noted in both groups over time; the comparisons of interval to baseline values in each treatment group are shown in Fig. 3, *B*. Only the values at 8 hours of treatment differed significantly when interval values were compared between groups.

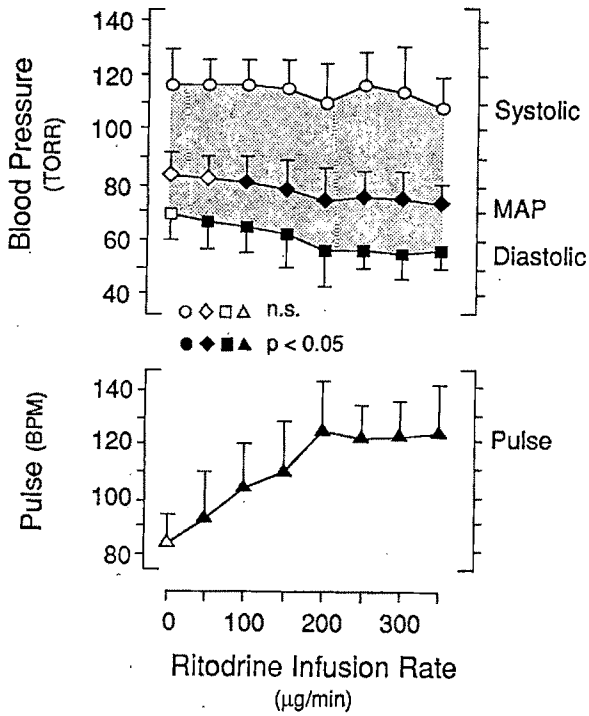

Fig. 2. Systolic and diastolic blood pressure, mean arterial pressure *(MAP)*, and pulse rate measured after stepwise increases with equal doses in the infusion rate of ritodrine. *Solid symbols* represent $p < 0.05$, compared with baseline values. Values expressed as mean ± SD.

Serum electrolyte values are tabulated in Table IV. Sodium values did not change with time in either group. During therapy, potassium values remained unchanged in the nifedipine group, but fell significantly in the ritodrine group. When comparisons were made between groups at the 8-, 16-, and 24-hour intervals of therapy, ritodrine values were lower ($p = 0.0001$, $p = 0.0001$, and $p = 0.0001$, respectively). Chloride values were unchanged over time in the nifedipine group, but increased significantly in the ritodrine group at 8 and 16 hours of treatment. Only the values at 24 hours of therapy differed between groups ($p = 0.004$). As shown in Table IV, interval values for bicarbonate did not differ from baseline in the nifedipine group; however, they decreased in the ritodrine group. When comparisons were made at the 8-, 16-, and 24-hour intervals of therapy between groups, the lower values in the ritodrine patients were only significant at the 8- and 16-hour comparisons ($p = 0.005$, $p = 0.001$, respectively). The anion gap did not change significantly over time in either group, but the anion gap was greater in the ritodrine group at the 8-hour determination when compared with the nifedipine group ($p = 0.0001$) and at the 16-hour comparison ($p = 0.025$).

Nif., Nifedipine; *Rit.*, ritodrine.

*Values are mean ± SD; number of subjects in parentheses.

†$p < 0.05$ comparison between values in the nifedipine and ritodrine patients at the specified interval.

‡$p < 0.05$ compared with baseline value.

The 24-hour values for blood urea nitrogen, creatinine, serum glutamic-oxaloacetic and glutamic-pyruvic transaminase, hematocrit, glucose, sodium, potassium, chloride, bicarbonate, and anion gap were compared with their respective baseline values and compared with the cumulative nifedipine dosage over 24 hours expressed on a milligram per kilogram basis. There were no significant correlations.

Comment

Nifedipine has been used with increasing frequency for the treatment of preterm labor, but the possibility that sublingual and oral nifedipine may cause cardiovascular or metabolic alterations had not been intensively investigated. Neither nifedipine nor ritodrine caused a significant change in systolic blood pressure during treatment. However, dramatically different results were noted between the two agents when diastolic and mean arterial pressure changes were evaluated (Figs. 1, *A* and *B*, and 2). Although statistically significant declines in diastolic blood pressure occurred after sublingual nifedipine administration, values at the time of maximum mean change still represented 92% of control and are unlikely to be of physiologic significance. During oral nifedipine administration, diastolic pressure also fell, but the decrease was significant in only one instance; the value represented 89% of control. Diastolic blood pressure decreases during ritodrine administration were more dramatic, and the magnitude and timing of the decreases approximated values previously reported when β-adrenergic agents were used.[7, 8] The maximum mean decrease (16 torr) occurred after the 300 μg/min infusion rate; the diastolic blood pressure at that time was only 77% of control. In addition, the pattern of change of diastolic blood pressure was different after nifedipine and ritodrine tocolysis. During nifedipine therapy, the diastolic pressure decreased initially but then remained relatively stable during additional doses. Conversely, increasing infusion rates of ritodrine were associated with progressive decreases in diastolic and mean arterial pressure until the 200 μg/min infusion rate was reached, at which time they tended to plateau. Increased pulse rates were noted in both patient groups. The magnitude of change was markedly different, however, probably reflecting the differences in diastolic and mean arterial pressure changes.

The exaggerated response to ritodrine and minimal alterations with nifedipine treatment are apparent (Table II). Similar differences between tocolytic treatment groups have previously been reported when insignificant cardiovascular changes were found after magnesium sulfate administration, compared with dramatic differences found during ritodrine infusion.[7] Since magnesium sulfate is functionally a calcium channel entry blocker, the similar significant differences between treatment groups we report in cardiovascular responses should perhaps have been expected.

When sublingual and oral nifedipine therapy are compared, it is interesting to note that pulse increases occurred 10 minutes after the first sublingual dose, but only 20 minutes after successive oral doses. In addition, although few significant changes in diastolic or mean arterial pressure occurred during oral therapy, when they did occur they were not noted before 20 minutes. These findings are similar to those noted by Raemsch and Sommer[9] and suggest a more rapid absorption and distribution of nifedipine after sublingual administration. Our findings support the contention of McAllister[10] that biting the capsule facilitates absorption of the liquid drug and lessens the time until the pharmacodynamic effects are observed when compared with oral administration of an intact capsule with the time delay before the capsule dissolves in the stomach and the drug is absorbed.

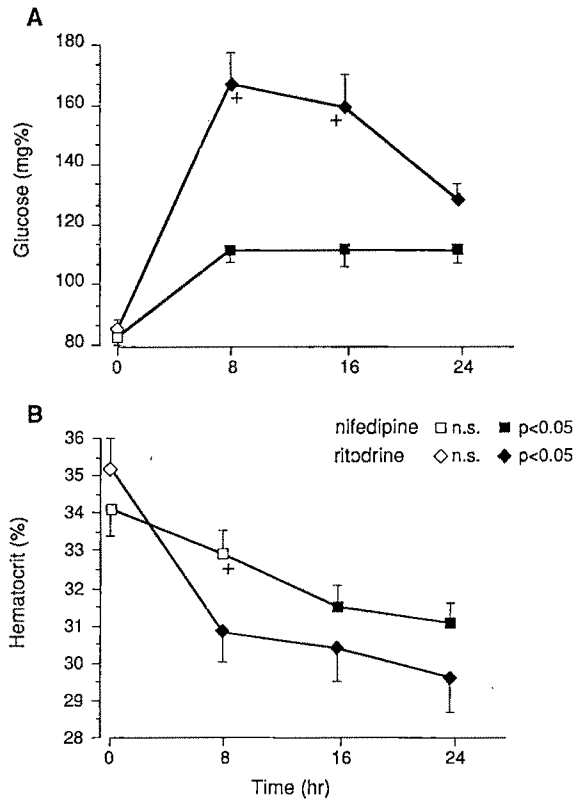

Fig. 3. Glucose values (**A**) and hematocrit values (**B**) (mean ± SEM) before and during nifedipine or ritodrine tocolysis. *Solid symbols* represent $p < 0.05$ compared with baseline values. *Cross*, $p < 0.05$ (comparison between values in nifedipine and ritodrine patients at specified interval).

This report provides the initial documentation of the cardiovascular changes of increased pulse rate and decreased diastolic pressure after the sublingual administration of nifedipine to treat preterm labor. Similar cardiovascular changes were noted with oral administration. The changes after oral administration are consistent with those reported by Ulmsten,[3] who used 30 mg as the initial dose, but discrepant from results of Read and Wellby,[4] who, using the same dosage schedule, did not note significant changes in the pulse rate or diastolic blood pressure. This discrepancy may be related to differences in the timing of measurement of the cardiovascular parameters.

Our study also contrasts the effects on metabolic parameters produced by the tocolytic agents nifedipine and ritodrine. It is well recognized that nifedipine ad-

ministration in nonpregnant patients causes vasodilatation and a resultant increase in plasma and extracellular volume.[11] The fall in hematocrit, calcium, and blood urea nitrogen levels recorded in patients in this study is consistent with the recognized vasodilatation and increased plasma volume. Ritodrine also affects fluid balance. Hemodilutional decreases in hematocrit and colloid osmotic pressure regularly accompany the clinical use of β-adrenergic tocolytic agents.[1, 2] In this study ritodrine was noted to cause a fall in calcium and a decrease in hematocrit during therapy. The decrease in hematocrit exceeded that noted with nifedipine at 8 hours of therapy.

We were especially interested in potassium values after nifedipine administration because hypokalemia has been documented previously in nonpregnant patients receiving nifedipine.[12] In the patients studied in the nifedipine group, potassium levels remained unchanged, as did the remainder of the electrolytes studied and the anion gap. Conversely, the ritodrine patients exhibited the same changes in electrolyte concentrations that have been previously documented and discussed.[2, 13, 14] Therefore differences between treatment groups in these parameters, when present, were the result of alterations of values in the ritodrine patients. Because of the lack of change of the bicarbonate and anion gap in the nifedipine group of patients it thus seems likely that this form of tocolysis is not associated with the increases in serum lactate and pyruvate that are commonly seen and responsible for the increase anion gap in patients receiving ritodrine.[13, 14]

There were marked differences in the magnitude of response demonstrated between groups for serum glucose concentrations. Patients in the ritodrine group exhibited the classic hyperglycemic response, with maximum values at 8 hours after initiation of infusion, with subsequent return toward baseline. Nifedipine patients demonstrated a modest degree of hyperglycemia. It was important to evaluate nifedipine's effect on glucose levels, because although most studies have documented that calcium channel entry blockers do not alter glucose homeostasis to a clinically relevant degree, some studies, (especially those with glucose loading and nifedipine doses >30 mg/day) have shown increased blood glucose and decreased insulin levels.[15] The mechanism is thought to involve blockade by nifedipine of a voltage-dependent "late" calcium channel of the pancreatic β-cell, which normally allows the further ingress of calcium and subsequent release of insulin.[15] Because all patients received a continuous intravenous infusion of a 5% glucose solution, we cannot discern if the increased glucose levels in the nifedipine patients were the direct result of nifedipine administration through the mechanism outlined above, a result of glucose-containing intravenous fluids, or both. The hyperglycemia noted with ritodrine was certainly much more dramatic when compared with that found with nifedipine administration, suggesting that nifedipine may be preferable if glucose homeostasis is a concern.

We have provided the initial documentation of cardiovascular responses after the sublingual use of nifedipine for tocolysis and evaluated possible metabolic changes. On the basis of this study, it appears that the use of nifedipine for preterm labor tocolysis is associated with hemodilutional changes but not the untoward and unwanted cadiovascular or metabolic effects reported with ritodrine tocolysis. Since animal studies with nifedipine have resulted in discrepant findings related to uteroplacental perfusion,[16, 17] a concern that presently limits the clinical use of calcium channel–blocking drugs is their possible effect on uteroplacental blood flow in the human. Carefully controlled human investigations that evaluate fetal response to nifedipine tocolysis are necessary before nifedipine is considered for routine clinical use in human pregnancies.

Prolactin levels in umbilical cord blood of human infants: Relation to gestational age, maternal complications, and neonatal lung function

C. Richard Parker, Jr., PhD,[a] Paul C. MacDonald, MD,[b] David S. Guzick, MD,[b] John C. Porter, PhD,[b] Charles R. Rosenfeld, MD,[b] and John C. Hauth, MD[a]
Birmingham, Alabama, and Dallas, Texas

The ontogeny of serum prolactin and its relation to several variables, especially lung function, in 543 neonates was studied. Umbilical cord serum prolactin levels rose between 24 and 42 weeks' gestation, correlating significantly ($p < 0.001$) with gestational age ($r = 0.44$) and birth weight ($r = 0.32$). Among infants of similar ages, however, there was no variation in serum prolactin level as a function of birth weight, sex, Apgar scores, or delivery method. Infants of women with pregnancy-induced hypertension had higher than normal prolactin levels; infants of diabetic women had normal prolactin levels. At 31.5 to 37 weeks' gestation, infants who developed respiratory distress syndrome had lower serum prolactin levels than those whose lung function was normal or else was abnormal from causes other than respiratory distress syndrome. The risk for respiratory distress syndrome was higher in newborns whose prolactin level was low (10th percentile) than in infants whose prolactin level was high (90th percentile). These results are suggestive that prolactin may play a role in fetal lung maturation. (AM J OBSTET GYNECOL 1989;161:795-802.)

Key words: Prolactin, respiratory distress syndrome (RDS), hyaline membrane disease, human fetal lung, pregnancy

The role of prolactin in lactation and the factors that serve to regulate pituitary prolactin production in adult humans are reasonably well characterized. On the other hand, the determinants of fetal pituitary prolactin production and the role circulating prolactin serves in the developing human are less well established. Two tissues in the fetus that may be regulated by prolactin are the lung and adrenal cortex. Serum levels of prolactin and the weight of the adrenals increase in concert during fetal development,[1] before the rise in the lecithin/sphingomyelin ratio in amniotic fluid.[2] Moreover, an augmentation of surfactant lipid synthesis in lung tissue by prolactin has been reported by some, but not all, investigators (see reference 3 for review). It also has been proposed that prolactin may, along with adrenocorticotropin, participate in regulation of adrenal steroid production in human adults[4] and fetuses.[5] If prolactin does, indeed, stimulate steroid production in the fetal adrenals, then prolactin also could play an indirect role in fetal lung maturation by means of inducing adrenal secretion of glucocorticoids and/or androgens that

are aromatized to estrogens in the placenta; glucocorticoids and estrogens have been shown, in turn, to stimulate surfactant lipid formation in fetal lung tissue.[6,7]

Several investigators[8-11] have provided evidence in favor of prolactin serving a role in fetal lung maturation by virtue of the observation that serum prolactin levels at birth were lower in infants who developed respiratory distress syndrome (RDS) than in infants of similar ages who did not develop RDS. More recently, however, it has been reported that umbilical cord serum levels of prolactin were not lower in newborns who developed RDS than in newborns who did not develop respiratory distress.[12] Therefore, we have continued to address the relation between prolactin in the developing fetus and several outcome variables and now provide our findings in 543 newborn infants, 361 of whom were delivered between 24 and 37 weeks of gestation.

Material and methods

Mixed umbilical arterial and venous cord blood was collected at the time of delivery over a 10-year period from newborns selected on the basis of gestational age and the presence or absence of maternal pregnancy complications. Since exogenous glucocorticosteroids can apparently affect fetal lung maturation and the fetal endocrine milieu, we excluded any newborns that had been exposed to synthetic glucocorticosteroids in utero. After clot formation, the serum was removed and stored frozen at −20° C. Serum prolactin was quantified by radioimmunoassay procedures described previously[8] that used reagents provided by the National Institute of Arthritis, Metabolism, and Digestive Diseases. The reference preparation was standardized against Research Standard A for human prolactin, 71/222, provided by the Division of Biological Standards, National Institute for Medical Research, London. Several assays were conducted to analyze all of the specimens, with each assay containing samples that were unselected with respect to any maternal or newborn parameter. The interassay coefficient of variation for the prolactin assay was 13%.

Of the 543 newborns included in this study, 228 were delivered of women whose pregnancy was considered to be uncomplicated, with the exception of premature delivery or prolonged rupture of the membranes in some; the remaining infants were delivered of women whose pregnancy was complicated by pregnancy-induced hypertension ($n = 144$), chronic hypertension ($n = 22$), diabetes ($n = 43$), or an assortment of other complications ($n = 106$). One hundred twenty-one of the newborns were the products of multiple gestations. Gestational ages of the 543 newborns ranged from 24 to 42 weeks since the onset of the last menstrual period and were determined by use of multiple clinical obstetric and fetal ultrasonographic criteria. Clinical obstetric criteria included a combination of the onset of the last normal menses, an early estimation of uterine size, fetal heart tones detected with a fetoscope at 18 to 20 weeks' gestation, quickening at 16 to 20 weeks' gestation, and concordance of uterine fundal height measurements between 20 and 30 weeks' gestation. Lung function of the newborns was determined by attending neonatologists who had no knowledge of the outcome of serum prolactin analyses. Lung function was normal in 370 of the infants whereas RDS was diagnosed in 90 infants and transient tachypnea or other respiratory abnormalities were diagnosed in 55 infants. The criteria used for establishing the diagnosis of RDS included the presence of grunting respirations and retractions, an increased oxygen requirement ($Fio_2 > 0.4$), a chest radiograph and laboratory findings consistent with a diagnosis of RDS, and exclusion of other causes of respiratory distress, especially pneumonia and/or sepsis.

Data pertaining to indices of lung function were inconclusive in 28 infants; serum prolactin levels of these infants were therefore excluded from analyses concerning lung function. By means of retrospective chart review, we also compiled data concerning Apgar scores (at 1 and 5 minutes), sex, birth weight, and delivery method (vaginal or cesarean section) on most (≥88% for each category above) of the newborns. The relationships between serum prolactin and various newborn outcome variables, maternal complications, and gestational age were evaluated by means of several statistical methods, including analysis of variance, multiple range t test, Student's t test, linear regression analysis, and logistic regression analysis. The protocol was reviewed and approved by the Institutional Review Board of the University of Texas Health Science Center at Dallas.

Results

Ontogeny of prolactin in newborn serum. When individual umbilical cord serum levels of prolactin were analyzed as a function of gestational age at delivery, a highly significant positive correlation was noted ($r = 0.44$, $p < 0.001$). A highly significant positive correlation was also observed between umbilical cord serum levels of prolactin and birth weight ($r = 0.32$, $p < 0.001$). When serum prolactin levels were subdivided according to gestational age groups (Table I), we found a highly significant variation as a function of gestational age ($F = 29.5$, $p < 0.001$). Serum levels of prolactin were significantly lower in infants whose gestational age was ≤28 weeks than in older newborns. Levels were significantly higher in infants having a gestational age that exceeded 34 weeks than in those delivered between 24 and 34 weeks of gestation. Whereas there was a significant correlation between birth weight

and serum prolactin levels for the entire group, the relation between these two variables among individuals within the same gestational age group was not significant.

Relation of umbilical cord serum levels of prolactin to maternal pregnancy complications. Umbilical cord serum levels of prolactin in newborns of women having no pregnancy complications are compared with those in infants of women with hypertension (chronic or pregnancy-induced) or diabetes in Table II. Within each gestational age group, cord prolactin levels from newborns of women with pregnancy-induced hypertension exceeded those from infants of women with normal pregnancies; these differences were statistically significant at all gestational periods except for infants delivered before 28.5 weeks of gestation. Serum levels of prolactin from newborns of women with chronic hypertension tended to be higher than those in infants delivered of women with a normal pregnancy; because of the small number of infants of women with chronic hypertension, however, the differences were not significant. Serum prolactin levels from infants of women with diabetes were similar to those from infants delivered of women with uncomplicated pregnancies.

Relation of umbilical cord serum levels of prolactin to intrauterine growth, Apgar scores, newborn sex, and delivery method. As shown in Table III, small-for-gestational-age infants had serum prolactin levels that were similar to those in appropriately grown infants. Also prolactin levels in newborns having Apgar scores <7 at 1 or 5 minutes were similar to those in infants with Apgar scores ≥7. Within each gestational age group, male and female infants had similar levels of prolactin in the umbilical cord serum. With the exception of infants delivered at or before 28 weeks of gestation, serum prolactin levels also were similar in those delivered vaginally and in those delivered by cesarean section.

Relation of umbilical cord serum levels of prolactin to newborn lung function. As shown in Fig. 1, umbilical cord serum levels of prolactin tended to be lower in infants who subsequently developed RDS than in newborns who did not develop RDS. The deficiency in serum prolactin levels among infants that developed respiratory problems was specific to RDS since newborns who had other causes of respiratory distress, such as transient tachypnea, were not significantly different from those in whom lung function was normal. Umbilical cord serum levels of prolactin were significantly lower in the RDS group than in newborns who did not develop RDS between 31.5 and 37 weeks of gestation.

During the intervals of 31.5 to 34 and 34.5 to 37 weeks of gestation, there were no significant differences in birth weights of the newborns as a function of their respiratory status (Table IV). On the other hand, the mean gestational age of newborns who developed RDS was slightly lower than that of infants whose lung function was normal (Table IV). Nevertheless, the deficiency in serum prolactin levels among the newborns who developed RDS was not attributable to the fact that

Data are presented as the mean ± SE. The number of infants in each group is indicated in parentheses. *AGA*, Appropriate for gestational age (≥10th percentile); *SGA*, small for gestational age (<10th percentile according to Brenner et al.[13]).

*Serum prolactin levels are higher in infants delivered by cesarean section than in those delivered vaginally at 24 to 28 weeks ($p < 0.05$). All other comparisons at each gestational period are not significantly different ($p > 0.05$).

their gestational age was somewhat less than that of the other two groups of newborns. This obtains because the weekly rate of increase in serum prolactin levels for all newborns during the gestational period of study was computed to be 13.1 ng/ml, a value much lower than the mean difference between serum prolactin levels in the RDS group and levels in either the normal group or the abnormal, non-RDS group (Fig. 1). At these two gestational periods, the proportion of small-for-gestational-age infants was not greater in the normal lung function group than in the RDS group (Table IV).

Since it has been suggested that maternal pregnancy-induced hypertension and/or impaired intrauterine growth might be somewhat protective against the development of RDS, we sought to determine whether such might be the case in our cohort of infants. During the interval of 31.5 to 34 weeks, the proportion of newborns of normal women having RDS was 30.7% (23 of 75), and that of newborns of women with pregnancy-induced hypertension was 29.4% (10 of 34). During the interval of 34.5 to 37 weeks, again the proportion of newborns having RDS in both groups was similar: normal women, 5.1% (4 of 79); women with pregnancy-induced hypertension, 4.2% (2 of 48). On the other hand, newborns of women having pregnancy-induced hypertension were more prone to be small-for-gestational-age [31.5 to 34 weeks, 44.1% (15 of 34); 34.5 to 37 weeks, 35.4% (17 of 48)] than were those of women having uncomplicated pregnancies [31.5 to 34 weeks, 6.7% (5 of 75); 34.5 to 37 weeks, 24.1% (19 of 79)]. Among small-for-gestational-age infants, the proportion of those having RDS was similar among newborns delivered of women having normal pregnancies (6 of 24) and those delivered of women with pregnancy-induced hypertension (5 of 32).

On the basis of our observation of an obvious tendency of premature newborns who developed RDS to have the lowest serum levels of prolactin, we subjected the data for prolactin and lung function to logistic regression analysis. As shown in Fig. 2, we found that the estimated probability of RDS developing in a newborn having a prolactin level at the 10th percentile for our population at any given gestational age was greater than that for an infant whose prolactic level is equal to the 50th percentile.

On the other hand, the probability of developing

*$p < 0.05$ compared with value for newborns with normal lung function.

respiratory distress syndrome is lower in a newborn having a high prolactin level (90th percentile) than in an infant whose prolactin level is equal to the 50th percentile. For example, at 30.5 weeks of gestation, the probability of RDS developing in an infant whose prolactin level is at the 10th percentile was computed to be 79%, that of an infant having a prolactin level at the 50th percentile was 66%, and that of an infant having a prolactin level at the 90th percentile was only 30.5%. At 34 weeks of gestation, the estimated probabilities of developing RDS at the 10th, 50th, and 90th percentiles for prolactin are 37%, 20%, and 6%, respectively.

Comment

In this study we found that the concentrations of prolactin in umbilical cord serum rose approximately threefold during the last trimester of gestation. The qualitative and quantitative aspects of these data

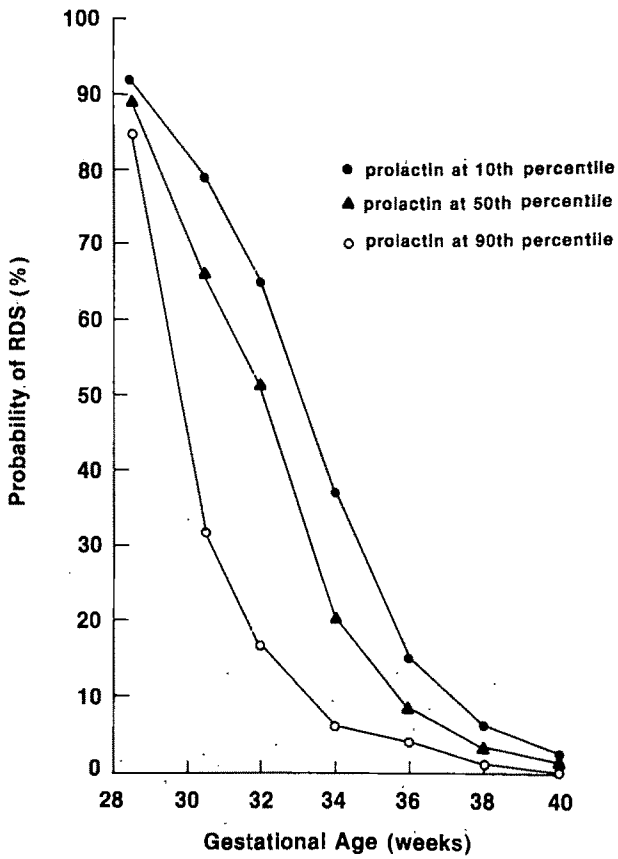

Fig. 2. Relationship between serum prolactin levels at birth and probability of developing RDS. Data for individual serum prolactin levels and for presence or absence of RDS were subjected to logistic regression analysis. Estimated probability of an infant developing RDS is plotted as a function of gestational age for newborns whose umbilical cord serum level of prolactin is equal to the 10th, 50th, and 90th percentile for the population that we studied.

are in general agreement with those reported previously.[1,3,8-12] Although there was a significant correlation throughout the entire gestational period of study between umbilical cord serum levels of prolactin and birth weight, we found no correlation between these variables among infants of similar gestational ages. Thus serum prolactin levels appear to correspond generally to developmental stage but are not appreciably influenced by the factor(s) that contribute to the extent of fetal growth at any given period of gestation. Also, whereas serum prolactin levels are believed to be influenced by acute stress,[14] we found no relation between umbilical cord serum prolactin levels and Apgar scores of the newborn infants. On the other hand, we (reference 15 and the present study) and others[11] have noted that serum prolactin levels in newborns of women with pregnancy-induced hypertension were significantly increased over those of newborns of women with normal pregnancy. A trend toward relative hyperprolactinemia also was noted in newborns of women with chronic hypertension. Such findings are suggestive that chronic intrauterine stress associated with various forms of maternal hypertension may lead to increased fetal prolactin production. In contrast to the recent report of Saltzman et al.,[16] however, we found no inhibitory effect of maternal diabetes on newborn prolactin levels either at or before term. The reasons for these discrepant findings are unclear at present but may be related to possible differences in the diabetic classes represented in the two studies.

In agreement with the results of our prior study[8] and those of several other investigators,[9-11] we find that newborns who subsequently develop RDS have a relative deficiency in serum prolactin levels at birth when compared with infants of similar ages who have normal lung function. The differences among these two groups of newborns are most apparent during the interval of 31.5 to 37 weeks of gestation. Because of the large number of premature infants in our study, we were able to perform logistic regression analysis on the relationship between umbilical cord serum levels of prolactin and lung function. On the basis of the results of these analyses, it seems reasonably clear that during the latter third of pregnancy the risk that RDS will develop is considerably less in a newborn who has a high serum prolactin level than in a newborn of similar age who has a low serum prolactin level.

Our current data also are suggestive that the prolactin deficit is specific to the occurrence of RDS; newborns who developed other types of respiratory problems had prolactin levels that were similar to those from newborns with normal lung function, but were significantly higher, at least between 31.5 and 37 weeks of gestation, than those from newborns who developed RDS. We are cognizant of the difficulty in differentiating between mild RDS and other respiratory abnormalities. Therefore, if some of the infants diagnosed with respiratory distress from causes other than RDS (who also tended to have normal or even elevated prolactin levels) actually did have RDS, then the deficiency in prolactin levels associated with RDS might be less apparent. On the other hand, if the RDS group contained infants who had respiratory distress from non-RDS causes, then the prolactin levels associated with true RDS might be even lower than we observed. It is likely that any errors in diagnosis would tend to be balanced in such a manner that our data are representative of meaningful physiologic differences between infants who develop RDS and those who develop other causes of respiratory distress. Among our selected group of newborns, those who were small-for-gestational-age were not found to be protected against RDS; the incidence of small-for-gestational-age was somewhat higher in those with RDS than among infants having normal lung function. Also, among this selected population, the incidence of RDS in newborns of women with pregnancy-

induced hypertension was not lower than that in similar-aged infants of normal women.

In addition to the relationship between low serum prolactin levels in the newborn and the development of RDS that has been demonstrated in this study, as well as others,[8-11] there also are reports that are suggestive of stimulatory effects of prolactin on the fetal lung, particularly in the production of surfactant lipids (see reference 3). Some investigators, however, have failed to detect any effect of prolactin on the developing lung (see reference 3). Other hormones also appear to participate in the induction of fetal lung maturation.[6, 7] Moreover, since the effects of prolactin on human fetal lung tissue have been evident in vitro only in the presence of other hormones (see reference 3), it seems likely that fetal lung maturation is subject to multifactorial regulation.

We believe that the human fetal adrenals play a role in the timing of the onset of surfactant production and fetal lung maturation. The human fetal adrenals produce glucocorticosteroids and large quantities of dehydroepiandrosterone sulfate,[17] which serves as precursor to placentally formed estrogens. Prolactin production in the pituitary of adult humans is stimulated by estrogens.[18] Thus at least three substances that have been suggested to participate in fetal lung maturation, i.e., glucocorticosteroids, estrogens, and prolactin, are produced directly or indirectly as a result of fetal adrenal activation. During the latter third of gestation, the human fetal lungs are exposed to ever-increasing quantities of estrogens, particularly estriol,[19] glucocorticosteroids,[20] and prolactin.[1, 3, 8-12] Coordinated production of all of these hormones and other factors, such as thyroid hormones,[6] may be required for the orderly maturation of the fetal respiratory apparatus. Disruption in the timely production of all or perhaps only some such substances may lead to delays in the maturation of the fetal lungs. We have found subnormal lecithin/sphingomyelin ratios in amniotic fluid of infants with hypoplastic adrenals caused by anencephaly[21]; Naeye et al.[22] have found morphologic evidence for lung immaturity in such infants. Moreover, deficiencies of estriol[19, 23] and cortisol[20] have been observed in infants who subsequently develop RDS. On the other hand, we have found that high umbilical cord serum levels of estriol (>90th percentile) are correlated with a low incidence of RDS in premature infants.[19]

On the basis of the findings of this study and the above considerations, we propose that prolactin, in addition to other factors, may play a role in lung maturation in the developing human fetus. We further suggest that pharmacologic induction of lung maturation in utero might be more successful if the agent(s) administered also possibly lead to increases in serum levels of prolactin and other hormones, such as estrogens (rather than reduced estrogen formation that occurs after glucocorticosteroid administration[24]).

We thank Kim Rivera and Jodie Roberts for excellent technical assistance and Barbara Quinnelly for editorial help.

Amniotic fluid leukotaxis assay as an early indicator of chorioamnionitis

Glenn A. Pankuch, BS, Peter H. Cherouny, MD, John J. Botti, MD, and Peter C. Appelbaum, MD, PhD
Hershey, Pennsylvania

A characteristic feature of histologic chorioamnionitis caused by ascending infection is the amniotropism displayed by polymorphonuclear leukocytes in the placental membranes. We tested the hypothesis that amniotic fluid from patients with histologic chorioamnionitis and intact membranes without clinical infection contains leukoattractants detectable by an in vitro leukotactic assay. Leukoattractants were detected in 13 cases (87%) and absent in 2 cases (13%) with histologic chorioamnionitis ($p < 0.005$). The two cases with histologic chorioamnionitis that had negative leukotaxis were classified as stage I/mild severity. A positive leukotactic response was a better predictor of histologic chorioamnionitis (87%) than positive Gram stain (33%), amniotic fluid culture (53%), gas-liquid chromatography (40%), or a combination of these three methods (60%). These results suggest that demonstration of leukoattractants in amniotic fluid is an earlier and more sensitive predictor of chorioamnionitis than is presently available. (Am J Obstet Gynecol 1989;161:802-7.)

Key words: Amniotic fluid, leukoattractant, histologic chorioamnionitis

Preterm birth is the major cause of perinatal morbidity and mortality. A predisposing cause cannot be found in most cases, thus making prevention difficult. Abundant research suggests that subclinical intrauterine infection is the cause of preterm labor.[1] However, clear understanding of the role of infection is hampered by traditional diagnostic tests, which are often insensitive and nonspecific.[2]

Histologic examination of the placenta for chorioamnionitis is often used to exclude intrauterine exposure of the fetus to infection. Unfortunately, this information is only available after delivery. Histologic chorioamnionitis is an inflammatory lesion of the placental and extraplacental fetal membranes that is frequently found after antenatal death and preterm birth.[3,4] The cause of chorioamnionitis has long been considered to be infectious. This view has not been universally accepted because correlation with clinical infection is poor and investigators have often failed to recover bacteria from the majority of inflamed placentas.[5] However, more recent studies using techniques that optimally culture for aerobes, anaerobes, chlamydia, and genital mycoplasmas have been able to demonstrate microorganisms by culture or serology in most cases of histologic chorioamnionitis.[5-7]

A characteristic feature of histologic chorioamnionitis is the amniotropism displayed by polymorphonuclear leukocytes in the extraplacental membranes, placenta, and umbilical cord. This suggests that diffusible leukotactic factors are released into the amniotic fluid or at membrane surfaces as part of the inflammatory response.[4] Although it is true that the placental inflammation that characterizes chorioamnionitis is nonspecific for a particular microorganism, in the majority of cases it is caused by intrauterine exposure to infectious agents in general. Therefore, an assay system designed to detect a broad range of leukoattractants in amniotic fluid should reflect chorioamnionitis and, indirectly, infection. To develop this system we have investigated use of a leukotactic assay as modified from Nelson et al.[8] The assay is based on the migration of polymorphonuclear leukocytes beneath an agarose gel in a random or directed manner in response to a leukotactic gradient, and is sensitive to a wide range and concentration of leukotactic factors.[9]

The purpose of this study is to evaluate the ability of the leukotaxis assay to predict histologic chorioamnionitis in asymptomatic patients with intact membranes. The assay is also compared with traditional microbiologic tests for infection.

Material and methods

Patients. Thirty-two amniotic fluid specimens were collected from 32 patients by transabdominal amniocentesis or needle amniotomy at cesarean section. Specimens were obtained after informed consent from patients who were delivered at The Milton S. Hershey Medical Center of The Pennsylvania State University. The study protocol was approved by the university committee on clinical investigation.

All patients had intact membranes and were without evidence of clinical infection[10] when fluid was obtained. Each patient was delivered within 48 hours of amniocentesis (mean ± SD) (gestational age, interval between fluid collection and delivery 32 ± 4 weeks' gestation and 8 ± 11 hours, respectively). Excluded from study were all cases of multiple gestation, polyhydramnios, and patients receiving antibiotics or immunosuppressants within 3 weeks of admission. Preterm labor was defined as four or more uterine contractions in 20 minutes associated with cervical change in patients with gestations of <37 weeks' gestation.

Initial processing and culture of amniotic fluid. Amniotic fluid was processed within 1 hour of collection. It was anticipated that some specimens would arrive at night. When delays of >1 hour but <12 hours occurred, a portion of the sample was reserved for bacterial culture and Gram stain by inoculating a Port-A-Cul vial (BBL Microbiology Systems, Cockeysville, Md.). Vials were kept at room temperature until cultured. Specimens stored ≥12 hours were not used. The remaining fluid was then refrigerated (4° C) until it could be processed as described below for gas-liquid chromatography (GLC), leukotaxis assay, and *Mycoplasma* culture.

After Gram staining,[11] each amniotic fluid was cultured as described below for aerobic and anaerobic bacteria. After culture, 1 ml of fluid was removed for GLC (details described below). The remaining fluid was then centrifuged for 10 minutes at 1000 *g*. Supernatants were removed and frozen (−70° C) for the leukotaxis assay. The resultant pellet was then examined for polymorphonuclear leukocytes and red blood cells after Wright's staining and cultured for *Mycoplasma hominis* and *Ureaplasma urealyticum*. For genital mycoplasma culture, 10 μl of the pellet was inoculated into urease color test broth U9C. Three tenfold serial dilutions were then prepared in U9C broth (incubated aerobically at 37° C for 21 days).[12] Ten microliters of the pellet and 10 μl from each serial broth dilution were spread onto A8 differential agar medium (incubated anaerobically in a glove box) (Coy Laboratory Products, Ann Arbor, Mich.) at 37° C for 21 days. Blind passage of negative broth cultures was performed on days 3 and 7 of incubation. Both U9C broth and A8 agar[12] were prepared from quality-controlled components.

Aerobic and anaerobic bacteria were cultured by spreading 0.1, 0.01, and 0.001 ml aliquots of uncentrifuged amniotic fluid in duplicate on the following media: trypticase soy agar with 5% sheep blood (BBL Microbiology Systems) (incubated aerobically at 37° C for 72 hours); chocolate agar (BBL Microbiology Systems) (incubated in 5% to 10% carbon dioxide at 37° C for 72 hours); prereduced chopped meat glucose broth (Scott Laboratories, Fiskeville, R.I.); enriched brucella blood and laked blood agars[11] (incubated anaerobically in a Coy glove box at 37° C for 21 days) (Coy Laboratory Products). The number of polymorphonuclear leukocytes, red blood cells, and bacteria in stained smears was examined by trained technologists and recorded as follows: few = <1 cell per oil immersion field; + = 1 cell per oil immersion field; + + = 2 to 4 cells per oil immersion field; + + + = 5 to 30 cells per oil immersion field; + + + + = >30 cells per oil immersion field. Smears were considered positive for polymorphonuclear leukocytes if ≥1 polymorphonuclear leukocyte/oil immersion field was found in the absence of red blood cells. Microorganisms were identified as described in standard texts.[11, 12]

Because a previous study at our institution failed to detect *Chlamydia trachomatis* by culture and serologic testing in our patient population,[5] these organisms were not studied. Viruses were not examined because no correlation has been found between acute chorioamnionitis and elevated maternal antibody titers during

pregnancy against those viruses most frequently infecting the placenta and fetus.[5]

GLC of amniotic fluid. Specimens were extracted and analyzed for volatile and nonvolatile organic acids using standard procedures.[11] Uninoculated controls treated the same as test samples were run with each analysis. Extracts were analyzed on a CAPCO model 700 gas chromatograph (DODECA, Fremont, Calif.) equipped with a thermal conductivity detector.[11]

Histology. After delivery sections of the central and peripheral area of the placenta, the umbilical cord, and rolled section of fetal membranes wre fixed in buffered formalin and stained with hematoxylin and eosin. Histologic chorioamnionitis was defined as the accumulation of polymorphonuclear leukocytes in the intervillous space immediately below the chorionic plate. The inflammatory process was classified both by stage and severity as described elsewhere.[13]

Leukotaxis assay. Details of the assay appear in Chenoweth et al.[14] Briefly, glass microscopic slides (Fisher Scientific, Springfield, N.J.) were coated with gelatin (Difco Laboratories, Detroit) and air dried. Five ml of agarose (Sigma Chemical Co., St. Louis) containing gelatin (Difco) and basal medium Eagle (GIBCO Laboratories, Grand Island, N.Y.) was layered onto each slide and allowed to solidify. Three precisely spaced circular wells were then cut into agarose gel with the aid of a specially made punch and template.[8] Ten microliters of the test amniotic fluid were placed into one of the outer wells and basal medium Eagle (control) in the other. Finally, 10 μl of human polymorphonuclear leukocytes suspended in basal medium Eagle (1×10^5 polymorphonuclear leukocytes per milliliters) were placed into the central well. The slide was incubated at 37° C in an atmosphere containing 5% carbon dioxide in air. After a 2-hour incubation period the slide was removed and fixed in anhydrous methanol. After fixation the gel was removed from the slide intact. The fixed cells on the slide surface were stained with Wrights stain and air dried. The cost and time required to complete the assay are approximately $2 per test and 8 hours, respectively.

Measurements of the distance polymorphonuclear leukocytes migrated toward the well containing amniotic fluid compared with the distance migrated in response to the control (neat basal medium Eagle) were assessed qualitatively and semiquantitatively (Fig. 1). Qualitative assessment of the migratory pattern (+ or −) was performed under a hand lens (×4 magnification). Migratory distances were semiquantified with a microscope (American Optical Corporation, Buffalo, N.Y.) equipped with a calibrated ocular micrometer (×100). Direct migration (A) was defined as the furthest point (linear distance) that three neutrophils in the same plane moved from the margin of the central well toward the outer well containing the test amniotic

fluid. Similarly, spontaneous migration (B) was defined as the distance toward the outer well containing the control basal medium Eagle. From these measurements the chemotactic index (CI) was calculated (CI = A/B).[8] Experiments were run in triplicate. The calculated chemotaxic index for each amniotic fluid was the mean of all three experiments. Fluids with a chemotaxic index of ≥1.2 were considered positive. Positive and negative controls were included with each experiment as a check on assay performance. The positive control was an amniotic fluid from a patient whose placenta showed evidence of histologic chorioamnionitis (stage III–severe) and the negative control was amniotic fluid from a patient without histologic chorioamnionitis. To test the effects of storage, five positive and five leukotaxis-negative fluids were stored at −70° C for 2 months. Fluid testing was performed without prior knowledge of results from histologic examination or clinical features of the case.

Statistical comparisons. Statistical comparisons were tested at the 5% level of significance ($p = 0.05$) using the Fisher's exact test. The diagnostic accuracy of laboratory tests was defined by sensitivity, specificity, and efficiency.[15]

Results

A comparison between placental histology and laboratory tests of amniotic fluid is shown in Table I. Histologic chorioamnionitis was found in 15 placentas, and correlated well with leukoattractants in amniotic fluid and, to a lesser extent (in decreasing order) with polymorphonuclear leukocytes in fluid pellets, culture, GLC, and Gram stain. The breakdown by histologic stage/severity was as follows: stage I–mild (two placentas), stage I–moderate (three placentas), stage II–mild (one placenta), stage II–moderate (two placentas), and stage III–severe (seven placentas). The leukotaxis assay was positive in 13 cases (87%) and negative in two cases (13%) with histologic chorioamnionitis ($p < 0.005$). The two cases with histologic chorioamnionitis that had negative leukotaxis were classified as stage I/mild severity.

Amniotic fluid cultures were positive in eight (53%) of the cases with histologic chorioamnionitis. Each fluid yielded a single isolate. Organisms recovered included *Fusobacterium nucleatum* (six fluids), microaerophilic streptococci (one fluid), and *U. urealyticum* (one fluid). The leukotaxis assay was positive in each of the culture-positive fluids. In every case in which positive polymorphonuclear leukocytes were found in fluid pellets, leukotaxis assays and histologic chorioamnionitis were positive. However, in two cases leukoattractants and histologic chorioamnionitis were found without significant numbers of polymorphonuclear leukocytes in fluids.

Leukoattractants were found in four fluids in which the combined results of culture, Gram stain, and GLC were negative (Table I). Fluid pellets of all four were positive for polymorphonuclear leukocytes and all matching placentas had histologic chorioamnionitis. The breakdown by histologic stage-severity was as follows: stage I–moderate (one placenta), stage II–mild (one placenta), and stage III–severe (two placentas).

Histologic chorioamnionitis was not detected in association with one leukotaxis-positive fluid from a patient who was delivered preterm (Table I). All other laboratory tests on this fluid were negative. This patient was not in labor at the time of amniocentesis, which was performed for fetal distress. After delivery histologic examination of the placenta revealed recent infarction. A comparison of the diagnostic accuracy of each laboratory test as a predictor of histologic chorioamnionitis is shown in Table II.

A positive leukotaxis result was associated with delivery within 48 hours in every case. Thirteen (93%) of the leukotaxis-positive fluids were from patients with preterm labor at amniocentesis. One leukotaxis-positive fluid was from a patient not in labor; infarction was

*Amniotic fluid from patients with intact membranes without clinical infection, and delivering within 48 hours of amniocentesis.
†Considered positive if ≥1 polymorphonuclear leukocyte per oil immersion field in fluid pellet.
‡≥1 test(s) (culture, Gram stain, GLC) positive.

found in this patient's placenta (see Table I). Of 18 leukotaxis-negative fluids from patients delivering within 48 hours, 10 were from patients in labor at amniocentesis. Placentas from two of these patients had histologic chorioamnionitis (stage I–mild severity). There were no complications related to tocolytic therapy in any patient.

One patient in this study developed clinical infection after amniocentesis and another developed postpartum endometritis. Fluid cultures yielded *Fusobacterium nucleatum* and microaerophilic streptococci, respectively. Both fluids were leukotaxis-positive. Neonatal sepsis strictly indicated by positive cultures of blood or cerebrospinal fluid was not found in any patient. No significant difference was found between qualitative and semiquantitative measurement of leukotaxis. No change in leukotaxis was found in fluids stored frozen at −70° C for 2 months.

Comment

It has been suggested that ascending intrauterine infection is a significant underlying cause of preterm labor and premature rupture of the membranes. This hypothesis is supported by histologic data that indicate an association between chorioamnionitis and these common clinical entities.[1] Because histologic information is not available before delivery, other criteria are used to define infection during the perinatal period. Signs and symptoms of clinical infection are typically used for diagnosis. Unfortunately, criteria for clinical infection are nonspecific, insensitive, and frequently only indicate advanced amniotic fluid infection. Other criteria used to define infection include amniotic fluid culture, Gram stain, GLC, and bacterial endotoxin assay.[2, 16]

In this study histologic chorioamnionitis was used as evidence of exposure to intrauterine infection. Amniotic fluid culture, Gram stain, and GLC were found to be less sensitive tests for intrauterine infection (as determined by histology) than the leukotaxis assay. The higher sensitivity of the leukotaxis assay may be attributed to detection of extraamniotic fluid infection. The above three microbiologic assays require microorganisms, or their products, to reach a detectable level in amniotic fluid. Although very specific for intraamniotic fluid infection, these tests may fail to detect the initial stage of an ascending infection, which is believed to begin within the intact membranes, spreading secondarily to the amniotic fluid.[17] Furthermore, the microbiologic approach of attempting to identify the etiologic agent is limited because a wide variety of microorganisms have been implicated,[1] thus making exhaustive detection difficult. The inability of microbiologic tests to detect the initial stages of an ascending infection may limit an understanding of the role played by infection in premature labor.

Another criterion occasionally used for detection of infection is assay of polymorphonuclear leukocytes in amniotic fluid, either by direct microscopic examination or indirectly by leukocyte esterase activity. The significance, origin, and role played by amniotic fluid polymorphonuclear leukocytes in perinatal infection is largely unknown. In our study the association found between amniotic fluid polymorphonuclear leukocytes, leukoattractants, and histologic chorioamnionitis supports the theory that polymorphonuclear leukocytes can derive from inflamed membranes.[4] These findings suggest that polymorphonuclear leukocytes in increased numbers (≥1 polymorphonuclear leukocytes/oil immersion field/pellet) may reflect histologic chorioamnionitis and, indirectly, exposure to intrauterine infection. The advantage of the leukotaxis assay is that leukoattractants must precede the arrival of polymorphonuclear leukocytes in amniotic fluid. Measurement of C-reactive protein in maternal blood has also been suggested as an early indicator of histologic chorioamnionitis. However, conflicting conclusions have been reached regarding its potential clinical application.[18]

Findings in this study raise several questions. (1) Leukoattractants and polymorphonuclear leukocytes were found in four fluids in which the combined results of culture, Gram stain, and GLC were negative. These patients' placentas had marked histologic chorioamnionitis. Do these four cases represent extraamniotic infection? Despite exhaustive microbiologic techniques

there remains the possibility that some microorganisms in amniotic fluid were not detected. (2) Can leukoattractants present in amniotic fluid be unrelated to infection? This is not likely, because with the exception of the patient described below, all leukotaxis-positive fluids were associated with histologic chorioamnionitis. Other than infection, no satisfactory explanation for chorioamnionitis has been demonstrated.[3] Leukoattractants (but not polymorphonuclear leukocytes) detected in one fluid from a patient without chorioamnionitis may have been related to placental infarction. (3) Did measurement of leukoattractants in amniotic fluid correlate with severity of chorioamnionitis? The lowest histologic stage and severity of choriomnionitis was found in two placentas, both of which were accompanied by fluid without leukoattractants. This suggests that leukoattractants did not reach detectable levels. We lack sufficient data to draw conclusions regarding measurement of leukotaxis with more severe grades of chorioamnionitis.

Leukoattractants were not characterized in this study because the goal was to determine whether leukoattractants detected by the assay reflect histologic chorioamnionitis. Products of bacteria, complement, degenerating cells, leukotrienes, and reactive oxygen species, all of which are present during an inflammatory response, represent a partial list of leukoattractants. In vivo any of these factors may act alone or in concert with others to cause polymorphonuclear leukocyte migration. Regardless of whether all instances of chorioamnionitis result from infection, it is clear that inflammation can contribute to,[19] and perhaps initiate, labor.

The importance of *Fusobacterium* as a cause of occult amniotic fluid infection in patients with intact membranes has been emphasized.[20] Although life-threatening *Fusobacterium* chorioamnionitis does occur, most morbidity associated with this organism is attributed to prematurity. This view is supported by our study in which *F. nucleatum* accounted for 75% of positive cultures. Each of these patients was delivered preterm, and neonatal cultures of blood and cerebrospinal fluid were uniformly sterile.

In summary, the leukotaxis assay provides a simple direct method of determining placental inflammation and indirectly, exposure to intrauterine infection before delivery. This assay contributes to ongoing efforts designed to determine the relationship between preterm delivery and infection. We plan to continue to study these tests for their ability to detect intrauterine infection at an earlier stage than is presently possible. This may permit earlier intervention in the form of delivery of a healthier neonate, or successful intrauterine treatment of infections with the option of continuation of preterm pregnancy.

We thank Alan Pankuch for making the punch and template used in preparing the agarose gel slides.

Evidence relating bacterial vaginosis to intraamniotic infection

Helayne M. Silver, MD, Rhoda S. Sperling, MD, Patricia J. St. Clair, BA, and Ronald S. Gibbs, MD

San Antonio, Texas

We performed a two-part study to determine relationships of bacterial vaginosis and intraamniotic infection. In the first part of the study, we determined whether bacterial vaginosis organisms (*Gardnerella vaginalis, Mycoplasma hominis,* and anaerobes) were associated with each other in the amniotic fluid of 408 cases of intraamniotic infection. In the second part, we determined the association of bacterial vaginosis itself with intraamniotic infection in 125 cases at high risk for intraamniotic infection. Strong associations were observed among the bacterial vaginosis organisms in amniotic fluid ($p < 0.01$ to $p < 0.001$). Women with bacterial vaginosis were more likely to develop intraamniotic infection than those without bacterial vaginosis (69% vs. 46%, $p = 0.03$). Women with bacterial vaginosis were more likely to have *G. vaginalis* and *M. hominis* in the amniotic fluid ($p < 0.01$ and 0.04, respectively). These observations implicate bacterial vaginosis as a cause of intraamniotic infection. (AM J OBSTET GYNECOL 1989;161:808-12.)

Key words: Bacterial vaginosis, intraamniotic infection, amniotic fluid, *Gardnerella vaginalis, Mycoplasma hominis*

Bacterial vaginosis (also called nonspecific vaginitis and *Gardnerella vaginalis* vaginitis) is a common cause of vaginal symptoms.[1] Although bacterial vaginosis has a complex and at times controversial microbial etiology, evidence now supports a major role for anaerobes.[2, 3] *G. vaginalis* and *Mycoplasma hominis* are also found more commonly in vaginal secretions of affected women.[4, 5]

Other investigators have implicated bacterial vaginosis in preterm labor, preterm birth, preterm premature rupture of membranes, and amniotic fluid infection.[6-8] The purposes of this study were to (1) identify significant associations of organisms in amniotic fluid (especially of anaerobes, *G. vaginalis,* and *M. hominis*) from a series of cases of intraamniotic infection, (2) determine characteristics of intraamniotic infection associated with these organisms, and (3) determine whether bacterial vaginosis was associated with intraamniotic infection.

Methods

Data were gathered in two consecutive groups of women. In both groups intraamniotic infection was defined on the basis of a temperature ≥37.8° C and rupture of the membranes plus two or more of the following: maternal tachycardia (>100 beats/min), fetal tachycardia (>160 beats/min), uterine tenderness, foul odor of the amniotic fluid, or peripheral leukocytosis (>12,000/mm³).[9] Asymptomatic women had membrane rupture but no temperature ≥37.8° C and no other signs or symptoms of infection. Neonatal sepsis was defined as typical signs plus isolation from the blood of a pathogenic organism. Neonatal pneumonia was defined as respiratory symptoms with a patchy infiltrate on chest x-ray film.

Amniotic fluid was obtained by aspiration of an intrauterine pressure catheter that had been inserted for obstetric indications. Because of the possibility of contamination, the first 7 ml (equivalent to the volume of the catheter) was discarded, and the next 5 to 20 ml was collected in a separate plastic syringe. After air was expressed and the syringe was tightly capped, the specimen was transported to the laboratory where it was plated quantitatively within 60 minutes on a variety of media for aerobes and anaerobes.[9] After 1983, specimens were also plated on V-selective agar (Remel, Lenexa, Kan.) as a selective media for *G. vaginalis.* Otherwise, bacteriologic methods were similar throughout. Maternal and neonatal blood samples were collected by sterile venipuncture and inoculated into a set of two bottles, each containing 100 ml trypticase soy broth with 3% carbon dioxide and 0.03% sodium polyanethol sulfonate (BBL, Cockeysville, Md.). Amniotic fluid and blood isolates were identified by standard techniques. Amniotic fluid specimens were qualitatively cultured for genital mycoplasmas with a modification of the method of Kenny.[10] Blood was not cultured for mycoplasmas.

After collection of specimens, infected mothers were treated with penicillin G (5 million units intravenously every 6 hours) and gentamicin (1.5 mg/kg intravenously every 8 hours), usually beginning during labor. After 1982, for women with cesarean delivery, clindamycin was usually added after cord clamping for improved activity against anaerobes. In neonates, blood cultures and a chest radiograph were performed, collection of cerebrospinal fluid was performed only in infants with central nervous system signs. Neonates were treated within 2 hours of birth with ampicillin (75 mg/kg intravenously every 12 hours) and gentamicin (2.5 mg/kg intravenously every 12 hours) for at least 3 days. If results of the sepsis evaluation were negative, antibiotics were discontinued after 72 hours. For sepsis or pneumonia, infants were treated for approximately 10 days with appropriate therapy. Clinical data were collected on 29 variables.

Specific methods of each part of the study follow. In the first part, amniotic fluid was collected from patients with intraamniotic infection between July 1979 and October 1986. In determining associations and characteristics of intraamniotic infection with an index organism, we compared those cases containing the index organism (regardless of any other organism isolated) with cases not containing the index organism by the χ^2 goodness of fit test for discrete variables and a two-tailed Student's t test for continuous variables. A value of $p < 0.05$ was considered significant.

After completion of the first part of the study, we then enrolled a group of women at high risk for intraamniotic infection on the basis of rupture of membranes greater than 10 hours. We collected a vaginal Gram stain and amniotic fluid specimen (as above) and clinical data from these women. The vaginal Gram stain was scored from 0 to 10 by a single examiner (who was unaware of the clinical diagnosis) on the basis of semiquantitative estimates of *G. vaginalis*, *Lactobacillus*, and *Mobiluncus* morphotypes (unpublished observations).* A score of 0 to 3 was considered normal, 4 to 6 intermediate, and 7 to 10 as bacterial vaginosis. Other features of bacterial vaginosis (such as high pH, clue cells, amine odor) were not used because of the potential effect of membrane rupture on them. However, Eschenbach et al.[1] have shown that Gram stain criteria very similar to the ones we used correlated well with other clinical and microbiologic criteria of bacterial vaginosis in an outpatient population. Women who developed puerperal fever were excluded from the analysis because of the confounding influences such as cesarean delivery. Discrete data were compared by χ^2 test; $p < 0.05$ was considered significant.

*The vaginal Gram stain score was determined as follows:

Morphotype	*Points*	*Morphotype*	*Points*
4+ Lactobacilli	0	1 + *G. vaginalis*	1
3+ Lactobacilli	1	2 + *G. vaginalis*	2
2+ Lactobacilli	2	3 + *G. vaginalis*	3
1+ Lactobacilli	3	4 + *G. vaginalis*	4

Results

During the first part of the study, there were 408 cases representing approximately 1% of all deliveries and an estimated 40% of all cases of intraamniotic infection. In the remaining cases of intraamniotic infection, no amniotic fluid could be aspirated for study. The overall microbiologic results and neonatal outcomes, have previously been reported in part.[11] As in previous studies, these pregnancies were characterized by long intervals of membrane rupture (23.4 ± 19.7 hours, mean ± SD) and of internal monitoring (12.3 ± 6.8 hours, mean ± SD). Most patients were at term (39.5 ± 3.2 weeks, mean gestational age), and 174 (43%) had cesarean delivery. The mean temperature at diagnosis was 38.3° ± 0.4° C.

There were several significant associations found among organisms. As shown in Table I, strong associations were seen among *M. hominis*, *G. vaginalis*, and some anaerobes. Group B streptococci were associated with *Bacteroides bivius*. When group B streptococci were present in the amniotic fluid, *B. bivius* was present in 42% (25 of 60), whereas in fluid without group B streptococci *B. bivius* was present in 27% (95 of 348, $p = 0.02$). Stronger associations were observed among *Escherichia coli*, enterococci, and other aerobic gram-negative rods. When *E. coli* was present, enterococci were found in 21% (7 of 33) and other aerobic gram-negative rods in 24% (8 of 33). In fluid without *E. coli*, enterococci were present in only 4% (15 of 375), and other aerobic gram-negative rods were present in only 3% (13 of 373, $p < 0.001$ for both). We found no other significant association of any organism in amniotic fluid.

There were 26 (6.4%) mothers with bacteremia, but none had *G. vaginalis* organisms isolated. Only two (0.5%) had anaerobic bacteremia, both with Bacteroides species. Other maternal blood isolates were group B streptococci (11 cases), *E. coli* (7), *Staphylococcus aureus* (2), *Listeria monocytogenes* (2), and one each enterococci, viridans streptococci, *Streptococcus pneumoniae*, and *Pseudomonas aeruginosa*. There were 28 isolates (two patients had polymicrobial bacteremias). Isolates in cases of neonatal bacteremias have been previously reported.

When clinical features for intraamniotic infection associated with any index organism were compared with all other intraamniotic infection cases, there were few pertinent and significant differences. Specifically, clin-

Cesarean delivery (%)	35	31	

*Data are shown as mean ± 1 SD.

ical features such as maximum temperature in labor, labor duration, and duration of internal monitoring were not significantly different for anaerobe-, *M. hominis*–, or *G. vaginalis*–associated intraamniotic infection.

B. bivius–associated intraamniotic infection was accompanied by an increased number of maternal febrile days (1.8 ± 1.3 vs. 1.4 ± 1.3 days, $p = 0.02$), even though it was not associated with any other variable predisposing to more febrile days such as increased rate of cesarean section. In comparison, cases of *E. coli*–associated intraamniotic infection were accompanied by a significantly increased number of maternal febrile days after delivery (2.4 ± 1.8 vs. 1.5 ± 1.4 days, $p < 0.01$), but group B streptococci-associated intraamniotic infection was not (1.8 ± 1.7 vs. 1.5 ± 1.4 ± 1.3 days, $p = 0.2$).

In the second part of the study, 155 women were enrolled between October 1986 and March 1988. Overall 63 had intraamniotic infection and 62 remained asymptomatic. Thirty who developed puerperal fever were excluded from analysis because of major confounding influences of additional factors such as cesarean section. Bacterial vaginosis was present in 32 patients (26%), determined by Gram stain criteria. Characteristics of women with and without bacterial vaginosis are shown in Table II. The groups were not significantly different in any measure except labor duration.

Women with bacterial vaginosis developed intraamniotic infection in 69% (22 of 32) of cases, whereas those without bacterial vaginosis had intraamniotic infection less commonly, 46% (43 of 93, $p = 0.03$). Women with bacterial vaginosis were more likely to have *G. vaginalis* and *M. hominis* in the amniotic fluid and were less likely to have group B streptococci and enterococci in the amniotic fluid (Table III). Anaerobes were not isolated significantly more often in amniotic fluid of women with bacterial vaginosis.

Comment

In this study we made three observations associating bacterial vaginosis with intraamniotic infection. First, organisms previously reported to be associated with bacterial vaginosis (i.e., anaerobes, *G. vaginalis*, and *M. hominis*) were also found in association with each other in the amniotic fluid of women with intraamniotic infection.[1-4] Second, bacterial vaginosis was significantly associated with intraamniotic infection in a group of women at risk. Third, in this high-risk group, women with bacterial vaginosis were more likely to have *G. vaginalis* ($p < 0.01$) and *M. hominis* ($p = 0.04$) in the amniotic fluid.

The association of *G. vaginalis*, some anaerobes, and *M. hominis* in amniotic fluid of women with intraamniotic infection suggests that the organisms arise from bacterial vaginosis rather than independently from the vagina. We also observed associations of *E. coli*, other aerobic gram-negative rods, and enterococci—all organisms commonly isolated in the lower gastrointestinal tract. Group B streptococci, a major neonatal pathogen,

Table III. Organisms isolated in amniotic fluid by vaginal Gram stain score

	Organism(s) in amniotic fluid				
Vaginal score	*G. vaginalis* (%)	*M. hominis* (%)	*Anaerobes* (%)	*Group B streptococci* (%)	*Enterococci* (%)
0-3 (n = 43)	26	12	14	31	20
4-6 (n = 50)	60	23	23	15	8
7-10 (n = 32)	85	35	26	9	3
p	<0.01	0.04	NS	0.03	0.03

Score: 0 to 3, normal; 4 to 6, intermediate; 7 to 10, bacterial vaginosis.

was associated with *B. bivius*, but the association was weak. Because multiple associations were evaluated, there is danger of an α-type error, yet our major associations had values of $p < 0.05$. Thus from patterns of organisms in amniotic fluid of intraamniotic infection cases bacteria did not appear to enter the amniotic cavity by chance or by independent action. Instead, the bacterial vaginosis group often enter in concert as do the enteric organisms (*E. coli, enterococci,* other aerobic gram-negative rods); group B streptococci act more or less independently.

After we observed the interaction of bacterial vaginosis organisms in amniotic fluid, we then proceeded to determine whether bacterial vaginosis itself (as diagnosed by Gram stain) was associated with intraamniotic infection. Use of Gram stain to diagnose bacterial vaginosis was first suggested by Spiegel et al.[12] in 1983. A diagnosis of bacterial vaginosis was based on mixed flora consisting of gram-positive, gram-negative, or gram-variable bacteria with decreased or absent *Lactobacillus* morphotypes. Gram stains that showed a predominance of *Lactobacillus* morphotypes with or without *G. vaginalis* morphotype were interpreted as normal. Compared with composite clinical criteria (homogeneous discharge, pH ≥4.7, amine odor, and presence of clue cells), Eschenbach et al.[1] found the independent diagnosis of bacterial vaginosis by Gram stain had a sensitivity of 97%, a specificity of 79%, and a positive predictive value of 69%. Gram stain criteria for bacterial vaginosis correlated better than semiquantitative cultures for *G. vaginalis* with composite clinical criteria.

Recently, workers have compared the Gram stain score to clinical findings and culture results in 3985 pregnant women at 23 to 26 weeks' gestation. High scores (≥7) correlated with all typical clinical findings of bacterial vaginosis, increasing isolation from the vagina of anaerobes, genital mycoplasmas and *G. vaginalis*, and decreasing vaginal isolation of lactobacilli (unpublished observations).

We applied the Gram stain score to women in labor with membrane rupture. Others have previously applied Gram stain criteria to patients in labor or with ruptured membranes.[7,8,13] We reasoned that Gram stain criteria would be less influenced by membrane rupture and the conduct of labor (bloody show, vaginal examinations, use of lubricants) than would be description of secretions, pH, odor, or vaginal cultures. Since Gram stain criteria were sensitive measures of bacterial vaginosis in other groups of women, we anticipated that these criteria would also be sensitive during labor.

In the high-risk group, women with bacterial vaginosis were similar to those without bacterial vaginosis in regard to age, parity, gestational age, and five intrapartum characteristics (rupture of membranes, vaginal examination, internal monitoring, oxytocin use, and cesarean delivery). Because mean labor duration was longer in the group with bacterial vaginosis, it may be argued that the longer duration of labor rather than bacterial vaginosis per se explains the excess rate of intraamniotic infection in the bacterial vaginosis group. However, we believe that bacterial vaginosis is the more likely factor for three reasons. First, in a logistic regression of analysis of risk factors in intraamniotic infection on this obstetric service during the same time as the current data were collected, we found that parity, duration of membrane rupture, and duration of internal monitoring were independent risk factors (labor duration was not).[14] These three factors were all similar in the groups with and without bacterial vaginosis. Second, since we were examining nine variables it is possible that this one difference (with $p = 0.043$) occurred by chance. Third, because onset of true labor is difficult to pinpoint, this measure is less objective than any other.

Increasing isolation rates of both *G. vaginalis* and *M. hominis* in the amniotic fluid with increasing Gram stain score support bacterial vaginosis as the source of these organisms, yet we did not find that anaerobes, which play a central role in bacterial vaginosis, were increased in the amniotic fluid of women with bacterial vaginosis. Considering the absolute rate of isolating anaerobes was higher in the group with high scores than

in those with low scores (26% vs. 14%), we suspect that there is a real but undetected difference. Interestingly, group B streptococci and enterococci, organisms unrelated to the pathophysiology of bacterial vaginosis, were found with decreasing frequency in the amniotic fluid of women with bacterial vaginosis. Although a mechanism for this relationship is not certain, there is an implication that the "bacterial vaginosis organisms" compete with group B streptococci, enterococci, and perhaps others for ascent into the amniotic cavity. Unfortunately, our data set did not include detailed vaginal cultures and cannot address this relationship more completely.

Our selection of a very high-risk group, with a prevalence of intraamniotic infection of 50%, increased our likelihood of demonstrating a significant association, yet our findings add support to other reports that show an association between bacterial vaginosis and infection. Gravett et al.[6] also found that bacterial vaginosis was associated with subsequent development of "amniotic fluid infection" (9% in women with bacterial vaginosis vs. 4% in those without; $p < 0.05$; odds ratio 2.1 [1.2 to 3.9, 95% confidence interval]). More recently, Hillier et al.,[13] in a multiple regression analysis controlling for confounding variables, found that the intrapartum diagnosis of bacterial vaginosis was associated with recovery of organisms between the chorion and amnion in both term and preterm pregnancies. We speculate that among women with recognized clinical risk factors for intraamniotic infection such as prolonged rupture of the membranes and duration of prolonged internal monitoring,[14] the detection of bacterial vaginosis may identify a group at still higher risk. Identification of such a high-risk group may lead to the development of an intervention strategy such as administration of systemic or local prophylactic antibiotics in labor.

The incidence of positive amniotic fluid cultures in patients in preterm labor with intact membranes

M. Amanda Skoll, MD, Michael L. Moretti, MD, and Baha M. Sibai, MD
Memphis, Tennessee

The possible relationship between intrauterine infection and preterm labor has received considerable attention in recent years. The purpose of this study was twofold: first, to determine the frequency of asymptomatic infection in patients who came to the hospital in preterm labor, and second, to determine the significance of a positive amniotic fluid culture in relation to latency period and likelihood of preterm delivery. Patients who came to the hospital in preterm labor with intact membranes between 20 and 35 weeks' gestation underwent transabdominal amniocentesis. Amniotic fluid was sent for Gram stain and culture. Patients received tocolytic therapy as clinically indicated. Of 127 patients cultured, seven (5.5%) had positive amniotic fluid cultures. These patients had a significantly decreased latency period from amniocentesis to delivery (4.4 days versus 28.6 days), and a significantly increased chance of being delivered of preterm infants (100% versus 52.5%), as compared with patients with negative cultures. The rate of positive Gram stain was 7 of 125 positive. However, there was no correlation between positive Gram stain and positive culture results. Similarly, positive Gram stain results were not associated with any difference in the latency period or rate of preterm delivery. (Am J Obstet Gynecol 1989;161:813-6.)

Key words: Preterm labor, amniocentesis, infection

Despite the development of prevention programs, pharmacologic therapies and other interventions, the preterm delivery rate remains disappointingly stable at approximately 7% of births. Prematurity is responsible for a disproportionately large fraction of perinatal and neonatal morbidity and mortality. Although the mechansims that lead to the onset of preterm labor are not clearly understood, much interest has been devoted in recent years to the possibility of an infectious cause.

Several investigators have studied the role of infection in preterm labor by performing microbiologic studies on amniotic fluid obtained by amniocentesis. Published rates of positive amniotic fluid cultures of patients who are in preterm labor vary from 0 to 46.8%.[1-10] Unfortunately, many of these studies are hampered by small numbers of patients. In addition, it is difficult to know whether results from a particular population can be extrapolated to other populations.

The purpose of this study was to investigate the incidence of positive amniotic fluid cultures in patients who were in preterm labor when they came to the E. H. Crump Women's Hospital in Memphis, Tennessee.

Material and methods

The E.H. Crump Women's Hospital is a tertiary care perinatal center affiliated with the University of Tennessee, Memphis. It serves a primarily indigent population with approximately 80% black and 20% white patients. The study was carried out from January 1, 1986, to July 31, 1987, after approval by the Institutional Review Board of the University of Tennessee.

Patients were included in the study if they came to the hospital with evidence of uterine activity or cervical dilatation or effacement between 20 and 35 weeks' gestation. Gestational age was determined by early ultrasonography if available; otherwise, an estimate was made based on last menstrual period combined with ultrasonography on admission. Patients were excluded if they had ruptured membranes before admission, cessation of contractions with an intravenous fluid bolus and sedation, advanced labor (≥5 cm dilatation), clinical evidence of chorioamnionitis, or refused amniocentesis. Qualifying patients were commenced on tocolytic therapy as per the hospital's current protocol. The first-choice tocolytic agent was ritodrine hydrochloride, administered by intravenous infusion pump. In patients with contraindications to betamimetic therapy, magnesium sulfate was started, also by intravenous infusion.

Patients underwent ultrasound-guided transabdominal amniocentesis. Fluid was sent for pulmonary maturity studies including lecithin to sphingomyelin (L/S) ratio and foam stability index. At the same time, fluid was collected for microbiologic study. After im-

Table I. Organisms isolated in culture

mediate transfer to the microbiology laboratory, the specimen for Gram stain was centrifuged, treated to standard Gram stain, and read by experienced technicians. Amniotic fluid was plated aerobically on blood agar, chocolate agar, Thayer-Martin agar, McConkey agar, and thioglycollate broth. Amniotic fluid was plated anaerobically on Schaedler's, calcium nutrient agar, *Pisum sativum* agglutinin, and chopped-meat broth. Specific cultures for *Mycoplasma* species were not performed. Results were reported semiquantitatively. The results of microbiology studies were not made available for clinical management.

Patients who responded to tocolytic therapy with cessation of contractions were maintained on intravenous infusion of either ritodrine or magnesium sulfate for approximately 12 hours. They were then weaned onto oral betamimetic therapy and were subsequently discharged from the hsopital in 2 to 3 days if contractions did not recur. Indications for delivery included failed tocolysis, clinical suspicion of chorioamnionitis (based on the presence of fever >100° F, uterine tenderness, or leukocytosis with no other evidence of an infective site), or fetal distress. In addition, in those patients in whom rupture of the membranes occurred subsequent to admission to hospital, the presence of a mature lung profile constituted an indication for delivery. Labor was not induced in patients in whom tocolysis failed. The only patients in whom induction was performed preterm were those with a clinical diagnosis of chorioamnionitis or those with ruptured membranes plus a mature L/S ratio.

Neonatal records were reviewed for evidence of neonatal sepsis as documented by positive blood, urine, or cerebral spinal fluid cultures.

Statistical analysis was performed with Student's t test for unpaired samples and χ^2 where appropriate.

Results

Of the 127 amniotic fluid samples obtained, seven (5.5%) were found to be positive. The organisms are detailed in Table I.

Comparisons between the groups with positive cultures and negative cultures (Table II) do not reveal significant differences with regard to gravidity, parity, gestational age at presentation, or cervical dilatation on admission. The group with positive cultures included four patients who were 3 or 4 cm dilated, and another three who were <2 cm dilated on admission, but demonstrated cervical change despite hydration and sedation. There was a significant difference ($p < 0.001$) in the latent period from amniocentesis to delivery between the two groups based on culture results. Of interest is one patient who was culture positive for rare Group B streptococci after a negative Gram stain. She responded quickly to tocolytic agents and subsequently was delivered of an infant 12 days later and never received antibiotics. Her infant did not have septic complications.

Two of the patients in the group with positive cultures received antibiotics before delivery. The first was a twin gestation at 32 weeks who received erythromycin for *Chlamydia* diagnosed on cervical culture. She ruptured membranes in the hospital and was delivered of infants 10 days after amniocentesis. The other patient was treated with ampicillin and gentamicin for a clinical diangosis of chorioamnionitis based on fever and uterine tenderness. She also ruptured membranes during attempted tocolysis, and was delivered of an infant within 24 hours of admission. None of the remaining five patients with positive cultures had spontaneous rupture of the membranes during admission.

Within the group with negative cultures, 14 of 120 patients received antibiotics, including nine patients treated for urinary tract infections (seven with intravenous ampicillin, one with oral nitrofurantoin, and one with intravenous cefazolin). One patient received intravenous ampicillin and gentamicin as prophylaxis because of mitral valve prolapse, and four patients received the same medications because of clinical chorioamnionitis.

A total of 83 patients (65.4%) were delivered of preterm infants. This includes all seven of the patients with

positive cultures (8.4% of whom were delivered of preterm infants). Table III shows the rates of preterm delivery based on culture results.

There was no correlation between results of the Gram stain and subsequent culture. Of the seven positive culture results, only two (28.6%) had positive Gram stains. In addition, there were five false-positive Gram stains. When we analyzed the incidence of preterm delivery by dividing the patients on the basis of Gram stain results, there was no difference in the rate of preterm delivery with positive Gram stain. In addition, the presence of white blood cells in the amniotic fluid did not influence the rate of preterm delivery (64.7% with white blood cells, versus 67% without).

Of the eight offspring of mothers with positive cultures (including one set of twins), only one had clinical sepsis, with blood cultures positive for *Pseudomonas aeruginosa*. A total of 25 neonates received parenteral antibiotics (ampicillin and gentamicin in all cases). Four of these were from the group with positive amniotic fluid cultures, and 21 from the group with negative cultures. Indications for treatment included maternal diagnosis of chorioamnionitis (four cases), positive blood cultures (one case, as above), and prophylaxis (20 cases).

Table III. Correlation between culture results and preterm delivery

	Positive culture n = 7	*Negative culture n = 120*
Patients delivered of infants <37 weeks (%)	7 (100)*	76 (63.3)*
Patients delivered of infants ≥37 weeks (%)	0 (0)	44 (36.7)

Comment

Our data, like those of other groups, suggest a role for an infectious cause in some patients in preterm labor. Although a rate of positive cultures of 5.5% falls toward the lower end of the reported range, there are several possible explanations. First, no specific cultures were performed for *Mycoplasma* species. Although one of the patients was found to be culture positive for *Ureaplasma urealyticum*, this was fortuitous and the culture techniques were not designed to detect the presence of *Ureaplasma* species. There is some evidence that this may be a significant organism in relation to preterm labor.[11] Second, patients who were seen with cervical dilatation >4 cm were not eligible for amniocentesis because they were not candidates for tocolytic therapy. It may be that the patients who are seen in advanced labor are more likely to harbor otherwise asymptomatic intrauterine infection.

Previous studies at the University of Tennessee, Memphis[12] have shown that up to two thirds of patients who were delivered of infants <1000 gm arrived at the hospital >4 cm dilated; however, such patients would have been excluded from the present study. These findings would explain the discrepancy between our data and that of other groups that have found that patients with positive amniotic fluid cultures tend to present at an earlier gestational age. Hillier et al.[13] have presented evidence from pathologic and microbiologic examination of the placenta that also supports the view that patients who present at earlier gestational ages are significantly more likely to have histologic chorioamnionitis. These are the very patients who would most benefit from prolongation of pregnancy, but are, in fact, least likely to respond to our efforts to achieve this. A few investigations of the use of antibiotics in the treatment of preterm labor may hold promise in this regard.[14, 15]

An attempt to minimize the chance of a false-positive diagnosis of preterm labor was made by excluding all patients who responded to a fluid bolus or sedation with cessation of uterine activity. In view of the well-recognized difficulty in making the diagnosis of preterm labor, it is useful to look at patients who were delivered of preterm infants. Our findings reveal that 8.4% of these patients had positive amniotic fluid cultures.

The lack of correlation between Gram stain and culture is disappointing. False-positive Gram stains may occur when extremely fastidious organisms present in the initial sample fail to grow in culture. To investigate the impact of such so-called "false-negative cultures," we analyzed the occurrence of preterm delivery by Gram stain results. This analysis failed to show any difference in the rate of preterm delivery with positive Gram stain. Our finding is different from that reported by other authors,[10] and at present we have no explanation for this difference. Of note is the fact that the negative predictive value of the Gram stain in our series is still 95.8%, so that a negative Gram stain is still reassuring as to the absence of infection.

False-negative Gram stains may occur when the number of organisms present in the initial Gram stain is very low but the organisms subsequently grow in culture. One method suggested to minimize this problem is to use ultracentrifugation of the specimen before performance of the Gram stain to concentrate the number of organisms. However, Romero et al.[10] failed to show any increase in the sensitivity of the Gram stain of amniotic fluid with this technique.

In terms of the significance of white blood cells found on Gram stain, our results agree with those of other investigators who found no relationship with sepsis or occurrence of preterm delivery.[6, 10]

Overall, we conclude that in a defined population, approximately 5% of patients with preterm labor and intact membranes have positive amniotic fluid cultures. Furthermore, these patients have a significantly shorter time from amniocentesis to delivery, as well as an increased likelihood of preterm delivery as compared with the group of patients with negative cultures. Unfortunately, we have not found the Gram stain to be a sensitive indicator of intrauterine infection, and we cannot suggest active delivery based on a positive Gram stain result. However, a negative Gram stain, with a negative predictive value of >95%, is reassuring.

Correction

In the article by Humphreys-Beher and Blackwell, "Identification of a deoxyribonucleic acid allelic variant for β1-4 galactosyltransferase expression associated with male sperm binding/penetration infertility" (Am J Obstet Gynecol 1989;160: 1160-5), it was reported that the complementary deoxyribonucleic acid clone used corresponded with a putative human β1-4 galactosyltransferase. Analysis of the complete nucleotide sequence and expression of this clone has revealed that it is not the catalytic enzyme. Further studies by Lopez and Shur (Biochem Biophys Res Commun 1988;156:1223-9) and our research suggest it indirectly influences enzyme activity.

Infection and labor

V. Prevalence, microbiology, and clinical significance of intraamniotic infection in women with preterm labor and intact membranes

Roberto Romero, MD,* Marina Sirtori, MD, Enrique Oyarzun, MD, Cecilia Avila, MD, Moshe Mazor, MD, Robert Callahan, BS, Virginia Sabo, MSN, Apostolos P. Athanassiadis, MD, and John C. Hobbins, MD

New Haven, Connecticut

Amniotic fluid was retrieved by amniocentesis from 264 patients with preterm labor and intact membranes admitted to Yale–New Haven Hospital from Jan. 1, 1985, to July 31, 1988. The prevalence of a positive amniotic fluid culture was 9.1% (24/264). A total of 111 patients (42%) delivered preterm neonates, and 24 (21.6%) of those had positive amniotic fluid cultures. The diagnostic indexes of the Gram stain of amniotic fluid in the prediction of a positive amniotic fluid culture were as follows: sensitivity, 79.1%; specificity, 99.6%; positive predictive value, 95%; and negative predictive value, 98%. Endotoxin was detected with the limulus amebocyte lysate assay in 4.9% (13/264) of patients with preterm labor. All patients with endotoxin in the amniotic fluid delivered preterm neonates. The three most frequently isolated organisms were *Ureaplasma urealyticum* ($n = 6$), *Fusobacterium* species ($n = 5$), and *Mycoplasma hominis* ($n = 4$). Clinical chorioamnionitis was present in only 12.5% of the patients with positive amniotic fluid cultures. Women with positive amniotic fluid cultures had lower gestational ages and more advanced cervical dilatation on admission than women with negative cultures. Preterm infants born to mothers with positive amniotic fluid cultures had a higher incidence of respiratory distress syndrome and infectious complications than preterm neonates born after negative amniotic fluid cultures. These data underscore the frequency and importance of intraamniotic infections in women with preterm labor. (AM J OBSTET GYNECOL 1989;161:817-24.)

Key words: Preterm labor, prematurity, intraamniotic infection, lipopolysaccharide, limulus amebocyte lysate, Gram stain, amniotic fluid

Intrauterine infection has been recognized as a major etiologic factor for preterm delivery.[1] Bobitt and Ledger[2] were the first to present microbiologic data suggesting that unrecognized amnionitis is causally related to preterm labor and delivery. Subsequently, several investigators have used amniocentesis to assess the microbiologic state of the amniotic cavity in women with preterm labor and intact membranes. The prevalence of positive amniotic fluid cultures has varied from 0%[3] to 25.8%.[3-16] These discrepant results have been attributed to differences in population characteristics and microbiologic techniques.

The study reported herein was conducted on women with preterm labor and intact membranes. The objectives were: (1) to determine the prevalence of intraamniotic infection; (2) to establish the detection rate of lipopolysaccharide in amniotic fluid; (3) to determine the diagnostic value of the Gram stain and the limulus amebocyte lysate test in the detection of intraamniotic infection; (4) to describe the quantitative and qualitative microbiology of intraamniotic infection in this patient population; and (5) to ascertain maternal and neonatal outcomes according to amniotic fluid culture results.

Material and methods

Patient population. Patients admitted to Yale–New Haven Hospital with preterm labor and intact membranes from Jan. 1, 1985, to July 31, 1988, underwent amniocenteses for evaluation of the microbiologic status of the amniotic fluid. Preterm labor was defined as the presence of regular uterine contractions

Positive	12	1	13
Negative	12	239	251
Limulus amebocyte lysate and Gram stain combined			
Positive	21	2	23
Negative	3	238	241

with a frequency of at least two every 10 minutes. Nitrazine, pooling, and ferning tests were performed in every patient during a sterile speculum examination to exclude patients with leakage of amniotic fluid into the vagina. Ritodrine, terbutaline, or magnesium sulfate was administered intravenously for tocolysis. Failure of tocolysis was diagnosed when cervical dilatation progressed beyond 5 cm or delivery occurred.

Retrieval of amniotic fluid. Amniotic fluid was retrieved by transabdominal amniocentesis in all cases. Amniocentesis was performed under ultrasound guidance.

Microbiologic culture technique. Amniotic fluid was transported to the laboratory in a capped plastic syringe immediately after collection. These conditions precluded air contact with the specimen. Plating occurred within 30 minutes of collection. Amniotic fluid was cultured for aerobic and anaerobic bacteria, as well as for *Mycoplasma* species.[16] An intraamniotic infection was defined as the presence of a positive amniotic fluid culture.[1]

Endotoxin bioassay. All amniotic fluid samples were assayed with the limulus amebocyte lysate gel clot test for detection of endotoxin. The assay was performed by a method previously described in detail.[5] Briefly, the assay consists of adding 200 μl of freshly obtained, unspun amniotic fluid to a single test vial of 200 μl of high-sensitivity lyophilized limulus amebocyte lysate (sensitivity, 0.06 endotoxin units/ml) (Associates of Cape Cod, Woods Hole, Mass.). The mixture was incubated for 60 minutes in a 37° C motionless water bath. The positive control consisted of Associates of Cape Cod control standard lipopolysaccharide *Escherichia coli* 0113, and the negative control consisted of pyrogen-free water. The formation of an adherent gel was scored as a positive result. The absence of a clot was considered indicative of a negative result. These tests were performed immediately after collection of the amniotic fluid, and the results were not used for patient management.

Gram stain examination. Gram stain examinations were performed with commercial reagents (crystal violet, saffranin, and Gram's iodine [Difco Laboratories, Detroit, Mich.]) under standard conditions. Stained slides were then examined by trained technologists, and the presence or absence of microorganisms was noted. The results of the Gram stain examinations were shared with the clinicians. Patients with negative Gram stain examinations for bacteria were given tocolysis. Patients with positive Gram stain examinations of amniotic fluid for bacteria were given parenteral antibiotics and allowed to labor. A positive Gram stain for bacteria was an indication for discontinuation of tocolysis.

Criteria for the diagnosis of chorioamnionitis, puerperal endometritis, and neonatal sepsis. Intraamniotic infection was diagnosed by the presence of a positive amniotic fluid culture.[1] Clinical chorioamnionitis was defined according to the criteria proposed by Gibbs et al.[6] Neonatal sepsis was diagnosed by the presence of a positive culture of blood, urine, or cerebrospinal fluid. Possible neonatal sepsis was diagnosed in the absence of a positive culture when two or more of the following criteria were present: white blood cell count of $<5000/mm^3$, polymorphonuclear leukocyte count of $<1800/mm^3$, I:T ratio (ratio of bands to total neutrophils) >0.2, or a positive gastric aspirate for polymorphonuclear leukocytes showing >5 white blood cells/high-power field. These criteria have been previously used in the pediatric and obstetric literature.

Statistical analysis. Diagnostic indexes (sensitivity, specificity, positive, and negative predictive values) for the detection of a positive amniotic fluid culture were calculated for both the Gram stain and limulus amebocyte lysate test. Comparisons between proportions were performed with a χ^2 test or Fisher's exact test. Sensitivity and specificity comparisons between the limulus amebocyte lysate and the Gram stain were performed with a modified t test. A Mann-Whitney test was used to compare cervical dilatation between groups because this variable was not normally distributed.

Results

Amniocenteses were performed on 264 women admitted with the diagnosis of preterm labor. Amniotic fluid was obtained in all cases. The prevalence of intraamniotic infection in women admitted with preterm labor was 9.1% (24/264). A total of 111 (42%) women delivered preterm neonates, and 24 (21.6%) of those had positive amniotic fluid cultures.

amniotic fluid and the limulus amebocyte lysate in the detection of a positive amniotic fluid culture. The Gram stain had a sensitivity of 79.1% (19/24), a specificity of 99.6% (239/240), a positive predictive value of 95% (19/20), and a negative predictive value of 98% (239/244). One patient had a positive Gram stain of amniotic fluid but a negative culture. The patient had a cervical dilatation of 6 cm at the time of amniocentesis, did not have any clinical evidence of infection, and delivered spontaneously. She did not have clinical evidence of endometritis, and the newborn had no evidence of sepsis. Of the five patients with false-negative Gram stains, two had intraamniotic infections caused by *Mycoplasma* species (these organisms are not visible

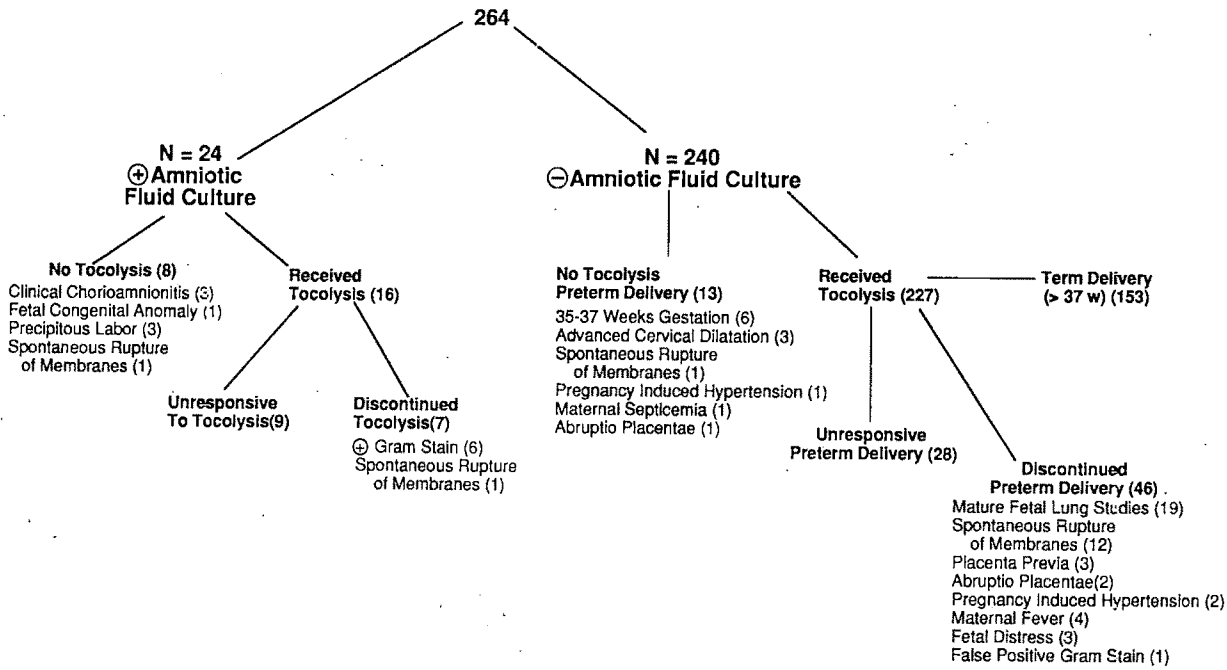

Fig. 1. Amniotic fluid culture and outcome of tocolysis of all patients in this study. *PIH,* Pregnancy-induced hypertension.

in a Gram stain). The remaining three false-negative stains occurred in one patient with *Fusobacterium nucleatum* with 25,000 colony-forming units (cfu) per milliliter, one with mixed flora, and one with *Staphylococcus aureus* ($>10^5$ cfu/ml).

This table also describes the results of the limulus amebocyte lysate assay and culture results. The limulus amebocyte lysate test had a sensitivity of 50% (12/24), a specificity of 99.6% (239/240), a positive predictive value of 92.3% (12/13), and a negative predictive value of 95.2% (239/251). One patient had a positive limulus amebocyte lysate test but a negative culture. This patient underwent a repeat amniocentesis four days later because of premature rupture of membranes. The second culture was positive for *Streptococcus viridans* ($>10^5$ cfu/ml).

Finally, Table I illustrates the results of combining the Gram stain of amniotic fluid with the limulus amebocyte lysate assay. The sensitivity was 87.5% (21/24), specificity was 99% (238/240), positive predictive value was 91% (21/23), and negative predictive value was 98.8% (238/241). The combined use of the Gram stain and the limulus amebocyte lysate did not result in a significant improvement in sensitivity with this sample size ($p > 0.05$).

Table II displays the results of the limulus amebocyte lysate and the Gram stain according to the classification of the microorganisms and culture results. The sensitivity of the Gram stain and limulus amebocyte lysate in detecting positive amniotic fluid cultures in pure infection for gram-positive or gram-negative bacteria was not different.

Table III illustrates the results of quantitative and qualitative microbiology, Gram stain, and limulus amebocyte lysate results in all 24 patients with positive amniotic fluid cultures. The three most frequent isolates were *U. urealyticum* ($n = 6$), *Fusobacterium* species ($n = 5$), and *M. hominis* ($n = 4$). Fifty percent (12/24) had more than one organism isolated from the amniotic fluid. Seventy-one percent (17/24) of all patients with positive amniotic fluid cultures had an inoculum size with more than 10^5 cfu/ml.

Table IV displays maternal clinical characteristics and complications according to amniotic fluid culture results. Women with positive amniotic fluid cultures had lower gestational ages and more advanced cervical dilatation on admission than did women with negative amniotic fluid cultures. All patients with abruptio placentae and toxemia of pregnancy had negative amniotic fluid cultures.

Fig. 1 shows the administration and response to tocolysis according to the results of the amniotic fluid culture. Successful tocolysis was more common in women with negative amniotic fluid cultures than in women with positive amniotic fluid cultures (84.5% [153/181] versus 0% [0/9]; $p < 0.001$, Fisher's exact test).

Table V shows the neonatal outcome according to culture results. Neonates born to mothers with intra-amniotic infections had lower gestational ages and birth weights than those born to mothers with negative amniotic fluid cultures. The incidence of respiratory distress syndrome, neonatal infectious morbidity, and low Apgar scores was greater in newborn infants of mothers

*One case.

with positive amniotic fluid cultures. A positive blood culture was documented in one neonate born to a mother with an intraamniotic infection. The amniotic fluid grew *Gardnerella vaginalis, M. hominis,* and *U. urealyticum,* and the neonatal blood culture was positive for *G. vaginalis.* On the other hand, one neonate born to a mother with a negative amniotic fluid culture had a positive blood culture for *Candida albicans.* The interval between amniocentesis and delivery was 72 hours, and results of histologic examination of the placenta were negative for chorioamnionitis. Two congenital anomalies were identified in the group of fetuses with positive amniotic fluid cultures (ascites and a bowel obstruction) and five in the group with negative amniotic fluid cultures (four cases of multiple congenital anomalies and one case of triploidy associated with a partial mole).

Comment

The prevalence of positive amniotic fluid cultures in the present study was 9.1%. Previous reports that used amniocentesis to determine the microbiologic state of the amniotic cavity in patients with preterm labor and intact membranes have documented a positive culture mean rate of 13.6% (46/339), with a range from 0% to 25.8%.[7] The disparity among different series is probably attributable to a combination of factors, including the definition of preterm labor, microbiologic techniques (i.e., cultures for *Mycoplasma* species), and the threshold required to perform an amniocentesis in patients in preterm labor among the different centers.

To circumvent the problems associated with differences in the diagnosis of preterm labor among the reports, we have analyzed the data by looking at patients with preterm labor leading to preterm delivery. In this case, the prevalence of positive amniotic fluid cultures is 21.6%. Of interest is that these findings are compatible with those of pathologic studies of the placenta. Guzick and Winn[15] found a 20.9% prevalence of histologic chorioamnionitis in patients delivering preterm infants without premature rupture of membranes. This information implies that one of every five preterm births occurring in women with premature labor and intact membranes is associated with intraamniotic infection. These data have major implications for the understanding and management of preterm labor.

The natural history of intraamniotic infection has not been well established. Several authors have suggested

AF, Amniotic fluid.

that women with positive amniotic fluid cultures and preterm labor are more likely to be refractory to tocolysis, to rupture membranes spontaneously, and to develop clinical chorioamnionitis than women with negative amniotic fluid cultures (reviewed in reference 1). Our data support these claims, since women with positive amniotic fluid culture were more likely to be refractory to tocolysis and develop clinical chorioamnionitis. A limitation of our study is that the result of the Gram stain examination of amniotic fluid was used in patient management; therefore the natural history of intraamniotic infection was altered. However, the net effect of this intervention was to remove patients with a larger inoculum size. Therefore our data indicate that refractoriness to tocolysis occurs even in patients with small microbial colony counts in the amniotic fluid. No empiric data suggest that women with a larger inoculum size behave differently.

The sensitivity of the Gram stain of amniotic fluid for the detection of intraamniotic infection was considerably better than our previous report (79.1% versus 44.8%). However, that study was conducted predominantly in patients with ruptured membranes. The improvement in the sensitivity noted in this study is probably attributable to greater experience with the test and the greater proportion of patients with an inoculum size of greater than 10^5 cfu/ml. Three of the five false-negative Gram stains occurred in patients with intraamniotic infections with *Mycoplasma* species. *Mycoplasma* species are not visible with the Gram stain. It is of note that one patient with an intraamniotic infection with *M. hominis* had a positive Gram stain for bacteria. This can be interpreted as either a false-positive stain or failure of the culture to grow fastidious microorganisms. The correlation between quantitative microbiology and Gram stain results has been previously discussed.[16] In amniotic fluid, as in other body fluids, an inoculum size $>10^5$ cfu/ml is associated with a positive Gram stain in 80% of the cases.[14] In this report, 15 of 17 patients with more than 10^5 cfu/ml had positive Gram stains of amniotic fluid (88%). The only false-positive Gram stain occurred in a patient who was dilated 6 cm and had a spontaneous delivery.

The diagnostic indexes of the limulus amebocyte lysate test were similar to those previously reported by our laboratory.[8] All patients with endotoxin in the amniotic fluid as detected by the limulus amebocyte lysate went on to deliver spontaneously. Although most of these patients had positive Gram stains of amniotic fluid and therefore did not receive tocolysis, one patient with a negative Gram stain and positive limulus amebocyte lysate test was refractory to tocolysis. The culture of amniotic fluid was positive for *Fusobacterium* species.

We have previously reported that the combined use of the limulus amebocyte lysate and the Gram stain increases the sensitivity of each test for the detection

of intraamniotic infection.[8] In the current study, the addition of the limulus amebocyte lysate increased the sensitivity of the Gram stain from 79.1% to 87.5%. However, this increment is not statistically significant. We attribute this apparent discrepancy with our previous report to the significant improvement in the sensitivity of the Gram stain (44.8% in the previous study).[16]

An interesting finding in our current study is that several patients had a positive limulus amebocyte lysate assay of amniotic fluid in the absence of gram-negative bacteria (Table II). We had documented similar findings in a study of women with preterm premature rupture of membranes.[17] These observations could be explained by (1) failure of fastidious gram-negative organisms to grow in culture, (2) presence of endotoxin in amniotic fluid from nonviable gram-negative bacteria, or (3) presence of other microbial products in amniotic fluid that stimulate the gelation of the limulus amebocyte lysate. Indeed, peptidoglycans from gram-positive bacteria, mannan from yeast, and lipoglycans from *Ureaplasma* species can yield a positive limulus amebocyte lysate test. However, the procedure used to purify these materials cannot exclude endotoxin contamination. It has been estimated that 1000 to 400,000 times higher concentrations of peptidoglycans than endotoxin are required to produce a positive limulus amebocyte lysate test. Contamination of these microbial preparations with as little as 0.00025% of endotoxin could account for the reported findings. Such low degrees of contamination cannot be ruled out in any material and may be found in "purified material."

A major finding of the current study is that the three most frequently isolated microorganisms from amniotic fluid are *Fusobacterium* species, *M. hominis*, and *U. urealyticum*. Previous studies have also hinted at the importance of *Fusobacterium* species in this setting (Table VI). The high prevalence of *M. hominis* and *U. urealyticum* was an unexpected observation; however, these findings are consistent with those found after culturing the membranes of patients with histologic chorioamnionitis.[18] This observation has clinical importance. First, microbiologic studies of the amniotic cavity that do not include cultures for *Mycoplasma* species may underestimate the rate of intraamniotic infection. Second, treatment of intraamniotic infection may require the addition of agents that are active against these organisms. Third, many of the suspected but not confirmed cases of neonatal sepsis may be caused by *Mycoplasma* organisms. Indeed, recent data indicate that these organisms have been isolated from the cerebrospinal fluid and pulmonary secretions of neonates.[19, 20]

Our results indicate that clinical chorioamnionitis is an insensitive indicator of intraamniotic infection. Indeed, only 12.5% of the women with positive amniotic fluid cultures met the clinical definition of chorioamnionitis; therefore reliance on standard clinical signs of infection results in an underestimation of the association between intraamniotic infection and preterm labor.

Another finding of this study is that neonates born to women with positive amniotic fluid cultures had lower gestational ages and a greater incidence of neonatal complications (respiratory distress syndrome and infectious morbidity) than preterm neonates of women with negative amniotic fluid cultures. The greater incidence of respiratory distress syndrome is probably related to the significantly lower gestational age at birth. Similar findings have been reported by other investigators.[7, 9, 12, 13]

Advanced cervical dilatation on admission has been traditionally considered a poor prognostic indicator of response to tocolysis. Our study indicates that women with preterm labor and intraamniotic infection had greater cervical dilatation than women with negative amniotic fluid cultures. Therefore it is possible that the unresponsiveness to tocolysis in women with advanced cervical dilatation is at least partially attributable to the presence of an intraamniotic infection.

One third of preterm neonates are born to women with preterm labor and intact membranes, a second third to patients with preterm PROM, and the remaining third to women with maternal or fetal indications for premature delivery. Our data suggest that in the

setting of preterm labor with intact membranes 22% of deliveries occurred to mothers with a positive amniotic fluid culture, while in the setting of preterm PROM 55% of patients will have a positive amniotic fluid culture at the time of the onset of parturition.[21] On the basis of these figures, we estimate that at least one of every four preterm deliveries occurs to a woman with an intraamniotic infection. We conclude that an intrauterine infection, which is often subclinical in nature, is a major etiologic factor for preterm delivery.

Diagnosis of birth asphyxia on the basis of fetal pH, Apgar score, and newborn cerebral dysfunction

Larry C. Gilstrap III, MD, Kenneth J. Leveno, MD, Jody Burris, RN, M. Lynne Williams, RN, and Bertis B. Little, PhD

Dallas, Texas

Imprecise diagnosis of birth asphyxia coupled with uncertainties about causal factors for neurologic abnormalities in the newborn have greatly fueled the current litigation crisis in obstetrics. Our goal was to more precisely define birth asphyxia based on fetal condition as measured by umbilical artery blood pH, Apgar scores, and neurologic condition of newborns. We selected for study 2738 patients with singleton pregnancies with cephalic presentations who were delivered of infants at term to avoid complications such as prematurity, which may affect infant outcome independent of birth condition. The basis for study of these particular patients were defined criteria for high risk and an indicated arterial cord pH value. A total of five infants demonstrated cerebral dysfunction as evidenced by seizures during the neonatal period. Infection was linked to seizures in three of these infants; one infant had neonatal asphyxia and only one infant's clinical course could be attributed solely to birth events (uterine rupture). Stratification of umbilical artery blood pH values, Apgar scores, and combinations of these dependent variables in relation to newborn clinical outcomes revealed that infants must be severely depressed at delivery before birth asphyxia can be reliably diagnosed. Such depression includes Apgar scores ≤3 at 1 and 5 minutes plus umbilical artery pH values <7.00. (Am J Obstet Gynecol 1989;161:825-30.)

Key words: Birth asphyxia, acidemia, Apgar score

Perinatal and *asphyxia* are overused terms in current obstetric-legal parlance. Typically these terms are used to implicate "birth asphyxia" as the sole cause of neurologically damaged infants. Imprecise definition of these terms coupled with uncertainties about causal factors for neurologic abnormalities in the newborn have greatly aided the current litigation crisis in obstetrics.

The term *perinatal* may be used to denote many different time periods during gestation. For example, according to *Webster's Dictionary,*[1] perinatal refers to "the period around the time of birth." However, this term is defined in *Dorland's Medical Dictionary*[2] as "beginning with completion of the twentieth to twenty-eighth week of gestation and ending 7 to 28 days after birth." The term *asphyxia* is also variously defined in these dictionaries. In *Webster's Dictionary,*[1] asphyxia is defined as "a lack of oxygen or excess of carbon dioxide that is usu. caused by interruption of breathing and that causes unconsciousness." According to *Dorland's Medical Dictionary,*[2] asphyxia is a "lack of oxygen in respired air, resulting in impending or actual cessation of apparent life." Other commonly used terms include *hypoxia,* defined as low content of oxygen, or *ischemia* to signify reduced perfusion.[3] Such variable and therefore imprecise definitions, when applied by laymen to neurologically damaged newborns, are usually accepted to signify that the infant's outcome was a result of oxygen deprivation during the birth process or "birth asphyxia."

The most common cause of hypoxia in the fetus is hypoperfusion, or ischemia.[3] Many investigators now emphasize that very recent hypoxia-ischemia can only be implicated as a cause of brain damage when central nervous system signs and symptoms are present in the immediate newborn period.[3-5] Cerebral dysfunction or encephalopathy in the newborn may be defined as a syndrome in which tone and primitive reflexes are altered from the norm and there is evidence of cerebral irritation manifested by seizure activity.[3, 6] Long-term neurologic outcome is related to the severity and duration of these signs in the newborn. For example, in a study by Robertson and Finer[5] seizures in the immediate newborn period were a marker for abnormal neurologic sequelae.

Ideas about the obstetric antecedents of cerebral palsy are dangerously simplistic[3, 7] and we sought to more precisely define "birth asphyxia" on the basis of both fetal condition at birth and clinical performance of the newborn in the nursery. Our goal was to correlate immediate neurologic outcomes of term infants with

fetal acid-base status as measured in umbilical artery blood and newborn condition as reflected by Apgar score. Singleton term infants with cephalic presentations were selected for study to avoid complications such as breech presentation, which may affect newborn condition. Similarly, preterm births were excluded inasmuch as complications of prematurity such as respiratory disease and intracranial hemorrhage may affect infant outcome independent of birth events.

Material and methods

Between August 1, 1987, and February 28, 1988, blood was obtained from the umbilical artery for pH measurement in 2738 complicated pregnancies delivered at Parkland Memorial Hospital. These study participants were chosen from a total of 8678 patients who were delivered of infants at our institution during this time period. The following complications were used to identify pregnancies for umbilical blood pH determination: cesarean section, forceps delivery, meconium in the amnionic fluid, oxytocin stimulation of labor, and abnormal fetal heart rate (FHR). Umbilical artery specimens were drawn from doubly clamped cord segments into 3 ml plastic syringes flushed with 1000 U/ml of heparin solution and the specimens were transferred in ice to the hospital laboratory for analysis. Results of these analyses were prospectively computerized and linked to a similarly computerized obstetric data base.

Term singleton pregnancies, defined to include birth weights ≥2500 gm, morphologically normal infants, and cephalic presentations, were subsequently selected for analysis. Pediatric house officers attended all deliveries and assigned Apgar scores. Low Apgar scores were defined in this study as ≤6 at 1 and 5 minutes because this score represented the criteria commonly used to define mild asphyxia and as ≤3 at 1 and 5 minutes because this score repsented the criteria used to define severe asphyxia.[8] Newborn records were systematically reviewed by research nurses with expertise in neonatal special care, and clinical indices of immediate newborn clinical performance were prospectively computerized. Special attention was given to neurologic signs and symptoms and their time of onset. The diagnosis of seizures and hypotonia was based on assessments by the attending pediatricians. Only hypotonia that persisted 24 to 48 hours after birth was considered significant. Follow-up the infants after discharge was not available.

Tests for statistical significance were performed by means of χ^2 contingency tables or Fisher's probability (Center for Disease Control Statistical Analysis Package written by J. D. Erickson). Probability values ≤0.05 were considered significant.

Results

The maternal demographic characteristics of 2738 pregnancies that resulted in live births and were included in this investigation are summarized in Table I. These demographic features were similar to those of the general obstetric population at Parkland Hospital. Pregnancy complications in the study group reflected criteria for umbilical artery sampling and included prolonged rupture of membranes (2%), chorioamnionitis (5%), hypertension (16%), use of oxytocin (25%), cesarean section (44%), meconium in the amniotic fluid (45%), and electronic FHR monitoring (70%).

The three most common indications for cesarean section were repeat operation (42%), dystocia (25%), and fetal distress (18%). The majority (85%) of participants who were delivered of infants vaginally had spontaneous births and the remainder were assisted by forceps.

The results of umbilical artery blood gas determinations are summarized in Table II. The majority (86%) of infants had pH values ≥7.20 and 18 (0.6%) had PH values <7.00.

The relation between low 1-minute Apgar scores (≤6 and ≤3) and umbilical artery blood pH is depicted in Fig. 1. Only 143 (8%) of the 1833 newborns with an umbilical artery pH ≥7.25 had 1-minute Apgar scores

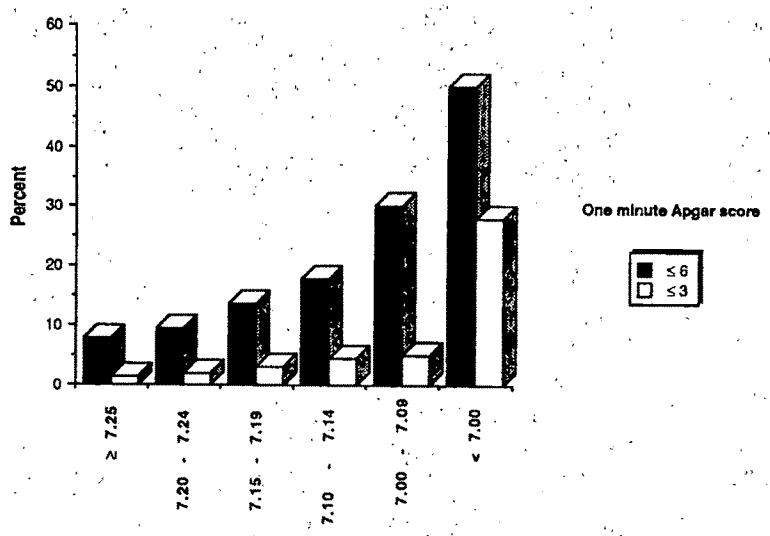

Fig. 1. Relation between low 1-minute Apgar scores and umbilical artery blood pH.

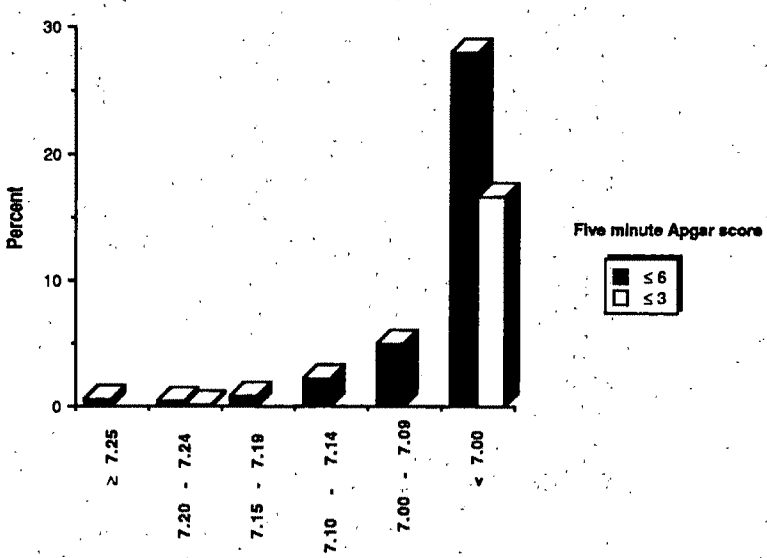

Fig. 2. Relation between low 5-minute Apgar scores and umbilical artery pH.

≤6. In contrast, 50% ($n = 9$) of those with a pH <7.00 had such Apgar scores at 1 minute ($p < 0.05$). There was a similar relation for 1-minute Apgar scores ≤3 (24 of 1833 or 1.3% versus 5 of 18 or 28%; $p < 0.05$). Shown in Fig. 2 is the distribution of these Apgar scores at 5 minutes according to pH. Apgar scores ≤6 at 5 minutes occurred in 10 of 1833 (0.5%) infants with pH ≥7.25 compared with 5 of 18 (28%) with a pH <7.00 ($p < 0.05$). The results for Apgar scores <3 at 5 minutes were 0 of 1833 with pH ≥7.25 versus 3 of 18 (17%) with pH <7.00 ($p < 0.05$). Apgar scores ≤3 at 10 minutes after birth were assigned to two infants and both had an umbilical artery blood pH <7.00.

Neonatal complications in relation to umbilical artery blood pH are summarized in Table III. With the exception of meconium aspiration syndrome, neonatal complications increased as the umbilical artery blood pH decreased and those with a pH <7.00 ($n = 18$) had singificantly more morbidity than did those in any other group. One third of these 18 infants required intubation, and the incidence of respiratory disease and hypotonia was 28% and 17%, respectively.

A total of five infants had seizures and these are summarized in Table IV. Four of these infants had seizures within the first 24 hours after birth and one convulsed on day 10. Three of the four neonates with early seizures had an umbilical artery blood pH <7.15 and two of these had a pH <7.00. Both of these infants

had metabolic acidemia, defined as a bicarbonate level ≥17.3 mEq/l and a P_{CO_2} ≤65 mm Hg.[9] All four of the infants with early seizures had 1-minute Apgar scores ≤3 and 5-minute scores ≤6. As shown in Table IV, two of the infants with early seizure activity had neonatal complications (group B streptococcal sepsis and syphilis) associated with such neurologic dysfunction.

Inasmuch as Apgar scores and acid-base status may be dependent variables in the determination of the newborn condition, we analyzed combinations of these indices and the results are summarized in Table V. None of the 13 neonates with a pH <7.00 and a 1-minute Apgar score >3 had either seizures or hypotonia. There were 12 of these 13 neonates who had either respiratory or a mixed pattern of acidemia.[9] Conversely, among those with pH values ≥7.00 and an Apgar score ≤3, seven (14%) had hypotonia and two (4%) had a seizure. One infant had an umbilical artery blood pH of 7.11 and early onset group B streptococcal sepsis. Importantly, when infants had both low Apgar scores and pH values the frequency of serious neonatal morbidity significantly increased ($p < 0.05$). Specifically, all required resuscitation at birth and approximately one half demonstrated neurologic dysfunction.

Comment

Both the American College of Obstetricians and Gynecologists[10] and the American Academy of Pediatrics[11] have challenged use of the Apgar score alone to define birth asphyxia. As both of these organizations have emphasized, Apgar scores are unsatisfactory for the prediction of neurologic outcomes of newborns. It is important to recognize that there are several other factors that can account for low Apgar scores besides "asphyxia" such as gestational age, maternal medications, type of anesthetic administered, and the person who assigned the score.[9] In an attempt to more objectively define immediate newborn condition, several investigators have recommended use of umbilical blood acid-base determinations.[9, 12-14] However, reliance solely on newborn acid-base status to define birth asphyxia has been thwarted by the unrealistically high pH values used to define pathologic acidosis. For example, a commonly used definition of newborn acidosis or "acidemia" is umbilical blood pH <7.20, but the majority of such newborns wil be vigorous at birth and will not have obvious neonatal sequelae.[9, 15] This was borne out in our investigation; 385 infants (14%) were acidotic by this definition and yet the majority were vigorous at birth and without neurologic sequelae.

It also has been reported that there is a poor correlation between Apgar scores and umbilical blood pH values. Sykes and associates[12] defined pathologic acidosis as pH <7.11 and reported that 81% of infants with low 5-minute Apgar scores (<7) were not acidotic at birth; conversely, 73% of those who were acidotic had normal Apgar scores. Regardless, the Apgar scoring system continues to be the most commonly used method to define birth asphyxia. for example, according to *The International Classification of Disease,*[8] mild asphyxia is defined as a 1-minute Apgar score ≤6 and severe asphyxia is defined as a 1-minute Apgar score ≤3. If these definitions were used in the present study,

267 or approximately 10% of the newborns would have been diagnosed to have mild asphyxia and 55 (2%) to have severe asphyxia. Yet virtually all of these infants were normal in the immediate newborn period.

Because neither the Apgar score nor acid-base status alone correlated well with neonatal morbidity, we analyzed the effects of combined low Apgar scores and low pH values. Of the newborn who had an Apgar score ≤3 and an umbilical artery blood pH <7.00, all resuscitation at birth and approximately one half had neurologic abnormalities that included hypotonia or seizures. No infant with an Apgar score >3 and a pH <7.00 had seizures. One infant with a 1-minute Apgar score of 3 and a pH of 7.11 had seizure activity in the first 24 hours of life. This infant had early onset group B streptococcal sepsis, which likely was the cause of hypoperfusion leading to brain damage and seizures. The combination of an Apgar score ≤3 and pH <7.00 was a sensitive predictor of all cases of serious neonatal morbidity.

Cerebral dysfunction as evidence by seizures in the newborn period may result from metabolic abnormalities (e.g., hypoglycemia), infection, malformations, trauma, or true birth asphyxia.[3] There were five (1.8 per 1000) infants in the present study who had significant neurologic sequelae (i.e., seizures) during the neonatal period. These five infants demonstrate the plurality of causes for newborn cerebral dysfunction. One newborn had a seizure on day 10 that was due to meningitis. Infection (group B streptococcal sepsis and congenital syphilis) was implicated in two other infants. The fourth infant had an umbilical artery blood pH of 7.20 at delivery and pulmonary insufficiency developed as a result of meconium aspiration. The pH of this infant decreased acutely to 6.91 soon after arrival in the nursery and the infant subsequently convulsed. This time sequence suggests neonatal asphyxia as opposed to birth asphyxia. The fifth infant had an umbilical artery blood pH of 6.59, 1- and 5-minute Apgar scores of 1 and 3, respectively, and was delivered by cesarean section because of fetal distress due to uterine rupture. This is the only infant in the entire study population who had seizures and no other associated causative factors for this brain disorder. Cerebral palsy was diagnosed in this infant before discharge.

It is evident from this investigation of 2738 term pregnancies with intrapartum complications that new-

born cerebral dysfunction manifested as seizures and attributable to true birth asphyxia is extremely rare. The study results now reported suggest the infant must be severely depressed at birth to implicate birth asphyxia as the sole cause of newborn seizures. Such depression includes (1) extremely low Apgar score ≤3, (2) umbilical artery blood pH <7.00, and (3) need for resuscitation at birth. Towbin[4] has also concluded that infants who sustain central nervous system damage are severely depressed at birth. He stated, "It is implausible to believe that cerebral palsy developing in an infant can be attributed to massive acute cerebral damage incurred intranatally in an infant who was in good clinical condition soon after delivery." Other also have observed that seizures within the first day of life may be a sign of newborn brain dysfunction as a result of asphyxia.[3, 16-18] This observation that newborn brain disorders can only be attributed to birth asphyxia when the infant is extremely ill at birth is also supported by animal studies. Such studies indicate that animals must have almost lethal hypoxia before encephalopathy and neurologic damage develop.[5, 19] We conclude that birth asphyxia that leads to newborn seizures is very rare and that such neurologic dysfunction may result from a plurality of causes. Caution must be exercised before attributing birth asphyxia as the sole explanation for seizures in the immediate newborn period. An infant who is asphyxiated at birth must be severely depressed to include Apgar scores ≤3, fetal pH <7.00, require resuscitation, and have seizures in the first day after birth. The impact of lesser degrees of asphyxia as measured by Apgar score and acid-base status at birth remains unknown. A limitation in the design of this study is that there is now follow-up beyond the newborn period and it is possible that other infants in the study group would later show signs of cerebral dysfunction. Thus long term follow-up studies are necessary to completely elucidate the role of birth events in the genesis of infant brain disorders. Until such information becomes available, we believe it is inappropriate to diagnose birth asphyxia unless the infant is both severely depressed and acidotic at birth.

First-trimester midgut herniation: A high-frequency transvaginal sonographic study

Ilan E. Timor-Tritsch, MD, Wendy B. Warren, MD, David B. Peisner, MD, and Exenia Pirrone, LPN

New York, New York

The application of high-frequency transvaginal sonography offers new opportunities in scanning for malformations during the first trimester of pregnancy. Scanning of the anterior abdominal wall and the umbilical cord insertion at this gestational age is feasible. A cross-sectional study of 61 embryos-fetuses from 7 to 12 weeks of gestation was performed to observe the physiologic midgut hernia. This herniation was detected in 64% of the cases at 8 weeks, in 100% during weeks 9 and 10, and in 25% at 11 weeks' gestation. None of the fetuses studied at 12 weeks had a midgut herniation. Vaginal sonography of the well-dated fetus at 12 weeks can confirm the final development of the anterior abdominal wall. (Am J Obstet Gynecol 1989;161:831-3.)

Key words: Embryo, fetus, ultrasonography, transvaginal ultrasonography, ventral wall hernia, physiologic midgut hernia

High-frequency transvaginal transducer probes produce a high-resolution image of the first-trimester embryo.[1] Indications for vaginal scans in the first trimester include the detection of structural abnormalities. Familiarity with the potential of this technique is necessary to discover various anatomic defects. Relatively common birth defects of the ventral wall are omphalocele and gastroschisis, which occur at a rate of 1 in 4000 to 1 in 6000 live births. The normal process of the physiologic midgut herniation is well known. Timely diagnosis of a fetal ventral wall defect at the end of the first trimester would benefit the obstetric management of the patient and the surgical management of the fetus or neonate.

We focused our study on the complete disppearance of the physiologic midgut herniation to determine any deviation from the norm in patients who were at high risk for a congenital abdominal wall defect.

Material and methods

Sixty-one first-trimester pregnancies ranging from 7 to 12 weeks (inclusive) were scanned to observe the appearance or disappearance of the midgut herniation into the umbilical cord. Every patient was studied only once. A 6.5 MHz mechanical sector transducer probe (ESI-1000 Elscint, Inc., Haifa, Israel) was used.

6/6/14091

Gestational ages are given in menstrual weeks and days calculated from the first day of a certain and regular last menstrual period or the known date of conception. Crown-rump length was measured for each patient. The mean values for the gestational age in weeks and the patient distribution are given in Table I. We examined views of a transverse plane at the level of the abdominal insertion of the umbilical cord and a midsagittal section of the embryo to demonstrate the same anatomic area (Figs. 1 and 2). If the cross-sectional measurement at the immediate abdominal insertion of the cord was at least 1.5 times larger than the size of the cord, the presence of the midgut herniation was assumed.

Regardless of its position in the cord or in the abdominal cavity, before and after 12 weeks, respectively, the midgut could be easily located by its hyperechoic properties.

Results

The gestational ages by mean measurement of the crown-rump length correlated well (± 1 to 2 days); the mean gestational age was calculated by the clinical dating for each gestational week.

During the seventh week, the exact location of the abdominal insertion of the cord could not be detected. Therefore the presence or the absence of a midgut herniation could not be seen.

The thickening of the cord was clearly seen in 7 of the 11 (64%) fetuses studied throughout the eighth week.

All fetuses studied during the ninth and tenth weeks (11 and 7 cases, respectively) demonstrated a significant thickening of the cord at the level of the abdominal

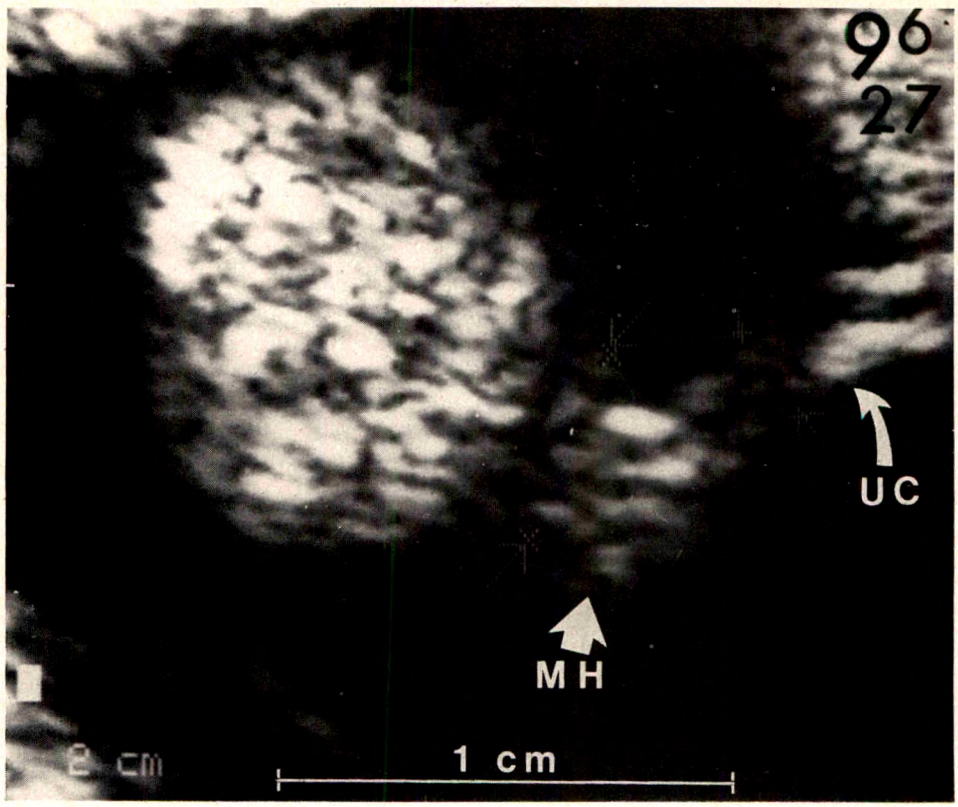

Fig. 1. Cross-section of 9-week 6-day fetus with crown-rump length of 27 mm at level of abdominal insertion of umbilical cord. Note that umbilical cord *(UC)* measures 2 mm and that diameter at its thickened abdominal insertion representing herniation of midgut *(MH)* is 4 mm.

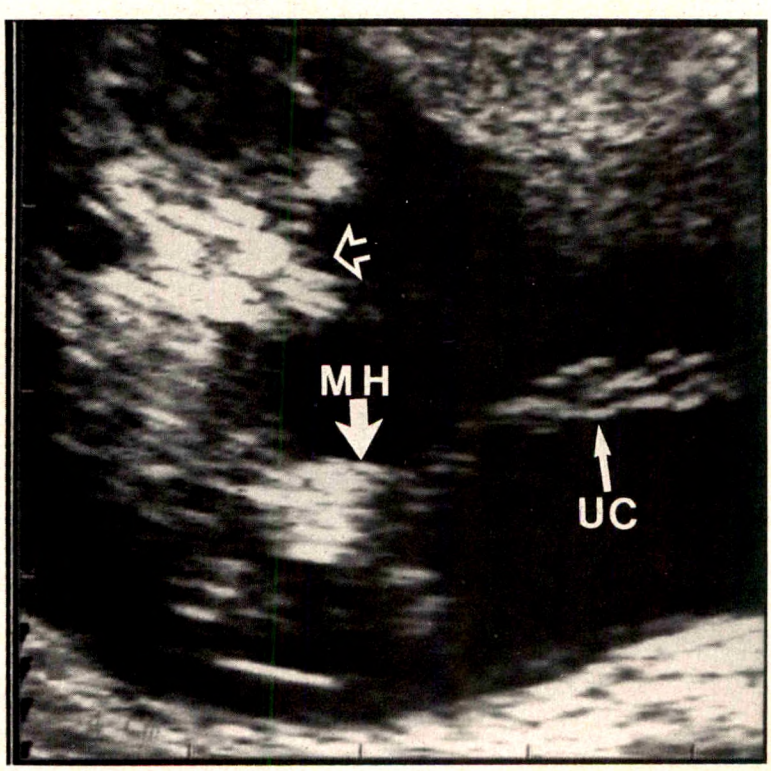

Fig. 2. Midsagittal section demonstrates difference in caliber between umbilical cord *(UC)* and hyperechogenic midgut herniation. Obvious high echogenicity of herniated midgut *(MH)* equals that generated by facial structures of face and upper limb *(open arrow)*.

Table I. Distribution of patient population

Gestation (wk)	*N*	*Mean gestational age by clinical dating*	*Mean crown-rump length (mm)*	*Gestational age by mean crown-rump length**	*Ventral hernia seen*
7	18	7 + 3	11.8	7 + 4	0
8	11	8 + 3	16.8	8 + 2	7 (64%)
9	11	9 + 3	26.0	9 + 3	11 (100%)
10	7	10 + 2	33.6	10 + 2	7 (100%)
11	8	11 + 2	48.0	11 + 5	2 (50%)
12	6	12 + 3	53.0	12 + 1	0
TOTAL	61				

*Gestational age expressed in weeks + days. Crown-rump length as determined by Robinson and Fleming.[4].

insertion. During this period it was relatively easy to image the finding.

Only four of the eight fetuses (25%) studied at 11 weeks demonstrated the midgut herniation. The remainder of the six fetuses were considered to have normal cord insertions.

The cord thickening containing the hyperechogenic content could not be imaged in any of the six fetuses scanned at 12 weeks.

Comment

Throughout its early embryologic development, the gut undergoes a counterclockwise rotation during which it is "forced" to assume an extracorporeal position within and along the base of the umbilical cord. This physiologic midgut herniation is probably caused by the relative lack of space created by the fast-growing liver during menstrual weeks 7 to 11.

The successful detection and significance of the physiologic midgut herniation by transabdominal ultrasonography has been reported.[2, 3] However, we project that the use of the high-frequency transvaginal ultrasonographic scanning method, when applied in the first and early second trimesters, will replace the ultrasonographic malformation workup currently done by transabdominal ultrasonography. The projected increase in the use of transvaginal scanning prompted us to evaluate its diagnostic abilities in imaging the physiologic midgut hernia.

The distinct hyperechogenicity of the bowel facilitated the identification of this well-defined structure in the cord before 11 to 12 weeks or within the abdominal wall during and after the twelfth week. The ventral herniation was not seen by vaginal ultrasonography in fetuses after 12 completed weeks of gestation. The particularly exaggerated curve of the fetal body before 8 weeks makes it difficult to identify the insertion of the umbilical cord; therefore the midgut herniation was not detected before 8 weeks.

The results of this study suggest that the final development of the fetal anterior abdominal wall, either normal or abnormal, can be seen by vaginal ultrasonography by 12 completed weeks, assuming that the gestation is well dated. Early identification of a ventral wall defect would allow time for further genetic evaluation of the fetus (i.e., chorionic villus sampling).

We conclude that vaginal ultrasonography by means of a higher-frequency probe, enables a reliable and relatively easy detection of the migrating midgut and its retraction into the fetal abdominal cavity before 12 weeks. This information is clinically important and useful.

CORRESPONDENCE

Calcium intake and pregnancy-induced hypertension

To the Editors:

Belizan, Villar, and Repke in their article (The relationship between calcium intake and pregnancy-induced hypertension: up-to-date evidence. AM J OBSTET GYNECOL 1988;158:898-902) detailed the relationship of calcium intake and the incidence of pregnancy-induced hypertension (PIH). They noted that supplementation of 1.0 gm of elemental calcium was associated with the reduction of diastolic blood pressure in reproductive women. They also cited a study from Equador in which calcium supplementation was associated with a lower (6.5%) incidence of PIH, as compared with the placebo group (28.2%).

In addition to their studies, they sited several studies in which the calcium intake was associated with a lower incidence of PIH even in the poor (often-sted as high-risk group for PIH). No mention was made to the relevance and function of magnesium, a critical counterpart of calcium. I would like to know whether the magnesium levels in their patients were noted either in their observations or in those to which they referred.

I am surprised to learn that if indeed "it has been widely documented that there is an inverse relationship between calcium intake and blood pressure" that "to date, there are no available reports conclusively demonstrating this association" and that "it could be premature to recommend calcium supplementation to all pregnant women with the prevention of pregnancy-induced hypertension as the only objective."

On the basis of my understanding of the role of magnesium in the physiology of pregnancy, I have used supplementation of magnesium[1, 2] in all pregnant women and have observed beneficial effects on PIH (incidence and severity) and the effects on low birth weight rates[3] (premature and intrauterine growth retardation).

Reply

To the Editors:

We thank Dr. Semchyshyn for his interest in our article and the opportunity to discuss some aspects of the relationship between magnesium load and prevention of pregnancy-induced hypertension (PIH).

As we mentioned in our article, magnesium reduces the transport of ionized calcium into the cell and then decreases the degree of tension of vascular smooth muscle cells. We hypothesized that the same effect is produced by a rise in calcium intake and could therefore explain why calcium and magnesium load could have beneficial effects on PIH.

We do not have experience with magnesium supplementation to prevent PIH but Dr. Semchyshyn quoted a retrospective study of Conradt et al.[1] that showed a reduction of the frequency of fetal growth retardation and PIH with magnesium supplementation. In a double-blinded randomized clinical trial of 568 pregnant women (278 with 15 μmol of magnesium aspartate-hydrochloride and 290 with a placebo) from the 16 weeks' gestation onward, Spälting and Spälting[2] showed no reduction in PIH in the supplemented group. However, they showed a reduction on the incidence of low birth weight infants (≤2500 gm) and a significant reduction to one half on the incidence of preterm deliveries (<37 weeks' gestation).

These observations in conjunction with the adjunt mechanisms of these two minerals on the intracellular calcium levels, encourage the performance of research on this subject with supplementation studies with a factorial design with independent and combined calcium and magnesium.

With regard to magnesium levels in our studies, no significant changes were evident in magnesium serum levels in calcium-deprived rats,[3] in calcium-supplemented young men and women,[4] and in pregnant women[5] in comparison with their control groups.

Finally, we would like to point out a pitfall in Dr. Semchyshyn's interpretation of the test. Although we said "it has been widely documented that there is an inverse relationship between calcium intake and blood pressure" when we stated that "to date, there are no available reports conclusively demonstrating this association," we referred to the association between calcium supplementation during pregnancy and reduction of PIH. Consequently "it could be premature to recommend calcium supplementation to all pregnant women with the prevention of pregnancy-induced hypertension as the only objective."

Analytical and clinical sensitivity and specificity in pregnancy testing

To the Editors:

Emanicipator et al. (Emanicipator K, Cadoff EM, Burke MD. Analytical versus clinical sensitivity and specificity in pregnancy testing. AM J OBSTET GYNECOL 1988;158:613-6) stated that whereas the clinical value of the newer immunoenzymetric monoclonal assays for human chorionic gonadotropin (hCG) are sufficient for early pregnancy testing, analytical sensitivity is still inferior to serum radioimmunoassay. There can be no doubt that these assays are well established as reliable and convenient methods of detection of urinary hCG in a variety of clinical states. We have shown that there is an approximately unitary relationship between blood and urine values of hCG in patients with first trimester pregnancy, whether the gestational sac is intrauterine[1] or in the fallopian tube.[2] This permits the use of qualitative urine hCG measurement to determine prgnancy status, and we have shown in several studies that the Tandem Icon pregnancy test (Hybritech Inc., San Diego, Calif.) will detect urine hCG in every case of ectopic pregnancy with a positive predictive index of 100% and a negative index of 99.6%[2-4] (serum radioimmunoassay results, 96.7% and 99.6%, respectively). Therefore, Emanicipator et al. confirm our proposal that the immunoenzymetric assays for hCG have a high clinical sensitivity and specificity for pregnancy.

However, they overlook the fact that when these newer assays are applied to urine the assays may have superior analytic qualities in addition to their clinical value. We have demonstrated that the Tandem Icon test can be made sufficiently sensitive to 1 IU/L (first international reference preparation) by a simple modification of filtration of 8 ml of urine.[5] The assay can be performed at the bedside by nonlaboratory personnel in 5 minutes[6] and has no significant crossreaction with undefined urinary interfering substances. All these parameters are superior to the conventional radioimmunoassays in which both serum and urine samples may give background "noise." In addition, newer densitometric equipment permits the quantitation of hCG levels with the Tandem Icon test, whether the test fluid is urine or (preferably) serum.

There is little doubt that serum radioimmunoassay has been replaced by qualitative immunoenzymetric hCG assays in the detection of pregnancy status. Where radioimmunoassay still has a role is in the determination of quantitative levels for discriminatory zones or rate of increase of hCG to assist in the determination of the site of the gestation.

Reply

To the Editors:

Our study[1] showed that results of the Tandem Icon human chorionic gonadotropin (hCG) urine pregnancy test, when performed according to the manufacturer's instructions, were positive in the overwhelming majority of cases in which there was detectable hCG in the serum by radioimmunoassay (RIA). Of nine patients with adequate clinical follow-up, negative results of a Tandem Icon hCG urine test, and detectable hCG in the serum by RIA, only one proved to be pregnant. By increasing the analytical sensitivity of the urine pregnancy test, a small increase in the clinical sensitivity would be achieved, but only at the expense of an equivalent decrease in clinical specificity. The net clinical efficiency would be slightly reduced. In general, there seems to be no advantage to increasing the analytical sensitivity of the urine pregnancy test.

Arguably, in certain circumstances it may be desirable to maximize clinical sensitivity at the expense of clinical specificity. Buck et al.[2] propose that two such circumstances are a woman awaiting roentgenography in the second half of her menstrual cycle and a woman with suspected ectopic pregnancy. With proper shielding of the uterus, roentgenography of the skull, chest, cervical spine, or extremities roentgenography increase the risk of birth defects by only 0.00001% to 0.0001%. Therefore necessary roentgenography should never be withheld. Elective roentgenography should be scheduled

during the first 10 days of the menstrual cycle.[3] Urine pregnancy tests with increased sensitivity may have a role in the evaluation of ectopic pregnancy; in our experience (unpublished data) and that of others,[4] undetectable serum hCG virtually excludes the diagnosis. On the other hand, as we have stated previously, experience has shown that it is safe to delay operation in patients with ectopic pregnancy and very low serum hCG levels, and that doing so probably increases preoperative diagnostic accuracy.[5]

We did not mean to imply that enzyme-linked monoclonal immunoassays in general have inferior analytical sensitivity compared with RIA. We stated that the analytical sensitivity of urine pregnancy tests (commercially available at the time) were inferior to that of the RIA. Recently, a quantitative serum enzyme-linked monoclonal immunoassay for hCG with an analytical sensitivity of 0.34 IU/L (first international reference preparation) was described.[6] Clearly, this assay rivals any RIA.

Finally, it should be noted that shortly after the conclusion of our study, Hybritech, Inc. (San Diego, Calif.) introduced the Tandem Icon II hCG urine test. This assay is more analytically sensitive than the older version. Fortunately, an internal standard allows the user to determine whether detectable urinary hCG levels are > or <50 IU/L (first international reference preparation). Therefore the test has three possible results: "negative," "borderline" (<50 IU/L), and "positive" (>50 IU/L). The physician may act on borderline results as deemed appropriate for the clinical situation.

Neonatal seizures and cesarean section

To the Editors:

Spellacy and colleagues (Spellacy WN, Peterson PQ, Winegar A, Quilligan EJ. Neonatal seizures after cesarean delivery: higher risk with labor. AM J OBSTET GYNECOL 1987;157:377-9) have shown that for infants with birth weights >2500 gm, primary cesarean section with labor is associated with a significantly higher incidence of neonatal seizures than is repeat elective cesarean section without labor. They suggest that labor, of itself, may cause a threefold increase in the incidence of seizures in these larger infants. Paradoxically, infants with birth weights <2500 gm did not appear to be adversely affected by labor, despite their inherent susceptibility to the adverse effects of intrapartum hypoxia. By looking only at patients delivered by cesarean section, the authors have biased their analysis. To attribute blame to labor they should have compared outcomes of all patients who labored with outcomes of those delivered by cesarean section. However, if Spellacy and colleagues are correct, the explanation must lie in the characteristics of labor in the group with larger infants. Further analysis of the data base may help to clarify matters. It is likely that the majority of cases of primary cesarean section involved primigravid women, whereas all the repeat cesarean sections were, by definition, in multiparous women. It is probable that in Illinois, as elsewhere, the incidence of seizures is higher in first-born infants.[1] The data from Illinois also suggest that the incidence of cesarean section in labor was significantly higher in primigravid women, similar to experience in our institution.[2]

If my interpretation of the data is correct, the real question revolves around what characteristics of *first* labors in Illinois predispose patients to a high incidence of both neonatal seizures and cesarean section where birth weight is >2500 gm. Previous studies suggest that the incidence of seizures may be related to the duration of labor.[1, 3] It would therefore be interesting to know the average duration of labor in primigravid women delivered of infants in Illinois. Perhaps a high incidence of prolonged or abnormal labor (dystocia) has resulted in a high incidence of both seizures and cesarean section. In primigravid patients at our institution the average duration of spontaneous labor is 7.0 hours (11.0 hrs if labor is induced), the incidence of cesarean section in spontaneous labor is 10%, and the incidence of seizures is 1.9 per 1000. Our low incidence of cesarean section is attributed to active management of labor.[4] An explanation of the lower incidence of seizures is not immediately apparent, although information with regard to duration of labor in primigravid women in Illinois might help us reach an answer. The fact that labor did not appear to have an effect on the smaller infants supports the proposition that length of labor has a significant influence on seizure incidence, inasmuch as labor is generally shorter with low birth weight. A solution to the apparently high incidence of seizures reported by Spellacy and colleagues may lie in a different approach to management of labor, such as active management, rather than the implied solution of more liberal use of cesarean section.

Finally, I fear that the figures reported by Spellacy and colleagues may encourage more liberal use of cesarean section in the management of dystocia in pri-

migravid women, a practice largely responsible for the current cesarean epidemic.[2,4]

Reply

To the Editors:

I appreciate the thoughtful letter from Dr. Boylan concerning our article on neonatal seizures and cesarean delivery. As expected, there were more primigravidous patients in the primary cesarean section group, but we could not show more seizures in first-born children when controlled for birth weight.

Whereas the duration of labor may be an important variable, even more critical may be the development of fetal hypoxia during that labor. The article did not suggest that long labors should be treated by cesarean section but rather that infant brain insults can occur during labor, as opposed to them all occurring before labor, and that this critical time in the infant's life must be carefully monitored and managed by the obstetrician.

Is central venous pressure monitoring "contraindicated" in patients with severe preeclampsia?

To the Editors:

We read with interest the article by Clark and Cotton in your March issue (Clark SL, Cotton DB. Clinical indications for pulmonary artery catheterization in the patient with severe preeclampsia. AM J OBSTET GYNECOL 1988;158:453-8). We found it to be a well-written review of the literature on the hemodynamic findings associated with severe preeclampsia. However, we do not believe that the literature to date supports all their conclusions. We are not convinced that simple central venous pressure monitoring is *contraindicated* in these patients. Nor have we seen any literature to support their contention that such patients can be managed better clinically than with the additional information provided by central venous pressure monitoring. Finally, we believe the proposal to place a pulmonary artery catheter each time the use of nitroprusside "is contemplated" would unjustifiably increase the use of pulmonary artery catheters.

We agree that one must not seek to translate a central venous pressure value into a value of pulmonary capillary wedge pressure as this has been repeatedly shown to be inaccurate.[1-3] But we hope that the clinician does not treat any of his patients (preeclamptic or not) solely on the basis of a central venous pressure reading or any other single number. It is important to note that the literature does show some relationships of the central venous pressure level to the pulmonary capillary wedge pressure values in patients with severe preeclampsia. It can be noted in the Cotton et al.[1] study in the same March issue, and in previous studies,[2-3] that when the central venous pressure level is <4 mm Hg the pulmonary capillary wedge pressure will be <18 mm Hg. The study by Cotton et al.[1] demonstrated that 51% of their patients will be seen with a central venous pressure value <3 mm Hg; thus it follows that the central venous pressure level alone will produce reliable information in the majority of patients. Only when the central venous pressure begin to rise above this value (typically to values of 7 or 8 mm Hg) is there a risk that the patient will have an elevated pulmonary capillary wedge pressure level with a normal central venous pressure level. This information can be used to assist therapeutic decisions without subjecting the patient to the unique risks of floating a pulmonary artery catheter (particularly in patients with potential bleeding disorders).[4] In fact, the central venous pressure level may be a "more accurate" indicator of low intravascular volume than is the wedge pressure.[1] This is often the information that is necessary when attempts are made to replenish a patient's intravascular volume before initiation of an epidural or general anesthetic.[5] It is important to realize the limitations of central venous pressure monitoring; but if used with caution in the proper circumstances it can provide clinically useful information with minimal risk to the patient.[6] One can also use the initial central venous pressure value and its subsequent response to a gentle fluid challenge to help determine the need to go on to pulmonary artery catheter monitoring.[4]

It is stated by Clark and Cotton that a patient with severe preeclampsia should be managed either clinically or with the aid of a pulmonary artery catheter. Multiple studies have demonstrated the inaccuracy of attempts to predict clinically the volume status in critically ill patients.[7-8] There is no data to suggest otherwise in patients with severe preeclampsia. Nor is there any study that supports the contention that physicians can determine a patient's volume status more accurately by

clinical examination alone than they can by clinical examination and central venous pressure monitoring.

Finally, Clark and Cotton dictate that when nitroprusside "is contemplated" a pulmonary artery catheter should be placed. This statement would encompass all severe and many moderate preeclamptic patients about to receive a general anesthetic agent inasmuch as nitroprusside (or another potent vasodilator) is usually on standby. This practice would greatly increase the number of pulmonary artery catheters placed in obstetrics suites across the United States. In light of the extra cost and potential risks, this recommendation should be supported by comparative outcome studies before it is labeled as "mandatory."

In conclusion, although the central venous pressure value cannot be directly translated into a number that always matches the pulmonary capillary wedge pressure value, it is certainly not a useless piece of information. We believe it is unwarranted to claim that this long-used indicator of intravascular volume is contraindicated in the patient with severe preeclampsia.

Reply

To the Editors:

We would like to thank Drs. Woodward and Romanoff for their interest in our article. These authors focus on the utility of central venous pressure monitoring for the determination of intravascular volume in patients with severe preeclampsia. This is puzzling inasmuch as it is well known that patients with severe preeclampsia are volume contracted; the clinician does not need any type of invasive monitoring to be assured of this principle.

The information we seek from pulmonary artery catheterization goes far beyond simple assessment of intravascular volume. Assessment of myocardial function and systemic vascular resistance is far more important in complicated preeclamptic patients than is the assessment of intravascular volume, which is already known to be decreased. When volume considerations are important in any individual patient, it is meaningless to know that central venous pressure levels correlate with wedge pressure levels in "most" (70% to 80%) patients.

Further, we fail to understand the authors' statement with regard to "unique risks" of a pulmonary artery catheter in patients with bleeding disorders. In such patients obtaining central venous access is the problem. The additional risks of floating the pulmonary artery catheter through the central venous sheath have nothing to do with bleeding disorders. Large studies that deal with both obstetric and nonobstetric patients have shown clearly that most complications of pulmonary artery catheterization involve obtaining central venous access and would be the same whether simple central venous pressure assessment or the more comprehensive information derived from pulmonary artery catheterization is obtained.[1-2]

Finally, the authors are concerned that our recommendations "would encompass all severe and many moderate preeclamptic patients about to receive a general anesthetic agent." With very few exceptions, epidural anesthesia is the anesthetic method of choice for patients with severe preeclampsia. Thus, preeclamptic patients who are about to receive a general anesthetic agent should be few and far between in most modern obstetric centers. For such patients, agents that are less potentially dangerous including β-blockers and nitroglycerine are effective in the reduction of blood pressure fluctuations associated with induction of general anesthesia. The use of such agents would not require invasive monitoring.

We remain emphatic in our belief that the overwhelming majority of patients with severe preeclampsia may be expertly managed without resorting to invasive monitoring of any type. However, for those few complicated patients in whom invasive monitoring is contemplated, we see no benefit in being content with central venous pressure assessment of intravascular volume. Simple assessment of central venous pressure levels has essentially disappeared from modern critical

care medicine. As obstetricians become familiar with pulmonary artery catheterization, assessment of central venous pressure levels in obstetrics should likewise become obsolete.

Recurrence of functional ovarian cysts after laparoscopic fenestration

To the Editors:

After preoperative vaginal examination and echography, we performed operative laparoscopic fenestrations in young women with ovarian cysts. The mean diameter of the cysts was 6.0 cm (range, 3.7 to 11.3 cm). Only follicular and corpus luteum cysts were studied. As in endometriomas, teratomas, and paraovarian cysts, we made a total laparoscopic extraction of the cyst wall.

In a series of 104 patients with a mean age of 30.4 years, the ovarian cysts were fenestrated[1] by the same endoscopic surgeon during 1985 to 1987. We saw no postoperative complications such as bleeding or pelvic inflammatory disease. The histopathology of the window revealed 58% follicular cysts and 42% corpus luteum cysts; no malignancy was found.

When we looked at the influence of combined oral contraceptives taken preoperatively we found that 29% of the patients took oral contraceptives at the time the functional cyst developed. A total of 91 women were followed up. The mean follow-up time was 20 months. With the use of vaginal examination and echography, we found a recurrence rate of 8% (7/91). It was, however, impossible to distinguish between a new disease or a recurrent cyst. Again, no malignancy was found.

When pelvic adhesions were seen at the laparoscopy, a higher recurrence rate of 11%, compared with 6% (Table I) was observed. At-random postoperative hormonal therapy with progestogenic agents or combined oral contraceptives showed no protective effect (Table II). Follicular cysts had a recurrence rate of 2%; corpus luteum cysts recurred in 14% (Table III).

We can conclude from our study there was no protective effect of postoperative hormonal therapy. We demonstrated a higher recurrence rate for corpus luteum cysts than that for follicular cysts. In the presence of pelvic adhesions, new cysts tend to occur. Our data confirm the safety and efficacy of the operative laparoscopic fenestration of functional ovarian cysts in young women and point out the factors that lead to a higher recurrence rate.

Table I. Influence of pelvic adhesions (n = 91)

	No adhesions	*Adhesions*
No recurrence	59	25
Recurrence	4	3
Recurrence rate	4/63 (6%)	3/28 (11%)

Table II. Influence of postoperative hormonal therapy (n = 91)

	No hormonal therapy	*Progestogens-combined oral contraceptives*
No recurrence	63	21
Recurrence	3	4
Recurrence rate	3/66 (5%)	4/25 (16%)

Table III. Influence of histopathology (7 patients had both types) (n = 91)

	Follicular cyst	*Corpus luteum cyst*
No recurrence	53	38
Recurrence	1	6
Recurrence rate	1/54 (2%)	6/44 (14%)

Criticism of publication of pharmaceutical-supported research results draws response

To the Editors:

A thought-provoking letter by Dr. Robert Goodlin was published in the March 1989 issue of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY (Goodlin RC. Pharmaceutical-supported supplements. 1989; 160:764). Inasmuch as I was cited in the letter as the editor of a criticized pharmaceutical-supported sym-

posium, I would like to comment on Dr. Goodlin's views.

I have a different view of antibiotic research than does Dr. Goodlin. I agree with him that there are probably too many antibiotics, but I disagree with the logic that "It is not necessarily progress to develop and test new antibiotics, particularly when present drugs and regimens do so well." This was the same type of statement that I heard as a medical student in the 1950s when I was taught that prophylactic antibiotics were of no value and the treatment of choice for postpartum endomyometritis was penicillin G and streptomycin. Infections have been a dynamic process in which changes in the bacterial pathogens and antibiotic susceptibilities have modified our therapeutic approaches. Much of our knowledge about the importance of such things as anaerobic bacteria and *Chlamydia trachomatis* in pelvic infections have come from studies supported by the pharmaceutical industry. For the future health of our specialty, I hope that support continues.

I disagree with Dr. Goodlin's view that results in the symposium in question have been modified to present only favorable findings. As the editor for this symposium, I know the clinical studies were adequately controlled with results accurately portrayed. Initial reports of antibiotics are usually enthusiastic, but that is the rule, not the exception for any new treatment regimen. Not every study is controlled in the symposium, but even Dr. Goodlin has recommended new therapeutic interventions from studies without concomitant controls (Goodlin RC. Surgical treatment of patients with hour glass–shaped or ruptured membranes prior to the 25th week of gestation. Surg Gynecol Obstet 1987;165:410.).

Like Dr. Goodlin, I am concerned about the lack of journal space. I believe that symposia should be published as supplements separate from the main journal. This is a recent decision by the JOURNAL and it is an improvement over the inclusion of the supplement within regular journal pages. However, I believe the weakness of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY has always been the publication of meeting papers. Despite peer review, I do not think the articles from the meetings of the American Gynecological and Obstetrical Society, Central Association of Obstetricians and Gynecologists, South Atlantic Association of Obstetricians and Gynecologists, and Pacific Coast Obstetrical and Gynecological Society are as good as the other published articles. This is a two-tier system that causes pressure on JOURNAL space for articles outside of those meetings.

William J. Ledger, MD

The New York Hospital
Cornell University Medical Center
525 E. 68th St.
New York, NY 10021

Reply

Dr. Ledger properly brings out the point that infections are a dynamic process in which changes in bacterial pathogens and antibiotic susceptibilities have modified therapeutic approaches. Research and development continue to bring out new approaches to therapy and education in obstetrics and gynecology, medicine, and surgery. Dr. Ledger correctly noted that the pharmaceutical industry has provided support for many of these advancements. With this we agree.

The AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY does publish reports of observations and randomized, blinded, controlled trials in the various sections of the JOURNAL, including symposia, if they are believed to have value for our readers.

Dr. Ledger expressed concern about lack of JOURNAL space and mentioned that symposia should be published as freestanding supplements, not within regular JOURNAL pages. The inference is that a symposium published within a regular issue of the JOURNAL with consecutively numbered pages reduces the number of pages for the publication of manuscripts that are individually submitted to the JOURNAL. Such is not the case. Whether the supplement is freestanding or within the JOURNAL issue, no space (pages) is taken or will be taken from that allotted for regularly submitted manuscripts.

The publication of society papers as a means of disseminating information to a wide spectrum of obstetricians and gynecologists was the objective of the predecessor of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY, namely, the *American Journal of Obstetrics and Diseases of Women and Children,* which was founded and began publication in 1868. The first and subsequent issues contained society articles. In 1876 they published papers of the first meeting of the American Gynecological Society and in 1888 the papers of the first meeting of the American Association of Obstetricians and Gynecologists. Articles from both societies have been published yearly since then (now, with the union of the two, as the American Gynecological and Obstetrical Society). When the C.V. Mosby Company purchased the *American Journal of Obstetrics and Diseases of Women and Children* in 1920, it maintained this objective and, as new societies were formed, selected the ones for which papers would be published. In addition to the ones mentioned by Dr. Ledger the Society for Gynecologic Investigation and the Society of Perinatal Obstetricians have been added. Societies, their annual meetings, and publication of their papers have played and are playing an important role in the development and progress of obstetrics and gynecology. Each has a purpose. We are pleased to play a role, both historically and presently, by publishing articles from their annual meetings.

Maternal-Fetal Medicine

The Department of Obstetrics and Gynecology at the University of Tennessee Medical Center at Knoxville, Tennessee is currently accepting applications for an additional Maternal-Fetal Medicine Specialist.

This position requires Board certification or eligibility in Maternal-Fetal Medicine. Responsibilities include resident and medical student education, participation in Regionalization Program and clinical or basic research. Specialized areas of interest such as critical care, ultrasonography and Doppler studies, and prenatal diagnosis are encouraged. A private practice opportunity is available.

Academic rank is commensurate with qualifications and experience.

Interested persons should send curriculum vitae to:

PRINCIPLES AND PRACTICE OF CLINICAL GYNECOLOGY, Second Edition

Edited by **Nathan G. Kase,** MD,
Allan B. Weingold, MD, and **David M. Gershenson,** MD
With 36 contributors

The revised, up-to-date **new edition** — with many new expert contributors and first-time chapters on geriatric patients . . . genital tract lesions . . . risk management; plus crucial new information on toxic shock syndrome and AIDS. The clinical approach stresses understanding of the basic sciences as key to proper diagnosis and treatment.

November 1989. 1,056 pages plus index. 754 illustrations, 280 tables. $89.95 *tentative*

OBSTETRICS

Edited by **Sir Alec Turnbull,** CBE MD FRCOG, and
Geoffrey Chamberlain, MD FRCS FRCOG
With 85 contributors

A comprehensive account of all aspects of current obstetric knowledge and practice, presented by a distinguished team of experts. Includes major sections on fetal monitoring, abnormal pregnancy, neonatal care, contraception and medicolegal issues.

October 1989. 1,201 pages. 350 illustrations. $150.00

MANUAL OF GYNECOLOGIC ONCOLOGY

By **Enrique Hernandez,** MD FACOG FACS, and
Neil B. Rosenshein, MD FACOG

Provides the fundamentals of effective care for gynecologic cancer patients. The book features disease- **and** procedure-related coverage, *plus* discussions of nutritional support, blood component therapy, and the Hickman catheter — topics not often found in gynecology texts.

1989. 184 pages. 24 illustrations, 37 tables. Flexible binding. $24.95

DEPARTMENT CHAIR
OBSTETRICS AND GYNECOLOGY

The University of South Alabama invites applications and/or nominations for the position of Professor and Chair of the Department of Obstetrics and Gynecology. The College of Medicine admitted its first class of medical students in 1973. It is a relatively small, state assisted, medical school with approximately 55 basic science faculty and 140 full-time clinical faculty members. Residency programs are well established in all major specialties, with a total of approximately 175 resident positions. This position provides an outstanding opportunity to build an excellent, progressive department in this geographic region. Candidates should have demonstrated academic administration and clinical experience. Proven leadership skills are required. Candidates must be committed to excellence in patient care, teaching, and research.

Please send nominations and/or applications to:

Joseph H. Coggin, Jr., Ph.D.
Chair, Search Committee
Department of Microbiology, 2118 MSB
University of South Alabama
Mobile, AL 36688

Applications should include curriculum vitae and the names and addresses of those who will provide letters of reference.

The University of South Alabama is an Affirmative Action/Equal Opportunity employer.

OB/GYN
Boston, MA

We are a community health center in Boston currently seeking a temporary full-time, or permanent part-time OB/GYN. Strong medical network includes CNM and NP support.

We offer a competitive salary and generous fringe benefits including malpractice insurance.

Please send CV, or contact: Dr. Albert K. Yee, Medical Director, South Cove Community Health Center, 885 Washington Street, Boston, MA 02111, (617) 482-7555.

SOUTH COVE COMMUNITY HEALTH CENTER

健康

Generalist in OB-GYN

We have an opportunity for a generalist in obstetrics and gynecology to join the full time faculty of the University of Rochester Department of Obstetrics and Gynecology at Rochester General Hospital. Rochester General is a 540 bed hospital, located in upstate New York. We serve women from the inner city and suburban areas with a successful mix of privately insured and medicaid patients. Our recently opened Birth Center is the first phase of our master plan to modernize our labor and delivery and surgery facilities. The successful candidate will have a commitment to clinical excellence and patient teaching. The teaching of residents and medical students requires a solid knowledge of general obstetrics and gynecology. Excellent communication and interpersonal skills are essential.

The University of Rochester offers an excellent salary and benefit package commensurate with academic credentials and clinical experience. Board certified or eligible individuals are requested to submit your curriculum vitae in confidence to:

Phyllis C. Leppert, CNM, MD, PhD
Chief of Obstetrics & Gynecology
Rochester General Hospital
1425 Portland Avenue
Rochester, New York 14621

The University of Rochester is an equal opportunity employer.

Medical Staff Fellowships

Genetics and Endocrinology
National Institutes of Health

The National Institute of Child Health and Human Development of the National Institutes of Health is offering a limited number of three-year Medical Staff Fellowship positions to candidates of the highest caliber. Fellowships begin July 1, 1990 and 1991. Positions are available for physicians who have completed at least two years of training in Internal Medicine, Pediatrics, or Obstetrics and Gynecology. Other medical specialty credentials will be considered on a case by case basis. Candidates must be United States citizens or permanent residents; graduates of foreign medical schools must be certified by the ECFMG.

The training programs consist either of one clinical year and two years of laboratory-based research (Human Genetics, Adult Endocrinology, Pediatric Endocrinology, Gynecologic Endocrinology). The endocrinology fellowships are integrated with the NIH Interinstitute Endocrinology Fellowship Program, and the human genetics fellowships are integrated with the NIH Interinstitute Medical Genetics Program. The gynecologic-endocrinology fellowship is integrated with programs at the Walter Reed Hospital and the National Naval Medical Center.

Research experience will be obtained in the Laboratory or Branch of the Fellow's choice from among the Institute's three clinical research Branches and nine basic science Laboratories.

The major emphasis of the NICHD Intramural Research Program is on basic and clinically applied research in the broad area of developmental biology. Areas presently being examined include developmental endocrinology, reproductive biology, cellular differentiation, human genetics and inborn metabolic errors, molecular endocrinology; developmental and molecular immunology, developmental neurobiology, molecular genetics (bacteria, virus, yeast, drosophila, and animal cell), pharmacogenetics, growth factors, neurochemistry and neuroimmunology, theoretical and physical biology, cell biology, (especially receptors and organelles), and comparative ethology.

For physicians interested in pursuing a career in academic medicine and research, these Fellowships offer an opportunity to train with scientists and physicians of international stature. Excellent facilities are available on the 306-acre NIH campus in Bethesda, Maryland, including a 480-bed research and teaching hospital, more than 1,000 laboratories, and the National Library of Medicine. Medical Staff Fellows receive an initial salary of $37,000 with increments of $2,000 per year and may be appointed to the Civil Service or the Public Health Service. Moving and travel allowances and Federal health care benefits are available.

Applications may be obtained from:

The NIH Medical Staff Fellowship Program
Ms. Vicki Malick
National Institutes of Health
Building 10, Room 1C292
9000 Rockville Pike
Bethesda, Maryland 20892
(301) 496-2427

Further information may be obtained from:

Arthur S. Levine, M.D.
Scientific Director, National Institute of Child Health and Human Development
National Institutes of Health
Building 31, Room 2A50
9000 Rockville Pike
Bethesda, Maryland 20892
(301) 496-2133

Deadline for applications is November 10, 1989.

NIH IS AN EQUAL OPPORTUNITY EMPLOYER.

POSITIONS OPEN – OBSTETRICS AND GYNECOLOGY
University of Utah – School of Medicine

Division of General Obstetrics and Gynecology

We are seeking an individual at the rank of Instructor or Assistant Professor who is committed to a career in academic medicine. We have a particular need for someone interested in practicing and teaching obstetrics. A variety of opportunities for clinical investigation and career development are available. The applicant must be board certified or an active candidate for such certification.

Division of Maternal-Fetal Medicine

We are seeking someone to join four certified perinatologists and two fellows at the rank of Assistant Professor. The applicant must be interested in research, teaching, and patient care. We are especially interested in someone with interest and special expertise in obstetric ultrasound, and fetal therapy. Applicants must be certified in maternal fetal medicine, or active candidates for certification.

Interested candidates should send curriculum vitae to:

James R. Scott, M.D.
Professor and Chairman
Department of Obstetrics and Gynecology
University of Utah School of Medicine
Salt Lake City, Utah 84132

Applications must be postmarked by September 01, 1989. Applications received after that deadline may be considered if no qualified applications have been received by that time. The University of Utah is an Equal Opportunity Affirmative Action Employer.

FELLOWSHIP
MATERNAL-FETAL MEDICINE
JULY, 1990

The Division of Maternal-Fetal Medicine, Department of Obstetrics and Gynecology, MacDonalc Hospital for Women, University Hospitals of Cleveland, and Case Western Reserve University, has an opening at the instructor level beginning July 1, 1990. Applicants should desire a career in academic medicine and must be Board certified/eligible by the American Board of Obstetrics and Gynecology.

Fellows will be involved in teaching medical students and house officers. The fellowship program emphasizes clinical and basic research in clinical perinatology with a particular interest in ultrasound, Doppler and perinatal diagnosis. The individual will also be responsible for some general duties in obstetrics and gynecology.

Applicants should send a curriculum vitae to:

J.C. Veille, M.D.
Director, Division of Maternal-Fetal Medicine
MacDonald Hospital for Women, University Hospitals of Cleveland
2074 Abington Road
Cleveland, OH 44106
216/844-3338

The University is an equal opportunity/affirmative action employer.

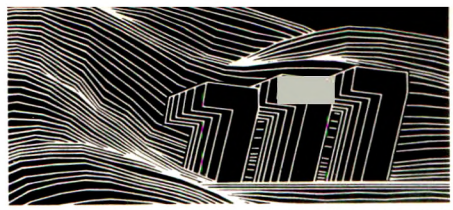
norethindrone/ethinyl estradiol

Each white tablet contains 0.5 mg norethindrone and 0.035 mg ethinyl estradiol. Each light peach tablet contains 0.75 mg norethindrone and 0.035 mg ethinyl estradiol. Each peach tablet contains 1 mg norethindrone and 0.035 mg ethinyl estradiol. Each green tablet in 28-day regimen contains inert ingredients.

IMPORTANT NOTE—This information is a BRIEF SUMMARY of the complete prescribing information provided with the product and therefore should not be used as the basis for prescribing the product. This summary was prepared by deleting from the complete prescribing information certain text, tables and references. The physician should be thoroughly familiar with the complete prescribing information before prescribing the product.

INDICATIONS AND USAGE: PREVENTION OF PREGNANCY.



CONTRAINDICATIONS: Oral contraceptives should not be used in women who currently have the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep vein thrombophlebitis or thromboembolic disorders. 3. Cerebral vascular or coronary artery disease. 4. Known or suspected carcinoma of the breast. 5. Carcinoma of the endometrium or other known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Cholestatic jaundice of pregnancy or jaundice with prior pill use. 8. Hepatic adenomas or carcinomas. 9. Known or suspected pregnancy.

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risks of several serious conditions including myocardial infarction, thromboembolism, stroke, hepatic neoplasia, and gallbladder disease, although the risk of serious morbidity or mortality is very small in healthy women without underlying risk factors. The risk of morbidity and mortality increases significantly in the presence of other underlying risk factors such as hypertension, hyperlipidemias, obesity and diabetes. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks. The information contained in this brief summary is principally based on studies carried out in patients who used oral contraceptives with higher formulations of estrogens and progestogens than those in common use today. The effect of long term use of the oral contraceptives with lower formulations of both estrogens and progestogens remains to be determined. Throughout this brief summary epidemiological studies reported are of two types: retrospective or case control studies and prospective or cohort studies. Case control studies provide a measure of the relative risk of a disease, namely a *ratio* of the incidence of a disease among oral contraceptive users to that among nonusers. The relative risk does not provide information on the actual clinical occurrence of a disease. Cohort studies provide a measure of attributable risk, which is the *difference* in the incidence of disease between oral contraceptive users and nonusers. The attributable risk does provide information about the actual occurrence of a disease in the population. For further information, the reader is referred to a text on epidemiological methods. 1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS. a. Myocardial Infarction. An increased risk of myocardial infarction has been associated with oral contraceptive use. This risk is primarily in smokers or women with other underlying risk factors for coronary artery disease such as hypertension, hypercholesterolemia, morbid obesity, and diabetes. The relative risk of heart attack for current oral contraceptive users has been estimated to be two to six. The risk is very low under the age of 30. Smoking in combination with oral contraceptive use has been shown to contribute substantially to the incidence of myocardial infarctions in women in their mid-thirties or older with smoking accounting for the majority of excess cases. Mortality rates associated with circulatory disease have been shown to increase substantially in smokers, especially in those 36 years of age and older among women who use oral contraceptives. Oral contraceptives may compound the effects of well-known risk factors, such as hypertension, diabetes, hyperlipidemias, age and obesity. In particular, some progestogens are known to decrease HDL cholesterol and cause glucose intolerance, while estrogens may create a state of hyperinsulinism. Oral contraceptives have been shown to increase blood pressure among users (see section 9 in WARNINGS). Similar effects on risk factors have been associated with an increased risk of heart disease. Oral contraceptives must be used with caution in women with cardiovascular disease risk factors. b. Thromboembolism. An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Case control studies have found the relative risk of users compared to non-users to be 3 for the first episode of superficial venous thrombosis, 4 to 11 for deep vein thrombosis or pulmonary embolism, and 1.5 to 6 for women with predisposing conditions for venous thromboembolic disease. Cohort studies have shown the relative risk to be somewhat lower, about 3 for new cases and about 4.5 for new cases requiring hospitalization. The risk of thromboembolic disease associated with oral contraceptives is not related to length of use and disappears after pill use is stopped. A two- to four-fold increase in relative risk of post-operative thromboembolic complications has been reported with the use of oral contraceptives. The relative risk of venous thrombosis in women who have predisposing conditions is twice that of women without such medical conditions. If feasible, oral contraceptives should be discontinued at least four weeks prior to and for two weeks after elective surgery of a type associated with an increase in risk of thromboembolism and during and following prolonged immobilization. Since the immediate postpartum period is also associated with an increased risk of thromboembolism, oral contraceptives should be started no earlier than four weeks after delivery in women who elect not to breast feed. c. Cerebrovascular diseases. Oral contraceptives have been shown to increase both the relative and attributable risks of cerebrovascular events (thrombotic and hemorrhagic strokes), although, in general, the risk is greatest among older (>35 years), hypertensive women who also smoke. Hypertension was found to be a risk factor for both users and non-users, for both types of strokes, and smoking interacted to increase the risk of stroke. In a large study, the relative risk of thrombotic strokes has been shown to range from 3 for normotensive users to 14 for users with severe hypertension. The relative risk of hemorrhagic stroke is reported to be 1.2 for nonsmokers who used oral contraceptives, 2.6 for smokers who did not use oral contraceptives, 7.6 for smokers who used oral contraceptives, 1.8 for normotensive users and 25.7 for users with severe hypertension. The attributable risk is also greater in older women. d. Dose-related risk of vascular disease from oral contraceptives. A positive association has been observed between the amount of estrogen and progestogen in oral contraceptives and the risk of vascular disease. A decline in serum high density lipoproteins (HDL) has been reported with many progestational agents. A decline in serum high density lipoproteins has been associated with an increased incidence of ischemic heart disease. Because estrogens increase HDL cholesterol, the net effect of an oral contraceptive depends on a balance achieved between doses of estrogen and progestogen and the activity of the progestogen used in the contraceptive. The activity and amount of both hormones should be considered in the choice of an oral contraceptive. Minimizing exposure to estrogen and progestogen is in keeping with good principles of therapeutics. For any particular estrogen/progestogen combination, the dosage regimen prescribed should be one which contains the least amount of estrogen and progestogen that is compatible with a low failure rate and the needs of the individual patient. New acceptors of oral contraceptive agents should be started on preparations containing 0.035 mg or less of estrogen. e. Persistence of risk of vascular disease. There are two studies which have shown persistence of risk of vascular disease for ever-users of oral contraceptives. In a study in the United States, the risk of developing myocardial infarction after discontinuing oral contraceptives persists for at least 9 years for women 40-49 years who had used oral contraceptives for five or more years, but this increased risk was not demonstrated in other age groups. In another study in Great Britain, the risk of developing cerebrovascular disease persisted for at least 6 years after discontinuation of oral contraceptives, although excess risk was very small. However, both studies were performed with oral contraceptive formulations containing 50 micrograms or higher of estrogens. 2. ESTIMATES OF MORTALITY FROM CONTRACEPTIVE USE. One study gathered data from a variety of sources which have estimated the mortality rate associated with different methods of contraception at different ages. These estimates include the combined risk of death associated with contraceptive methods plus the risk attributable to pregnancy in the event of method failure. Each method of contraception has its specific benefits and risks. The study concluded that with the exception of oral contraceptive users 35 and older who smoke and 40 and older who do not smoke, mortality associated with all methods of birth control is low and below that associated with childbirth. However, smokers 35 and older and non-smokers 40 and older who use oral contraceptives have a significant increase in mortality higher than those using other methods of birth control. These facts must be weighed in conjunction with failure rates for other methods and the risk associated with subsequent pregnancy. 3. CARCINOMA OF THE REPRODUCTIVE ORGANS. Numerous epidemiological studies have been performed on the incidence of breast, endometrial, ovarian and cervical cancer in women using oral contraceptives. While there are conflicting reports the overall evidence in the literature suggests that use of oral contraceptives is not associated with an increase in the risk of developing breast cancer. The Cancer and Steroid Hormone (CASH) study also showed no latent effect on the risk of breast cancer for at least a decade following long term use. Some studies have shown a slightly increased relative risk of developing breast cancer. Some studies suggest that oral contraceptive use has been associated with an increase in the risk of cervical intraepithelial neoplasia in some populations of

Revised 11/88

women. However, there continues to be controversy about the extent to which such findings may be due to differences in sexual behavior and other factors. In spite of many studies of the relationship between oral contraceptive use and breast and cervical cancers, a cause and effect relationship has not been established. 4. HEPATIC NEOPLASIA. Benign hepatic adenomas are associated with oral contraceptive use, although the incidence of benign tumors is rare in the United States. Indirect calculations have estimated the attributable risk to be in the range of 3.3 cases/100,000 for users, a risk that increases after four or more years of use especially with oral contraceptives of higher dose. Rupture of benign, hepatic adenomas may cause death through intra-abdominal hemorrhage. Studies from Britain have shown an increased risk of developing hepatocellular carcinoma in long-term (>8 years) oral contraceptive users. However, these cancers are rare in the U.S. and the attributable risk (the excess incidence) of liver cancers in oral contraceptive users approaches less than one per million users. 5. OCULAR LESIONS. There have been clinical case reports of retinal thrombosis associated with the use of oral contraceptives. Oral contraceptives should be discontinued if there is unexplained partial or complete loss of vision; onset of proptosis or diplopia; papilledema, or retinal vascular lesions. Appropriate diagnostic and therapeutic measures should be undertaken immediately. 6. ORAL CONTRACEPTIVE USE BEFORE OR DURING EARLY PREGNANCY: RISK OF BIRTH DEFECTS. Extensive epidemiological studies have revealed no increased risk of birth defects in women who have used oral contraceptives prior to pregnancy. The majority of recent studies also do not indicate a teratogenic effect, particularly in so far as cardiac anomalies and limb reduction defects are concerned, when taken inadvertently during early pregnancy. The administration of oral contraceptives to induce withdrawal bleeding should not be used as a test for pregnancy. Oral contraceptives should not be used during pregnancy to treat threatened or habitual abortion. It is recommended that for any patient who has missed two consecutive periods pregnancy should be ruled out before continuing oral contraceptive use. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period. Oral contraceptive use should be discontinued until pregnancy is ruled out. 7. GALLBLADDER DISEASE. Earlier studies have reported an increased lifetime relative risk of gallbladder surgery in users of oral contraceptives and estrogens. More recent studies, however, have shown that the relative risk of developing gallbladder disease among oral contraceptive users may be minimal. The recent findings of minimal risk may be related to the use of oral contraceptive formulations containing lower hormonal doses of estrogens and progestogens. 8. CARBOHYDRATE AND LIPID METABOLIC EFFECTS. Oral contraceptives have been shown to cause a decrease in glucose tolerance in a significant percentage of users. This effect has been shown to be directly related to estrogen dose. Progestogens increase insulin secretion and create insulin resistance; this effect varying with different progestational agents. However, in the non-diabetic woman, oral contraceptives appear to have no effect on fasting blood glucose. Because of these demonstrated effects prediabetic and diabetic women in particular should be carefully monitored while taking oral contraceptives. A small proportion of women will have persistent hypertriglyceridemia while on the pill. As discussed earlier (see WARNINGS 1a and 1d), changes in serum triglycerides and lipoprotein levels have been reported in oral contraceptive users. 9. ELEVATED BLOOD PRESSURE. An increase in blood pressure has been reported in women taking oral contraceptives, and this increase is more likely in older oral contraceptive users and with extended duration of use. Data from the Royal College of General Practitioners and subsequent randomized trials have shown that the incidence of hypertension increases with increasing progestational activity. Women with a history of hypertension or hypertension-related diseases, or renal disease, should be encouraged to use another method of contraception. If women elect to use oral contraceptives, they should be monitored closely and if significant elevation of blood pressure occurs, oral contraceptives should be discontinued. For most women, elevated blood pressure will return to normal after stopping oral contraceptives, and there is no difference in the occurrence of hypertension between former and never users. 10. HEADACHE. The onset or exacerbation of migraine or development of headache with a new pattern which is recurrent, persistent or severe requires discontinuation of oral contraceptives and evaluation of the cause. 11. BLEEDING IRREGULARITIES. Breakthrough bleeding and spotting are sometimes encountered in patients on oral contraceptives, especially during the first three months of use. Non-hormonal causes should be considered and adequate diagnostic measures taken to rule out malignancy or pregnancy in the event of breakthrough bleeding as in the case of any abnormal vaginal bleeding. If pathology has been excluded, time or a change to another formulation may solve the problem. In the event of amenorrhea, pregnancy should be ruled out. Some women may encounter post-pill amenorrhea or oligomenorrhea, especially when such a condition was preexistent. 12. ECTOPIC PREGNANCY. Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. **PRECAUTIONS:** 1. PHYSICAL EXAMINATION AND FOLLOW UP. A complete medical history and physical examination should be taken prior to the initiation or reinstitution of oral contraceptives and at least annually during use of oral contraceptives. These physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including cervical cytology, and relevant laboratory tests. In case of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be conducted to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules should be monitored with particular care. 2. LIPID DISORDERS. Women who are being treated for hyperlipidemias should be followed closely if they elect to use oral contraceptives. Some progestogens may elevate LDL levels and may render the control of hyperlipidemias more difficult. 3. LIVER FUNCTION. If jaundice develops in any woman receiving such drugs, the medication should be discontinued. Steroid hormones may be poorly metabolized in patients with impaired liver function. 4. FLUID RETENTION. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention. 5. EMOTIONAL DISORDERS. Women with a history of depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. 6. CONTACT LENSES. Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist. 7. DRUG INTERACTIONS. Reduced efficacy and increased incidence of breakthrough bleeding and menstrual irregularities have been associated with concomitant use of rifampin. A similar association, though less marked, has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and possibly with griseofulvin, ampicillin and tetracyclines. 8. INTERACTIONS WITH LABORATORY TESTS. Certain endocrine and liver function tests and blood components may be affected by oral contraceptives: a. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. b. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or by radio-immunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. c. Other binding proteins may be elevated in serum. d. Sex-binding globulins are increased and result in elevated levels of total circulating sex steroids and corticoids; however, free or biologically active levels remain unchanged. e. Triglycerides may be increased. f. Glucose tolerance may be decreased. g. Serum folate levels may be depressed by oral contraceptive therapy. This may be of clinical significance if a woman becomes pregnant shortly after discontinuing oral contraceptives. 9. CARCINOGENESIS. See WARNINGS section. 10. PREGNANCY. Pregnancy Category X. See CONTRAINDICATIONS and WARNINGS sections. 11. NURSING MOTHERS. Small amounts of oral contraceptive steroids have been identified in the milk of nursing mothers and a few adverse effects on the child have been reported, including jaundice and breast enlargement. In addition, oral contraceptives given in the postpartum period may interfere with lactation by decreasing the quantity and quality of breast milk. If possible, the nursing mother should be advised not to use oral contraceptives but to use other forms of contraception until she has completely weaned her child. **INFORMATION FOR THE PATIENT. See Patient Package Insert. ADVERSE REACTIONS:** An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see WARNINGS section). Thrombophlebitis and venous thrombosis with or without embolism. Arterial thromboembolism. Pulmonary embolism. Myocardial infarction. Cerebral hemorrhage. Cerebral thrombosis. Hypertension. Gallbladder disease. Hepatic adenomas or benign liver tumors. The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea. Vomiting. Gastrointestinal symptoms (such as abdominal cramps and bloating). Breakthrough bleeding. Spotting. Change in menstrual flow. Amenorrhea. Temporary infertility after discontinuation of treatment. Edema. Melasma which may persist. Breast changes: tenderness, enlargement, secretion. Change in weight (increase or decrease). Change in cervical erosion and secretion. Diminution in lactation when given immediately postpartum. Cholestatic jaundice. Migraine. Rash (allergic). Mental depression. Reduced tolerance to carbohydrates. Vaginal candidiasis. Change in corneal curvature (steepening). Intolerance to contact lenses. The following adverse reactions have been reported in users of oral contraceptives and the association has been neither confirmed nor refuted: Pre-menstrual syndrome. Cataracts. Changes in appetite. Cystitis-like syndrome. Headache. Nervousness. Dizziness. Hirsutism. Loss of scalp hair. Erythema multiforme. Erythema nodosum. Hemorrhagic eruption. Vaginitis. Porphyria. Impaired renal function. Hemolytic uremic syndrome. Acne. Changes in libido. Colitis. **OVERDOSAGE:** Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea and withdrawal bleeding may occur in females.

ORTHO PHARMACEUTICAL CORPORATION
Raritan, NJ 08869-0602

Low-impact norethindrone

No significant change in mean values for total cholesterol, HDL, and LDL†

21- and 28-day regimens

ORTHO-NOVUM® 777 Tablets

norethindrone/ethinyl estradiol

†Serious as well as minor side effects have been reported with the use of oral contraceptives. The physician should remain alert to the earliest manifestations of any symptoms of serious disease and discontinue oral contraceptive therapy when appropriate.

Please see brief summary of complete Prescribing Information on the preceding page.

TRI - NORINYL®

(NORETHINDRONE AND ETHINYL ESTRADIOL) TABLETS

TRI-NORINYL® 21-Day Tablets (7 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg, 9 yellow-green tablets of norethindrone 1.0 mg with ethinyl estradiol 0.035 mg, 5 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg)
TRI-NORINYL® 28-Day Tablets (7 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg, 9 yellow-green tablets of norethindrone 1.0 mg with ethinyl estradiol 0.035 mg, 5 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg, 7 inert orange tablets)
BREVICON® 21-Day Tablets (norethindrone 0.5 mg with ethinyl estradiol 0.035 mg)
BREVICON® 28-Day Tablets (21 norethindrone 0.5 mg with ethinyl estradiol 0.035 mg tablets followed by 7 inert tablets)
NORINYL® 1 + 35 21-Day Tablets (norethindrone 1 mg with ethinyl estradiol 0.035 mg)
NORINYL® 1 + 35 28-Day Tablets (21 norethindrone 1 mg with ethinyl estradiol 0.035 mg tablets followed by 7 inert tablets)
NORINYL® 1 + 50 21-Day Tablets (norethindrone 1 mg with mestranol 0.05 mg)
NORINYL® 1 + 50 28-Day Tablets (21 norethindrone 1 mg with mestranol 0.05 mg tablets followed by 7 inert tablets)
NOR-Q.D.® (norethindrone) Tablets 0.35 mg
ORAL CONTRACEPTIVE (O.C.) AGENTS

Indications: Prevention of pregnancy.

CONTRAINDICATIONS

Oral contraceptives should not be used in women who have the following conditions:
- Thrombophlebitis or thromboembolic disorders
- A past history of deep vein thrombophlebitis or thromboembolic disorders
- Cerebral vascular or coronary artery disease
- Known or suspected carcinoma of the breast
- Carcinoma of the endometrium, and known or suspected estrogen-dependent neoplasia
- Undiagnosed abnormal genital bleeding
- Cholestatic jaundice of pregnancy or jaundice with prior pill use
- Hepatic adenomas, carcinomas or benign liver tumors
- Known or suspected pregnancy

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risks of several serious conditions including myocardial infarction, thromboembolism, stroke, hepatic neoplasia and gallbladder disease, although the risk of serious morbidity and mortality increases significantly in the presence of other underlying risk factors such as hypertension, hyperlipidemias, hypercholesterolemia, obesity and diabetes.

Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

The information contained in this package insert is principally based on studies carried out in patients who used oral contraceptives with formulations containing 0.05 mg or higher of estrogen. The effects of long term use with lower dose formulations of both estrogens and progestogens remain to be determined.

Throughout this labeling, epidemiological studies reported are of two types: retrospective or case control studies and prospective or cohort studies. Case control studies provide a measure of the relative risk of a disease. Relative risk, the *ratio* of the incidence of a disease among oral contraceptive users to that among non-users cannot be assessed directly from case control studies, but the odds ratio obtained is a measure of relative risk. The relative risk does not provide information on the actual clinical occurrence of a disease. Cohort studies provide not only a measure of the relative risk but a measure of attributable risk, which is the *difference* in the incidence of disease between oral contraceptive users and non-users. The attributable risk does provide information about the actual occurrence of a disease in the population.

1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS

a. Myocardial Infarction

An increased risk of myocardial infarction has been attributed to oral contraceptive use. This risk is primarily in smokers or women with other underlying risk factors for coronary artery disease such as hypertension, hypercholesterolemia, morbid obesity and diabetes. The relative risk of heart attack for current oral contraceptive users has been estimated to be 2 to 6. The risk is very low under the age of 30. However, there is the possibility of a risk of cardiovascular disease even in very young women who take oral contraceptives.

Smoking in combination with oral contraceptive use has been shown to contribute substantially to the incidence of myocardial infarctions in women 35 or older, with smoking accounting for the majority of excess cases.

Mortality rates associated with circulatory disease have been shown to increase substantially in smokers over the age of 35 and non-smokers over the age of 40 among women who use oral contraceptives.

Oral contraceptives may compound the effects of well-known risk factors for coronary artery disease, such as hypertension, diabetes, hyperlipidemias, hypercholesterolemia, age and obesity. In particular, some progestogens are known to decrease HDL cholesterol and impair oral glucose tolerance, while estrogens may create a state of hyperinsulinism. Oral contraceptives have been shown to increase blood pressure among users (see **WARNINGS**, section 9). Similar effects on risk factors have been associated with an increased risk of heart disease. Oral contraceptives must be used with caution in women with cardiovascular disease risk factors.

b. Thromboembolism

An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Case control studies have found the relative risk of users compared to non-users to be 3 for the first episode of superficial venous thrombosis, 4 to 11 for deep vein thrombosis or pulmonary embolism, and 1.5 to 6 for women with predisposing conditions for venous thromboembolic disease. One cohort study has shown the relative risk to be somewhat lower, about 3 for new cases (subjects with no past history of venous thrombosis or varicose veins) and about 4.5 for new cases requiring hospitalization. The risk of thromboembolic disease due to oral contraceptives is not related to length of use and disappears after pill use is stopped.

A 2- to 6-fold increase in relative risk of post-operative thromboembolic complications has been reported with the use of oral contraceptives. If feasible, oral contraceptives should be discontinued at least 4 weeks prior to and for 2 weeks after elective surgery and during and following prolonged immobilization. Since the immediate postpartum period also is associated with an increased risk of thromboembolism, oral contraceptives should be started no earlier than 4 to 6 weeks after delivery in women who elect not to breast feed.

c. Cerebrovascular diseases

An increase in both the relative and attributable risks of cerebrovascular events (thrombotic and hemorrhagic strokes) has been shown in users of oral contraceptives. In general, the risk is greatest among older (>35 years), hypertensive women who also smoke. Hypertension was found to be a risk factor for both users and non-users for both types of strokes while smoking interacted to increase the risk for hemorrhagic strokes.

In a large study, the relative risk of thrombotic strokes has been shown to range from 3 for normotensive users to 14 for users with severe hypertension. The relative risk of hemorrhagic stroke is reported to be 1.2 for non-smokers who used oral contraceptives, 2.6 for smokers who did not use oral contraceptives, 7.6 for smokers who used oral contraceptives, 1.8 for normotensive users and 25.7 for users with severe hypertension. The attributable risk also is greater in women 35 or older and among smokers.

d. Dose-related risk of vascular disease from oral contraceptives

A positive association has been observed between the amount of estrogen and progestogen in oral contraceptives and the risk of vascular disease. A decline in serum high density lipoproteins (HDL) has been reported with some progestational agents. A decline in serum high density lipoproteins has been associated with an increased incidence of ischemic heart disease. Because estrogens increase HDL cholesterol, the net effect of an oral contraceptive depends on a balance achieved between doses of estrogen and progestogen and the nature and absolute amount of progestogens used in the contraceptives. The amount of both hormones should be considered in the choice of an oral contraceptive.

Minimizing exposure to estrogen and progestogen is in keeping with good principles of therapeutics. For any particular estrogen/progestogen combination, the dosage regimen prescribed should be one which contains the least amount of estrogen and progestogen that is compatible with a low failure rate and the needs of the individual patient. New acceptors of oral contraceptive agents should be started on preparations containing the lowest estrogen content that produces satisfactory results for the individual.

e. Persistence of risk of vascular disease

There are three studies which have shown persistence of risk of vascular disease for ever-users of oral contraceptives. In a study in the United States, the risk of developing myocardial infarction after discontinuing oral contraceptives persists for at least 9 years for women 40-49 years who had used oral contraceptives for 5 or more years, but this increased risk was not demonstrated in other age groups. In another study in Great Britain, the risk of developing cerebrovascular disease persisted for at least 6 years after discontinuation of oral contraceptives, although excess risk was very small. Subarachnoid hemorrhage also has a significantly increased relative risk after termination of use of oral contraceptives. However, these studies were performed with oral contraceptive formulations containing 0.05 mg or higher of estrogen.

2. ESTIMATES OF MORTALITY FROM CONTRACEPTIVE USE

One study gathered data from a variety of sources which have estimated the mortality rates associated with different methods of contraception at different ages. These estimates include the combined risk of death associated with contraceptive methods plus the risk attributable to pregnancy in the event of method failure. Each method of contraception has its specific benefits and risks. The study concluded that with the exception of oral contraceptive users 35 and older who smoke and 40 and older who do not smoke, mortality associated with all methods of birth control is low and below that associated with childbirth. However, smokers 35 and older and non-smokers 40 and older who use oral contraceptives have an increase in mortality greater than those using other methods of birth control. These facts must be weighed in conjunction with failure rates for other methods and the risk associated with subsequent pregnancy.

3. CARCINOMA OF THE BREAST AND REPRODUCTIVE ORGANS

Numerous epidemiological studies have been performed on the incidence of breast, endometrial, ovarian and cervical cancer in women using oral contraceptives. The evidence in the literature suggests that use of oral contraceptives is not associated with an increase in the risk of developing breast cancer, regardless of the age and parity of first use or with most of the marketed brands and doses. The Cancer and Steroid Hormone study also showed no latent effect on the risk of breast cancer for at least a decade following long term use. A few studies have shown a slightly increased relative risk of developing breast cancer, although the methodology of these studies, which included differences in examination of users and non-users and differences in age at start of use, has been questioned.

Some studies suggest that oral contraceptive use has been associated with an increase in the risk of cervical intraepithelial neoplasia in some populations of women. However, there continues to be controversy about the extent to which such findings may be due to differences in sexual behavior and other factors.

In spite of many studies of the relationship between oral contraceptive use and breast or cervical cancers, a cause and effect relationship has not been established.

4. HEPATIC NEOPLASIA

Benign hepatic adenomas are associated with oral contraceptive use although the incidence of benign tumors is rare in the United States. Indirect calculations have estimated the attributable risk to be in the range of 3.3 cases per 100,000 for users, a risk that increases after 4 or more years of use. Rupture of rare, benign, hepatic adenomas may cause death through intra-abdominal hemorrhage.

Studies in the United States and Britain have shown an increased risk of developing hepatocellular carcinoma in long term (>8 years) oral contraceptive users. However, these cancers are extremely rare in the United States and the attributable risk (the excess incidence) of liver cancers in oral contraceptive users is less than 1 per 1,000,000 users.

5. OCULAR LESIONS

There have been clinical case reports of retinal thrombosis associated with the use of oral contraceptives. Oral contraceptives should be discontinued if there is unexplained partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions. Appropriate diagnostic and therapeutic measures should be undertaken immediately.

6. ORAL CONTRACEPTIVE USE BEFORE OR DURING EARLY PREGNANCY

Extensive epidemiological studies have revealed no increased risk of birth defects in women who have used oral contraceptives prior to pregnancy. More recent studies do not suggest a teratogenic effect, particularly insofar as cardiac anomalies and limb reduction defects are concerned, when taken inadvertently during early pregnancy.

The administration of oral contraceptives to induce withdrawal bleeding should not be used as a test for pregnancy. Oral contraceptives should not be used during pregnancy to treat threatened or habitual abortion.

It is recommended that for any patient who has missed 2 consecutive periods, pregnancy should be ruled out before continuing oral contraceptive use. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period. Oral contraceptive use should be discontinued if pregnancy is confirmed.

7. GALLBLADDER DISEASE

Earlier studies have reported an increased lifetime relative risk of gallbladder surgery in users of oral contraceptives and estrogens. More recent studies, however, have shown that the relative risk of developing gallbladder disease among oral contraceptive users may be minimal. The recent findings of minimal risk may be related to the use of oral contraceptive formulations containing lower hormonal doses of estrogens and progestogens.

8. CARBOHYDRATE AND LIPID METABOLIC EFFECTS

Oral contraceptives have been shown to impair oral glucose tolerance. Oral contraceptives containing greater than 0.075 mg of estrogen cause glucose intolerance with impaired insulin secretion, while lower doses of estrogen may produce less glucose intolerance. Progestogens increase insulin secretion and create insulin resistance, this effect varying with different progestational agents. However, in the non-diabetic woman, oral contraceptives appear to have no effect on fasting blood glucose. Because of these demonstrated effects, prediabetic and diabetic women should be carefully observed while taking oral contraceptives.

Some women may develop persistent hypertriglyceridemia while on the pill. As discussed earlier (see **WARNINGS**, sections 1a. and 1d.), changes in serum triglycerides and lipoprotein levels have been reported in oral contraceptive users.

9. ELEVATED BLOOD PRESSURE

An increase in blood pressure has been reported in women taking oral contraceptives. The incidence of risk also was reported to increase with continued use and among older women. Data from the Royal College of General Practitioners and subsequent randomized trials have shown that the incidence of hypertension increases with increasing concentrations of progestogens.

Women with a history of hypertension or hypertension-related diseases or renal disease should be encouraged to use another method of contraception. If women elect to use oral contraceptives, they should be monitored closely and if significant elevation of blood pressure occurs oral contraceptives should be discontinued. For most women, elevated blood pressure will return to normal after stopping oral contraceptives and there is no difference in the occurrence of hypertension among ever- and never-users.

10. HEADACHE

The onset or exacerbation of migraine or development of headache with a new pattern which is recurrent, persistent or severe requires discontinuation of oral contraceptives and evaluation of the cause.

11. BLEEDING IRREGULARITIES

Breakthrough bleeding and spotting are sometimes encountered in patients on oral contraceptives, especially during the first 3 months of use. Non-hormonal causes should be considered and adequate diagnostic measures taken to rule out malignancy or pregnancy in the event of breakthrough bleeding, as in the case of any abnormal vaginal bleeding. If pathology has been excluded, time or a change to another formulation may solve the problem. In the event of amenorrhea, pregnancy should be ruled out.

Some women may encounter post-pill amenorrhea or oligomenorrhea, especially when such a condition was pre-existent.

PRECAUTIONS

1. PHYSICAL EXAMINATION AND FOLLOW-UP

A complete medical history and physical examination should be taken prior to the initiation or reinstitution of oral contraceptives and at least annually during use of oral contraceptives. These physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including cervical cytology and relevant laboratory tests. In case of undiagnosed, persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be conducted to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules should be monitored with particular care.

2. LIPID DISORDERS

Women who are being treated for hyperlipidemias should be followed closely if they elect to use oral contraceptives. Some progestogens may elevate LDL levels and may render the control of hyperlipidemias more difficult.

3. LIVER FUNCTION

If jaundice develops in any woman receiving oral contraceptives the medication should be discontinued. Steroid hormones may be poorly metabolized in patients with impaired liver function.

4. FLUID RETENTION

Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention.

5. EMOTIONAL DISORDERS

Women with a history of depression should be carefully observed and the drug discontinued if depression recurs to a serious degree.

6. CONTACT LENSES

Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist.

7. DRUG INTERACTIONS

Reduced efficacy and increased incidence of breakthrough bleeding and menstrual irregularities have been associated with concomitant use of rifampin. A similar association though less marked, has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and possibly with griseofulvin, ampicillin and tetracyclines.

8. INTERACTIONS WITH LABORATORY TESTS

Certain endocrine and liver function tests and blood components may be affected by oral contraceptives:

a. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability.

b. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG. Free T4 concentration is unaltered.

c. Other binding proteins may be elevated in serum.

d. Sex steroid binding globulins are increased and result in elevated levels of total circulating sex steroids and corticoids; however, free or biologically active levels remain unchanged.

e. Triglycerides may be increased.

f. Glucose tolerance may be decreased.

g. Serum folate levels may be depressed by oral contraceptive therapy. This may be of clinical significance if a woman becomes pregnant shortly after discontinuing oral contraceptives.

9. CARCINOGENESIS

See **WARNINGS** section.

10. PREGNANCY

Pregnancy Category X. See **CONTRAINDICATIONS** and **WARNINGS** sections.

11. NURSING MOTHERS

Small amounts of oral contraceptive steroids have been identified in the milk of nursing mothers and a few adverse effects on the child have been reported, including jaundice and breast enlargement. In addition, oral contraceptives given in the postpartum period may interfere with lactation by decreasing the quantity and quality of breast milk. If possible, the nursing mother should be advised not to use oral contraceptives but to use other forms of contraception until she has completely weaned her child.

INFORMATION FOR THE PATIENT

See **PATIENT LABELING**.

ADVERSE REACTIONS

An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see **WARNINGS** section):

• Thrombophlebitis • Arterial thromboembolism • Pulmonary embolism • Myocardial infarction • Cerebral hemorrhage • Cerebral thrombosis • Hypertension • Gallbladder disease • Hepatic adenomas, carcinomas or benign liver tumors

There is evidence of an association between the following conditions and the use of oral contraceptives, although additional confirmatory studies are needed:

• Mesenteric thrombosis • Retinal thrombosis

The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related:

• Nausea • Vomiting • Gastrointestinal symptoms (such as abdominal cramps and bloating) • Breakthrough bleeding • Spotting • Change in menstrual flow • Amenorrhea • Temporary infertility after discontinuation of treatment • Edema • Melasma which may persist • Breast changes: tenderness, enlargement, secretion • Change in weight (increase or decrease) • Change in cervical erosion and secretion • Diminution in lactation when given immediately postpartum • Cholestatic jaundice • Migraine • Rash (allergic) • Mental depression • Reduced tolerance to carbohydrates • Vaginal candidiasis • Change in corneal curvature (steepening) • Intolerance to contact lenses

The following adverse reactions have been reported in users of oral contraceptives and the association has been neither confirmed nor refuted:

• Pre-menstrual syndrome • Cataracts • Changes in appetite • Cystitis-like syndrome • Headache • Nervousness • Dizziness • Hirsutism • Loss of scalp hair • Erythema multiforme • Erythema nodosum • Hemorrhagic eruption • Vaginitis • Porphyria • Impaired renal function • Hemolytic uremic syndrome • Budd-Chiari syndrome • Acne • Changes in libido • Colitis

OVERDOSAGE

Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

NON-CONTRACEPTIVE HEALTH BENEFITS

The following non-contraceptive health benefits related to the use of oral contraceptives are supported by epidemiological studies which largely utilized oral contraceptive formulations containing estrogen doses exceeding 0.035 mg of ethinyl estradiol or 0.05 mg of mestranol.

Effects on menses:

• Increased menstrual cycle regularity • Decreased blood loss and decreased incidence of iron deficiency anemia • Decreased incidence of dysmenorrhea

Effects related to inhibition of ovulation:

• Decreased incidence of functional ovarian cysts • Decreased incidence of ectopic pregnancies

Effects from long-term use:

• Decreased incidence of fibroadenomas and fibrocystic disease of the breast • Decreased incidence of acute pelvic inflammatory disease • Decreased incidence of endometrial cancer • Decreased incidence of ovarian cancer

PAPERS OF THE SOCIETY FOR GYNECOLOGIC INVESTIGATION

Central hemodynamic assessment of normal term pregnancy 1439
Steven L. Clark, MD, David B. Cotton, MD, Wesley Lee, MD, Clark Bishop, MD, Tracy Hill, MD, James Southwick, MD, James Pivarnik, PhD, Thomas Spillman, PhD, Greggory R. DeVore, MD, Jeffrey Phelan, MD, Gary D. V. Hankins, MD, Thomas J. Benedetti, MD, and Dennis Tolley, PhD
Provo, Utah, Houston and San Antonio, Texas, Los Angeles, California, and Seattle, Washington

Central hemodynamic parameters were assessed with pulmonary artery catheterization in 10 normal patients during the third trimester and postpartum periods.

The central hemodynamics of severe preeclampsia 1443
William C. Mabie, MD, Thomas E. Ratts, MD, and Baha M. Sibai, MD
Memphis, Tennessee

The failure of the circulation to dilate in the setting of increasing cardiac output appears to be a characteristic feature of preeclampsia.

Cardiovascular changes in early phase of pregnancy 1449
Eleanor L. Capeless, MD, and James F. Clapp, MD
Burlington, Vermont

The majority of the pregnancy-induced changes in cardiac output and systemic vascular resistance occur during the embryonic period, as compared with the preconceptional baseline.

Vol. 161, No. 6, Part 1, December 1989. The American Journal of Obstetrics and Gynecology (ISSN 0002-9378) is published monthly (six issues per volume, two volumes per year) by The C.V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, Missouri 63146-3318. Second-class postage paid at St. Louis, Missouri, and additional mailing offices. POSTMASTER: Send address changes to The C.V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, Missouri 63146-3318, (314) 872-8370, ext. 351. Annual subscription rates for 1990: domestic, $71.50 for individuals and $130.00 for institutions. Printed in the U.S.A. Copyright © 1989 by The C.V. Mosby Company.

To be continued...

Continuation...an excellent indicator of patient satisfaction.

The Ortho ALL-FLEX* Arcing Spring Diaphragm

- Easy to insert and position
- Easy to clean and maintain
- Easy to use with unscented, colorless, stainless GYNOL II* (2% nonoxynol-9) Contraceptive Jelly
- The combination for continuation—with 4 out of 5 patients continuing after 1 year†

Continuation...it's one reason why physicians continue to make ORTHO ALL-FLEX and GYNOL II the #1 prescribed diaphragm combination in America.‡

Contents continued from page 3A

The effects of maternal exercise on early pregnancy outcome 1453
James F. Clapp III, MD
Burlington, Vermont

Running and aerobic dancing at high intensity at the time of conception and throughout early pregnancy did not influence early pregnancy outcome.

Oxygen consumption during treadmill exercise before, during, and after pregnancy 1458
James F. Clapp III, MD
Burlington, Vermont

The efficiency of low- and moderate-intensity treadmill exercise is increased early in pregnancy, maintained throughout pregnancy in most subjects, and enhanced by continued physical training during pregnancy.

Exercise prescription in pregnancy: Weight-bearing versus non-weight-bearing exercise 1464
Raul Artal, MD, Damon I. Masaki, MD, Nazareth Khodiguian, PhD, Yitzhak Romem, MD, Susan E. Rutherford, MD, and Robert A. Wiswell, PhD
Los Angeles, California

Weight-bearing exercise was compared with non-weight-bearing exercise in pregnant women by indirect calorimetry, which indicates preferential use of carbohydrates during non-weight-bearing exercise.

Human fetal behavioral states after vibratory stimulation 1470
Robert Gagnon, MD, Cora Hunse, RN, and John Foreman, PEng
London, Ontario, Canada

External vibratory stimulation of healthy term fetuses was associated with a transition from a quiet to an active sleep state.

Subscription rates include supplements. Single copies are $7.00. Remittances should be made by check, draft, or post office or express money order, in U.S. funds drawn through a U.S. bank, payable to this JOURNAL. Claims for missing issues will be serviced only within six months of cover date. Single copy prices will be charged on missing issue claims older than six months from cover date. Back issues generally are available for the previous five years. Contact the Publisher to confirm availability of specific issues.

°*Airmail breakdown—Domestic:* First-class and Priority rates for the U.S. and possessions are available upon request. *Canada:* All provinces of Canada. *Mexico:* All localities within Mexico. *Region 1:* Colombia, Venezuela, Central America, Caribbean Islands, Bahamas, Bermuda, and St. Pierre and Miquelon (also from American Samoa to Western Samoa and from Guam to the Philippines). *Region 2:* South America (except Colombia and Venezuela), Europe (except Estonia, Latvia, Lithuania, and U.S.S.R), and North Africa (Morocco, Algeria, Tunisia, Libya, and Egypt). *Region 3:* Estonia, Latvia, Lithuania, U.S.S.R., Asia, Australia, New Zealand, Pacific Ocean Islands, Africa (other than North Africa), Indian Ocean Islands, and the Middle East.

†Institutional (multiple-reader) subscriptions are available to public and private libraries, schools, hospitals, and clinics; city, county, state, provincial, and national government bureaus and departments; and all commercial and private institutions and organizations.

‡Individual subscriptions and all student-rate subscriptions must be in the names of, billed to, and paid by individuals. All student-rate requests must indicate training status and name of institution.

Subscriptions may begin at any time.

THE PERMANENTE MEDICAL GROUP

NORTHERN CALIFORNIA

QUALITY

STABILITY

LEADERSHIP

GROWTH

SUPPORT

REWARDS

The Permanente Medical Group, the largest multispecialty group practice in the U.S., is undergoing explosive growth in its Northern California region: the San Francisco Bay Area, Sacramento and the Central Valley. Our rapid increase in membership has created opportunities throughout the region for additional BC/BE Obstetricians and Gynecologists.

As part of a comprehensive health care system made up of the Kaiser Foundation Health Plan, Kaiser Foundation Hospitals, and our physician-managed group, you will have access to the latest medical technology and resources, the support of colleagues in all subspecialties — and the opportunity to provide excellent health care without the burdens of managing a practice.

Join us in one of these facilities:

Richmond — Small, congenial clinic setting staffed by five physicians and five nurse practitioners with ready consultation for other services, including perinatology. Practice general OB/GYN, high-risk obstetrics and infertility. Expertise in colposcopy, laparoscopy, hysteroscopy and laser welcome. Resident teaching opportunities exist. Staff call at Kaiser Hospital in Oakland, shared with resident staff.

Oakland — Twenty physicians, 12 residents offer services in oncology, infertility, maternal-fetal medicine and a large ICN.

Redwood City — Specializes in family-centered maternity care; offers modern LDR rooms and full range of gynecological surgery. With ten physicians, 24-hour call is required three times each month. Beautiful Peninsula location, near San Francisco and the Pacific Ocean.

Stockton — Small four physician department in a new clinic building with new equipment, including laser. Stockton's lifestyle is affordable and attractive, offering recreational activities such as boating on the inland waterways. Centrally located, with mountains to the east and San Francisco Bay Area to the west.

Roseville — Eight physicians and two nurse practitioners in clinic setting. Patients are hospitalized for delivery and surgery in Sacramento where physicians take call for L&D and emergency about 5 times each month.

San Francisco — Full range of services including large high-risk, tertiary care OB service. Eighteen physicians, including GYN Oncologist. Residency program. Clinical research and academic teaching appointments available.

Sacramento — Growing metropolitan area between San Francisco Bay Area and Sierra Nevada mountains. Up-to-date facility with active staff of 14 and excellent residency program affiliated with the University of California at Davis. Flexible call averaging five shifts per month covers L&D, emergency room and inpatient services.

Pleasanton — Staffed by four physicians and three nurse practitioners, clinic provides general OB/GYN services, non-stress tests, ultrasound and cystoscopy. Consultant support, including a Perinatologist, readily available. Share call with staff of Walnut Creek Medical Center. Affiliated with the University of California at San Francisco as clinical instructors.

Fresno — Ground-floor opportunities in growing area for clinically-oriented individuals. Provide general OB/GYN; special interests encouraged. Planning new $26 million outpatient facility to accompany current medical office building. On call every fourth night and weekend. Local residency program at Valley Medical Center affiliated with the University of California at San Francisco. Teaching positions possible.

South San Francisco — Full service except L&D. Nine physicians, six nurse practitioners. On San Francisco Peninsula, 15 minutes from downtown.

KAISER PERMANENTE
Good People. Good Medicine.

Member physicians share TPMG's many benefits, from our leading quality assurance and continuing education to malpractice coverage and substantial retirement programs. For application information, call or send CV to: The Permanente Medical Group, Inc., Richmond Prescott, M.D., Physician Recruitment Services, 1814 Franklin, 4th Floor, Oakland, CA 94612. 800-777-4912. EOE

Contents continued from page 5A

The effect of vibroacoustic stimulation on the nonstress test at gestational ages of thirty-two weeks or less 1476
Maurice L. Druzin, MD, Terri G. Edersheim, MD, J. M. Hutson, MD, and Annette L. Bond, MD
New York, New York

The incidence of reactive nonstress tests after vibroacoustic stimulation was significantly increased after 26 weeks' gestation, and this finding may have clinical applicability.

Effects of low-frequency vibration on human term fetuses 1479
Robert Gagnon, MD, John Foreman, PEng, Cora Hunse, RN, and John Patrick, MD
London, Ontario, Canada

External low-frequency vibratory stimulation of healthy term fetuses was associated with changes in fetal movement and fetal heart rate patterns suggesting a switch from a state of quiet sleep to a state of active sleep.

Nifedipine pharmacokinetics during preterm labor tocolysis 1485
James E. Ferguson II, MD, Thomas Schutz, BA, Robert Pershe, BS, David K. Stevenson, MD, and Terrence Blaschke, MD
Stanford, California

Tocolysis with sublingual and oral nifedipine resulted in variable but usually measurable maternal blood levels; placental transfer of nifedipine occurs.

Prediction of hematocrit decline after intravascular fetal transfusion 1491
Scott N. MacGregor, DO, Michael L. Socol, MD, Bruce W. Pielet, MD, John S. Sholl, MD, and Richard K. Silver, MD
Chicago and Evanston, Illinois

Fetal hematocrit decline after intravascular transfusion may be predicted to determine the optimum timing of repeat transfusion.

Effect of acute intravascular volume expansion on human fetal prostaglandin concentrations 1494
Carl P. Weiner, MD, and Jean E. Robillard, MD
Iowa City, Iowa

Intravenous transfusion of the anemic human fetus stimulates the release of prostaglandin E_2 and prostacyclin.

The effect of intravascular transfusion on umbilical venous pressure in anemic fetuses with and without hydrops 1498
Carl P. Weiner, MD, Gay D. Pelzer, RN, Joni Heilskov, RN, Katharine D. Wenstrom, MD, and Roger A. Williamson, MD
Iowa City, Iowa

The anemic human fetus tolerates direct intravascular transfusion with only a modest increase in umbilical venous pressure.

(Contents continued on page 8A)

Contents continued from page 7A

Duplex Doppler ultrasonographic evaluation of the fetal renal artery in normal and abnormal fetuses 1502
J. C. Veille, MD, and C. Kanaan, MD
Cleveland, Ohio

Duplex ultrasonography of the fetal renal artery was obtained in normal fetuses and in fetuses with intrauterine growth retardation; fetuses with intrauterine growth retardation have an increased vascular resistance within this bed.

Intrapartum Doppler velocimetry, amniotic fluid volume, and fetal heart rate as predictors of subsequent fetal distress. I. An initial report 1508
Albert P. Sarno, Jr., MD, MAJ, USA, Myoung Ock Ahn, MD, MPH, Harbinder S. Brar, MD, Jeffrey P. Phelan, MD, and Lawrence D. Platt, MD
Los Angeles, California

Amniotic fluid volume and the initial fetal heart rate tracing in early labor may be resonable predictors of subsequent fetal condition, whereas Doppler velocimetry alone was not.

Doppler assessment of the fetal and uteroplacental circulation during nifedipine therapy for preterm labor 1514
Giancarlo Mari, MD, Brian Kirshon, MD, Kenneth J. Moise, Jr., MD, Wesley Lee, MD, and David B. Cotton, MD
Houston, Texas

Nifedipine, when used for the treatment of preterm labor, did not alter the fetal or uteroplacental circulation as evaluated by the Doppler technique at 5 hours after the initiation of therapy.

Maternal and fetal blood flow velocity waveforms in patients with preterm labor: Relationship to outcome 1519
Harbinder S. Brar, MD, Arnold L. Medearis, MD, Greggory R. DeVore, MD, and Lawrence D. Platt, MD
Los Angeles, California

Abnormal pretherapy umbilical and/or uterine systolic to diastolic ratios in patients with preterm labor predict increased risk of preterm birth and poor pregnancy outcome.

Clinical management of the fetus with markedly diminished umbilical artery end-diastolic flow 1523
Michael Y. Divon, MD, Barbara A. Girz, DO, Richard Lieblich, MD, and Oded Langer, MD
Bronx, New York

Delivery of the preterm fetus with diminished end-diastolic flow may not be mandatory; the use of fetal biophysical testing, coupled with commonly used criteria for delivery, results in acceptable fetal outcome and prolongation of gestational age.

Contents

Doppler assessment of the pulsatility index of the middle cerebral artery during constriction of the fetal ductus arteriosus after indomethacin therapy 1528

Giancarlo Mari, MD, Kenneth J. Moise, Jr., MD, Russell L. Deter, MD, Brian Kirshon, MD, James C. Huhta, MD, Robert J. Carpenter, Jr., MD, and David B. Cotton, MD

Houston, Texas

A response to indomethacin therapy sufficient to cause fetal ductal constriction and tricuspid insufficiency decreased the pulsatility index of the middle cerebral artery.

Human fetal tricuspid and mitral deceleration time: Changes with normal pregnancy and intrauterine growth retardation 1532

Kathryn L. Reed, MD, Christopher P. Appleton, MD, David J. Sahn, MD, and Caroline F. Anderson, RDMS

Tucson, Arizona, and San Diego, California

Doppler echocardiography was used to show abnormal prolongation of the atrioventricular deceleration time in fetuses with intrauterine growth retardation and absent end-diastolic velocities in the umbilical artery.

Effect of placental laterality on uterine artery resistance and development of preeclampsia and intrauterine growth retardation 1536

Alexander D. Kofinas, MD, Mary Penry, RN, Melissa Swain, RN, and Christos G. Hatjis, MD

Winston-Salem, North Carolina

Placental laterality is associated with increased uterine artery resistance and almost a threefold increase in the incidence of preeclampsia and intrauterine growth retardation.

Ultrasonographic criteria for the prenatal diagnosis of placental chorionicity in twin gestations 1540

Hung N. Winn, MD, Sandro Gabrielli, MD, E. Albert Reece, MD, J. Andres Roberts, MD, Carolyn Salafia, MD, and John C. Hobbins, MD

New Haven, Connecticut

Quantitative assessment of the dividing membranes is helpful in the prenatal diagnosis of placental chorionicity by ultrasonography.

Esterase activity in second- and third-trimester amniotic fluid: An indicator of chorioamnionitis 1543

Iffath Abbasi Hoskins, MD, Joseph Katz, PhD, Steven A. Ordorica, MD, and Bruce K. Young, MD

New York, New York

An in vitro leukocyte esterase assay is a reliable alternative for the laboratory diagnosis of chorioamnionitis.

Rapid chromosome analysis with the use of spontaneously dividing cells derived from umbilical cord blood (fetal and neonatal) 1546

Robert E. Tipton, MD, Avirachan T. Tharapel, PhD, Hua-Hua T. Chang, BS, Joe Leigh Simpson, MD, and Sherman Elias, MD

Memphis, Tennessee

Rapid chromosome analysis with the use of umbilical cord blood provides high-quality metaphases that can be used to facilitate management of fetuses or neonates with malformations or intrauterine growth retardation.

(Contents continued on page 10A)

Contents continued from page 9A

Effects of fetal sex and dexamethasone on preterm maternal serum concentrations of human chorionic gonadotropin, progesterone, estrone, estradiol, and estriol 1549
Ray V. Haning, Jr., MD, Luis B. Curet, MD, W. Kenneth Poole, PhD, Lynn M. Boehnlein, BS, Donna L. Kuzma, BS, and Sandra M. Meier, BS
Providence, Rhode Island, Madison, Wisconsin, and Research Triangle Park, North Carolina

The serum human chorionic gonadotropin concentration was significantly higher in female pregnancies than in male pregnancies at an average gestational age of 32 weeks.

High glucose levels decrease proliferation of cultured human fetal cells from placenta 1553
D. Michael Nelson, MD, PhD, and Edward M. Curran, MS
St. Louis, Missouri

The proliferation of cultured human fetal cells from the placenta is decreased by elevated glucose levels in the range observed in some pregnant diabetic women.

Stimuli for fetal swallowing: Systemic factors 1559
Michael G. Ross, MD, Dan J. Sherman, MD, M. Gore Ervin, PhD, Linda Day, and James Humme
Torrance and Los Angeles, California, and Tel Aviv, Israel

Fetal electromyographic swallowing activity and volume swallowed increased significantly in response to acute plasma hyperosmolality.

Effect of whole-body pH changes on thoracic duct lymph flow in anesthetized sheep 1566
Guillermo J. Valenzuela, MD, Hugh W. Forbes, and Justo G. Alonso, MD
Loma Linda, California

Significant cardiovascular and lymph flow effects were noted after the whole-animal pH was changed by 0.15 units.

Does furosemide alter the hemodynamic response to rapid intravascular transfusion of the anemic fetal lamb? 1571
David H. Chestnut, MD, Kenneth L. Pollack, MD, Carl P. Weiner, MD, Jean E. Robillard, MD, Christine S. Thompson, and Craig S. DeBruyn
Iowa City, Iowa

Rapid intravascular transfusion of anemic fetal lambs resulted in modest increases in fetal central venous pressure and mean arterial pressure, with or without furosemide.

Intrauterine growth retardation and the circulatory responses to acute hypoxemia in fetal sheep 1576
Barry S. Block, MD, Donald H. Schlafer, DVM, PhD, Richard A. Wentworth, PhD, Lois A. Kreitzer, MS, and Peter W. Nathanielsz, MD, PhD
Chicago, Illinois, and Ithaca, New York

Despite chronic hypoxemia, fetuses with early intrauterine growth retardation have a regional blood flow distribution response to acute imposed hypoxemia similar to that of normally grown fetuses.

Contents

Prostaglandin E_2 metabolism in the human fetal membranes 1580
Paul Y. C. Cheung, BSc, and John R. G. Challis, PhD, DSc
London, Ontario, Canada

Conversion of prostaglandin E_2 to prostaglandin $F_{2\alpha}$ can occur in the human fetal membranes and decidua but does not normally contribute significantly to prostaglandin $F_{2\alpha}$ output by intrauterine tissues at labor.

Increased placental progesterone may cause decreased placental prostacyclin production in preeclampsia 1586
Scott W. Walsh, PhD, and Stephanie Coulter, BS
Houston, Texas

Addition in vitro of progesterone at a concentration equivalent to that present in the incubation medium of placentas from women with preeclampsia inhibits prostacyclin production by normal placentas to a rate characteristic of preeclampsia.

Aspirin differentially affects thromboxane and prostacyclin production by trophoblast and villous core compartments of human placental villi 1593
D. Michael Nelson, MD, PhD, and Scott W. Walsh, PhD
St. Louis, Missouri, and Houston, Texas

Aspirin can selectively inhibit thromboxane production in whole placental villi and can differentially affect thromboxane and prostacyclin production by the trophoblast and villous core compartments.

In vitro release of endothelium-derived relaxing factor by acetylcholine is increased during the guinea pig pregnancy 1599
Carl Weiner, MD, Ernest Martinez, BA, Liu Kang Zhu, MD, Abdi Ghodsi, BS, and David Chestnut, MD
Iowa City, Iowa

Pregnancy is associated with a systemic increase in endothelium-derived relaxing factor activity.

Effect of pregnancy on uterine and carotid artery response to norepinephrine, epinephrine, and phenylephrine in vessels with documented functional endothelium 1605
Carl P. Weiner, MD, Ernest Martinez, BA, David H. Chestnut, MD, and Abdi Ghodsi, BS
Iowa City, Iowa

Pregnancy is associated with a decrease in uterine artery response, efficacy, and sensitivity to catecholamines.

Evaluation of pulsed Doppler echocardiography for measurement of aortic blood flow in the fetal lamb 1610
Jean-Claude Veille, MD, Michael Tavill, BA, Mark Sivakoff, MD, Ilan Cohen, MD, Moshe Ben-Ami, MD, Yuh-Cheng Yang, MD, and Vasil Jovkovsky, MD
Cleveland, Ohio

Validation of pulsed Doppler echocardiography was done in the fetal lamb; invasive and noninvasive methods were found to be highly correlated ($r = 0.93$).

(Contents continued on page 12A)

Contents continued from page 11A

Lymph flow rate response to angiotensin II is decreased in pregnant sheep 1615
Guillermo J. Valenzuela, MD, and Lawrence D. Longo, MD
Loma Linda, California

Lymph flow response to angiotensin II was decreased in pregnant sheep; this characteristic may play a role in edema formation of pregnancy.

Atrial natriuretic factor: The effects of pregnancy and a high-salt diet on atrial levels 1620
Lony C. Castro, MD, Chander P. Arora, PhD, Jane L. Davis, MD, Calvin J. Hobel, MD, and Hassan Parvez, PhD
Los Angeles, California, and Paris, France

The concentration of atrial natriuretic factor was found to be elevated in the right and left atria of postpartum rats and in the left atria of term pregnant rats on a high-salt diet.

Is a decrease in plasma oncotic pressure enough to explain the edema of pregnancy? 1624
Guillermo J. Valenzuela, MD
Loma Linda, California

Decrease of the plasma protein produces a decrease in capillary filtration, thus maintaining a stable oncotic pressure difference across the capillary wall.

Treatment of oophorectomized guinea pigs with intrauterine 17β-estradiol pellets may modulate myometrial β-adrenergic receptor binding properties 1628
Christos G. Hatjis, MD, David M. Grogan, BA, and Donald R. Koritnik, PhD
Winston-Salem, North Carolina, and Columbus, Ohio

17β-Estradiol treatment in pharmacologic doses may result in a significant increase in the relative concentration of guinea pig myometrial β-adrenergic receptors capable of forming the "high affinity" state.

Pregnancy-induced changes in the interaction of guinea pig myometrial β-adrenergic receptors with *l*-isoproterenol 1633
Christos G. Hatjis, MD, and David M. Grogan, BA
Winston-Salem, North Carolina, and Columbus, Ohio

The ability of guinea pig myometrial β-adrenergic receptors to form a "high-affinity" state with *l*-isoproterenol is enhanced in pregnant animals at ≥0.9 of gestation.

Vasopressin receptors in human pregnant myometrium and decidua: Interactions with oxytocin and vasopressin agonists and antagonists 1637
Marina Ivanisevic, MD, Oliver Behrens, MD, Hanns Helmer, MD, Keith Demarest, PhD, and Anna-Riitta Fuchs, DSc
New York, New York, and Raritan, New Jersey

High concentrations of vasopressin receptors in decidua and myometrium with high affinity also to oxytocin and oxytocin antagonists may contribute significantly to uterine stimulation during labor.

Contents

The antagonistic effect of oxytocin and relaxin on rat uterine segment contractility 1644

Laura T. Goldsmith, PhD, Joan H. Skurnick, PhD, Andrea S. Wojtczuk, MS, Martin Linden, PhD, Mary Jeanne Kuhar, MD, and Gerson Weiss, MD

Newark, New Jersey

Relaxin and oxytocin have antagonistic effects on contractions in an in vitro system with rat uterine segments.

Decreased β-carotene tissue levels in uterine leiomyomas and cancers of reproductive and nonreproductive organs 1649

Prabhudas R. Palan, PhD, Magdy Mikhail, MD, and Seymour L. Romney, MD

Bronx, New York

Tissue β-carotene levels are significantly lower in uterine fibroids and malignant neoplasms than in adjacent normal sites.

Compensatory ovarian hypertrophy occurs by a mechanism distinct from compensatory growth in the regenerating liver 1653

Ronald D. Alvarez, MD, William E. Grizzle, MD, PhD, Lori J. Smith, and Donald M. Miller, MD, PhD

Birmingham, Alabama

A significant increase in proto-oncogene expression or deoxyribonucleic acid synthesis occurs in the contralateral ovary after hemioophorectomy in rats.

Assessment of epidermal growth factor in the healing process of clean full-thickness skin wounds 1658

Alfredo J. Jijon, MD, Donald G. Gallup, MD, M. Ali Behzadian, PhD, and William P. Metheny, PhD

Augusta, Georgia

A trend toward faster wound healing was noted with use of epidermal growth factor compared with Ringer's lactate solution in female pigs.

Immunocytochemical study of *ras* and *myc* proto-oncogene polypeptide expression in the human menstrual cycle 1663

Lawrence D. Odom, MD, J. Michael Barrett, PhD, Cooley G. Pantazis, MD, Leland D. Stoddard, MD, and Paul G. McDonough, MD

Augusta, Georgia

Evaluation of c-*ras* and c-*myc* polypeptide expression reveals no cyclic variation for c-*ras*, but the c-*myc* product is reduced in the secretory phase.

Comparison of Cytobrush and cervicovaginal lavage sampling methods for the detection of genital human papillomavirus 1669

Gary L. Goldberg, MD, Sten H. Vermund, MD, Mark H. Schiffman, MD, Diane B. Ritter, MD, Carol Spitzer, BS, MS, and Robert D. Burk, MD

Bronx, New York, and Bethesda, Maryland

Cervicovaginal lavage, together with human papillomavirus deoxyribonucleic acid hybridization, is the most sensitive noninvasive method of harvesting cells for detection of human papillomavirus.

Spontaneously resorbing ectopic pregnancy: Preservation of human chorionic gonadotropin bioactivity despite declining steroid hormone levels 1673

Mark V. Sauer, MD, Robert E. Anderson, MD, Michael Vermesh, MD, Bronte A. Stone, PhD, and Richard J. Paulson, MD

Los Angeles, California

Corpora lutea of spontaneously resorbing ectopic gestations produce very low levels of steroids despite continued serum human chorionic gonadotropin bioactivity.

Decreased in vitro production of 6-keto-prostaglandin $F_{1\alpha}$ by uterine arteries from postmenopausal women 1677

Alex Steinleitner, MD, Frank Z. Stanczyk, PhD, Jay H. Levin, MD, Gerritt d'Ablaing III, MD, Marcela A. Vijod, BS, Violette L. Shahbazian, BS, and Rogerio A. Lobo, MD

Los Angeles, California

In vitro production of prostacyclin by uterine arteries was significantly decreased in specimens obtained from postmenopausal women.

Depressive episodes in premenstrual syndrome 1682

Joseph F. Mortola, MD, Lyda Girton, PhD, and Samuel S. C. Yen, MD, DSc

La Jolla, California

Premenstrual depressive episodes are shown to be distinct from major depression with both psychometric measures and cortisol pulsatile activity used as indices.

Peri-implantation phase endometrial estrogen and progesterone receptors: Effect of ovulation induction with clomiphene citrate 1688

Bryan R. Hecht, MD, Firyal S. Khan-Dawood, PhD, and M. Yusoff Dawood, MD

Chicago, Illinois

Clomiphene citrate (50 and 150 mg) treatment did not significantly affect the concentrations and binding affinities of peri-implantation phase endometrial estrogen and progesterone receptors.

Aromatase in human fetal tissues 1694

Kevin J. Doody, MD, and Bruce R. Carr, MD

Dallas, Texas

The presence of aromatase in various human fetal tissues is shown.

Comparison of in vivo bioavailability of progestational agents into the rat uterus and liver and the effect of plasma protein binding 1698

Bradley Van Voorhis, MD, Dennis W. Matt, PhD, Maria L. Tedeschi, and Kenneth A. Steingold, MD

Richmond, Virginia

Compared with progesterone or 19-nortestosterone, medroxyprogesterone acetate exhibited greater uterine bioavailability as a result of decreased plasma protein binding.

Contents

Androgen sulfate and glucuronide conjugates in nonhirsute and hirsute women with polycystic ovarian syndrome 1704

Robert K. Matteri, MD, Frank Z. Stanczyk, PhD, Elisabet E. Gentzschein, BA, Clara Delgado, BA, and Rogerio A. Lobo, MD

Los Angeles, California

Several C_{19} conjugates that reflect peripheral androgen activity were measured; these conjugates (in particular, androsterone glucuronide) were elevated only in hirsute women.

In vivo administration of allopurinol affects ovulation and early embryonic development in rabbits 1709

Toyohiko Miyazaki, MD, PhD, Tsung-Cheng Kuo, MD, PhD, Arunasalam M. Dharmarajan, PhD, Susan J. Atlas, PhD, and Edward E. Wallach, MD

Baltimore, Maryland

Allopurinol, administered to rabbits along with an ovulation-inducing dose of human chorionic gonadotropin, significantly reduced the percent of large follicles ovulating, cumulus dispersal, and early embryonic development.

Effects of platelet activating factor on mouse oocyte fertilization in vitro 1714

Brijinder S. Minhas, PhD, Raj Kumar, PhD, Deborah D. Ricker, MS, William E. Roudebush, PhD, Melvin G. Dodson, MD, PhD, and Stephen J. Fortunato, MD

Johnson City, Tennessee, and San Antonio, Texas

In vitro fertilization of mouse oocytes is enhanced by platelet activating factor treatment of spermatozoa.

Release of tumor necrosis factor-α by human peritoneal macrophages in vivo and in vitro 1718

Jouko Halme, MD, PhD

Los Angeles, California, and Chapel Hill, North Carolina

Peritoneal macrophages released tumor necrosis factor activity in vitro and thus are a likely source of the activity in peritoneal fluid of patients with endometriosis.

Isolation and sequencing of a complementary deoxyribonucleic acid clone encoding human placental 17β-estradiol dehydrogenase: Identification of the putative cofactor binding site 1726

Michael J. Gast, MD, PhD, Harold F. Sims, BS, Gary L. Murdock, PhD, Peter M. Gast, and Arnold W. Strauss, MD

St. Louis, Missouri

We have isolated and cloned a complementary deoxyribonucleic acid encoding estradiol dehydrogenase from human placenta and delineated its primary protein structure and several important functional portions of the molecule.

Molecular scanning of Yq11 (interval 6) in men with Sertoli-cell-only syndrome 1732

Mark D. Johnson, MD, Sandra P. T. Tho, MD, Ali Behzadian, PhD, and Paul G. McDonough, MD

Augusta, Georgia

Probing Yq11 (interval 6) in six men with Sertoli-cell-only syndrome revealed absence of 50f2/C in one individual and conservation of pDP105/B in all subjects.

(Contents continued on page 16A)

Contents continued from page 15A

Steroid biosynthesis in the Sertoli-Leydig cell tumor: Effects of insulin and luteinizing hormone 1738
Manubai Nagamani, MD, Charles A. Stuart, MD, and Tung Van Dinh, MD
Galveston, Texas

A Sertoli-Leydig cell tumor of the ovary was found to have specific binding sites for insulin and the tumor tissue responded to luteinizing hormone and insulin with release of androstenedione.

Make researching easier with the Ten-Year Cumulative Index (1978-1987) to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY

The Ten-Year Cumulative Index is a complete guide to more than 30,000 pages of original articles, case reports, letters, and editorials published in the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY from 1978 through 1987 (volumes 130 to 157). Numbering more than 800 pages, the Cumulative Index includes both a subject and an author index. This hard-cover volume is $64.50 ($69.00 international). Prices include shipping. *Payment must accompany all orders and must be in U.S. funds, drawn on a U.S. bank.*

Contact The C.V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146-3318 USA; phone (314) 872-8370, ext. 394. In the U.S., call toll-free: 1-800-325-4177, ext. 394. Please allow six weeks for delivery.

The JOURNAL is abstracted and/or indexed in *Index Medicus, Science Citation Index, Current Contents/Clinical Medicine, Current Contents/Life Sciences, Excerpta Medica, BRS Colleague,* and MEDLINE.

Calcium every day
Aerobics every week
Bone loss every year

She needs PREMARIN to help prevent further bone loss

Calcium[1] and exercise are not enough to prevent post-menopausal osteoporosis, since estrogen deficiency is the primary cause.[2] PREMARIN is the only brand of estrogen indicated to prevent further bone loss and in a recently published study has been shown to reduce the risk of hip fractures by as much as 66%.[3]

Early PREMARIN therapy offers the best protection

The most significant rate of bone loss occurs in early menopause. PREMARIN can help maintain bone mass, preventing the progression of osteoporosis and its consequences.

Protection continues as long as estrogen therapy continues

Clinical studies show that within three years of menopause when therapy is withdrawn, bone loss begins again.[4]

PREMARIN®

(conjugated estrogens tablets)

Proven benefits for menopause and beyond

BRIEF SUMMARY *(FOR FULL PRESCRIBING INFORMATION AND PATIENT INFORMATION, SEE PACKAGE CIRCULARS.)*

PREMARIN® Brand of conjugated estrogens tablets, USP
PREMARIN® Brand of conjugated estrogens Vaginal Cream, in a nonliquefying base

1. ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA.
Three independent, case-controlled studies have reported an increased risk of endometrial cancer in postmenopausal women exposed to exogenous estrogens for more than one year. This risk was independent of the other known risk factors for endometrial cancer. These studies are further supported by the finding that incidence rates of endometrial cancer have increased sharply since 1969 in eight different areas of the United States with population-based cancer reporting systems, an increase which may be related to the rapidly expanding use of estrogens during the last decade. The three case-controlled studies reported that the risk of endometrial cancer in estrogen users was about 4.5 to 13.9 times greater than in nonusers. The risk appears to depend on both duration of treatment and on estrogen dose. In view of these findings, when estrogens are used for the treatment of menopausal symptoms, the lowest dose that will control symptoms should be utilized and medication should be discontinued as soon as possible. When prolonged treatment is medically indicated, the patient should be reassessed on at least a semi-annual basis to determine the need for continued therapy. Although the evidence must be considered preliminary, one study suggests that cyclic administration of low doses of estrogen may carry less risk than continuous administration; it therefore appears prudent to utilize such a regimen. Close clinical surveillance of all women taking estrogens is important. In all cases of undiagnosed persistent or recurring abnormal vaginal bleeding, adequate diagnostic measures should be undertaken to rule out malignancy. There is no evidence at present that "natural" estrogens are more or less hazardous than "synthetic" estrogens at equi-estrogenic doses.
2. ESTROGENS SHOULD NOT BE USED DURING PREGNANCY.
The use of female sex hormones, both estrogens and progestogens, during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing, in later life, a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated as not greater than 4 per 1,000 exposures. Furthermore, a high percentage of such exposed women (from 30% to 90%) have been found to have vaginal adenosis, epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether they are precursors of malignancy. Although similar data are not available with the use of other estrogens, it cannot be presumed they would not induce similar changes. Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies, including congenital heart defects and limb-reduction defects. One case-controlled study estimated a 4.7-fold increased risk of limb-reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than 1 per 1,000. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. If PREMARIN is used during pregnancy, or if the patient becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus, and the advisability of pregnancy continuation.

DESCRIPTION: PREMARIN (conjugated estrogens, USP) contains a mixture of estrogens, obtained exclusively from natural sources, blended to represent the average composition of material derived from pregnant mares' urine. It contains estrone, equilin, and 17α-dihydroequilin, together with smaller amounts of 17α-estradiol, equilenin, and 17α-dihydroequilenin as salts of their sulfate esters. Tablets are available in 0.3 mg, 0.625 mg, 0.9 mg, 1.25 mg, and 2.5 mg strengths of conjugated estrogens. Cream is available as 0.625 mg conjugated estrogens per gram.

INDICATIONS AND USAGE: PREMARIN (conjugated estrogens tablets, USP): Moderate-to-severe *vasomotor* symptoms associated with the menopause. (There is no evidence that estrogens are effective for nervous symptoms or depression without associated vasomotor symptoms and they should not be used to treat such conditions.) Osteoporosis (abnormally low bone mass). Atrophic vaginitis. Kraurosis vulvae. Female castration.

PREMARIN (conjugated estrogens) Vaginal Cream is indicated in the treatment of atrophic vaginitis and kraurosis vulvae.

PREMARIN HAS NOT BEEN SHOWN TO BE EFFECTIVE FOR ANY PURPOSE DURING PREGNANCY AND ITS USE MAY CAUSE SEVERE HARM TO THE FETUS (SEE BOXED WARNING).

CONTRAINDICATIONS: Estrogens should not be used in women (or men) with any of the following conditions: 1. Known or suspected cancer of the breast except in appropriately selected patients being treated for metastatic disease. 2. Known or suspected estrogen-dependent neoplasia. 3. Known or suspected pregnancy (see Boxed Warning). 4. Undiagnosed abnormal genital bleeding. 5. Active thrombophlebitis or thromboembolic disorders. 6. A past history of thrombophlebitis, thrombosis, or thromboembolic disorders associated with previous estrogen use (except when used in treatment of breast or prostatic malignancy).

WARNINGS: Estrogens have been reported to increase the risk of endometrial carcinoma (see Boxed Warning). However, a recent large, case-controlled study indicated no increase in risk of breast cancer in postmenopausal women. A recent study has reported a 2- to 3-fold increase in the risk of surgically confirmed gallbladder disease in women receiving postmenopausal estrogens.

Adverse effects of oral contraceptives may be expected at the larger doses of estrogen used to treat prostatic or breast cancer or postpartum breast engorgement; it has been shown that there is an increased risk of thrombosis in men receiving estrogens for prostatic cancer and women for postpartum breast engorgement. Users of oral contraceptives have an increased risk of diseases, such as thrombophlebitis, pulmonary embolism, stroke, and myocardial infarction. Cases of retinal thrombosis, mesenteric thrombosis, and optic neuritis have been reported in oral contraceptive users. An increased risk of postsurgery thromboembolic complications has also been reported in users of oral contraceptives. If feasible, estrogen should be discontinued at least 4 weeks before surgery of the type associated with an increased risk of thromboembolism, or during periods of prolonged immobilization. Estrogens should not be used in persons with active thrombophlebitis, thromboembolic disorders, or in persons with a history of such disorders in association with estrogen use. They should be used with caution in patients with cerebral vascular or coronary artery disease. Large doses (5 mg conjugated estrogens per day), comparable to those used to treat cancer of the prostate and breast, have been shown to increase the risk of nonfatal myocardial infarction, pulmonary embolism, and thrombophlebitis. When doses of this size are used, any of the thromboembolic and thrombotic adverse effects should be considered a clear risk.

Benign hepatic adenomas should be considered in estrogen users having abdominal pain and tenderness, abdominal mass, or hypovolemic shock. Hepatocellular carcinoma has been reported in women taking estrogen-containing oral contraceptives. Increased blood pressure may occur with use of estrogens in the menopause and blood pressure should be monitored with estrogen use. A worsening of glucose tolerance has been observed in patients on estrogen-containing oral contraceptives. For this reason, diabetic patients should be carefully observed. Estrogens may lead to severe hypercalcemia in patients with breast cancer and bone metastases.

PRECAUTIONS: Physical examination and a complete medical and family history should be taken prior to the initiation of any estrogen therapy with special reference to blood pressure, breasts, abdomen, and pelvic organs, and should include a Papanicolaou smear. As a general rule, estrogen should not be prescribed for longer than one year without another physical examination being performed. Conditions influenced by fluid retention, such as asthma, epilepsy, migraine, and cardiac or renal dysfunction, require careful observation. Certain patients may develop manifestations of excessive estrogenic stimulation, such as abnormal or excessive uterine bleeding, mastodynia, etc. Prolonged administration of unopposed estrogen therapy has been reported to increase the risk of endometrial hyperplasia in some patients. Oral contraceptives appear to be associated with an increased incidence of mental depression. Patients with a history of depression should be carefully observed. Pre-existing uterine leiomyomata may increase in size during estrogen use. The pathologist should be advised of estrogen therapy when relevant specimens are submitted. If jaundice develops in any patient receiving estrogen, the medication should be discontinued while the cause is investigated. Estrogens should be used with care in patients with impaired liver function, renal insufficiency, metabolic bone diseases associated with hypercalcemia, or in young patients in whom bone growth is not yet complete. If concomitant progestin therapy is used, potential risks may include adverse effects on carbohydrate and lipid metabolism.

Concomitant Progestin Use: The lowest effective dose appropriate for the specific indication should be utilized. Studies of the addition of a progestin for 7 or more days of a cycle of estrogen administration have reported a lowered incidence of endometrial hyperplasia. Morphological and biochemical studies of the endometrium suggest that 10 to 13 days of progestin are needed to provide maximal maturation of the endometrium and to eliminate any hyperplastic changes. Whether this will provide protection from endometrial carcinoma has not been clearly established. There are possible additional risks which may be associated with the inclusion of progestin in estrogen replacement regimens. The choice of progestin and dosage may be important in minimizing possible adverse effects.

The following changes may be expected with larger doses of estrogen:

a. Increased sulfobromophthalein retention.

b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability.

c. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by PBI, T_4 by column, or T_4 by radioimmunoassay. Free T_3 resin uptake is decreased, reflecting the elevated TBG; free T_4 concentration is unaltered.

d. Impaired glucose tolerance.

e. Decreased pregnanediol excretion.

f. Reduced response to metyrapone test.

g. Reduced serum folate concentration.

h. Increased serum triglyceride and phospholipid concentration.

As a general principle, the administration of any drug to nursing mothers should be done only when clearly necessary since many drugs are excreted in human milk.

Long-term, continuous administration of natural and synthetic estrogens in certain animal species increases the frequency of carcinomas of the breast, cervix, vagina, and liver. However, in a recent, large case-controlled study of postmenopausal women there was no increase in risk of breast cancer with use of conjugated estrogens.

ADVERSE REACTIONS: The following have been reported with estrogenic therapy, including oral contraceptives: breakthrough bleeding; spotting; change in menstrual flow; dysmenorrhea; premenstrual-like syndrome; amenorrhea during and after treatment; increase in size of uterine fibromyomata; vaginal candidiasis; change in cervical erosion and in degree of cervical secretion; cystitis-like syndrome; tenderness, enlargement, secretion (of breasts); nausea, vomiting, abdominal cramps, bloating; cholestatic jaundice; chloasma or melasma which may persist when drug is discontinued; erythema multiforme; erythema nodosum; hemorrhagic eruption; loss of scalp hair; hirsutism; steepening of corneal curvature; intolerance to contact lenses; headache, migraine, dizziness, mental depression, chorea; increase or decrease in weight; reduced carbohydrate tolerance; aggravation of porphyria; edema; changes in libido.

ACUTE OVERDOSAGE: May cause nausea, and withdrawal bleeding may occur in females.

DOSAGE AND ADMINISTRATION:

PREMARIN® Brand of conjugated estrogens tablets, USP

1. *Given cyclically for short-term use only.* For treatment of moderate-to-severe *vasomotor* symptoms, atrophic vaginitis, or kraurosis vulvae associated with the menopause (0.3 mg to 1.25 mg or more daily). The lowest dose that will control symptoms should be chosen and medication should be discontinued as promptly as possible. Administration should be cyclic (eg, three weeks on and one week off). Attempts to discontinue or taper medication should be made at three- to six-month intervals.

2. *Given cyclically:* Osteoporosis. Female castration. Osteoporosis —0.625 mg daily. Administration should be cyclic (eg, three weeks on and one week off). Female castration—1.25 mg daily, cyclically. Adjust upward or downward according to response of the patient. For maintenance, adjust dosage to lowest level that will provide effective control.

Patients with an intact uterus should be monitored for signs of endometrial cancer and appropriate measures taken to rule out malignancy in the event of persistent or recurring abnormal vaginal bleeding.

PREMARIN® Brand of conjugated estrogens Vaginal Cream

Given cyclically for short-term use only. For treatment of atrophic vaginitis or kraurosis vulvae.

The lowest dose that will control symptoms should be chosen and medication should be discontinued as promptly as possible.

Administration should be cyclic (eg, three weeks on and one week off).

Attempts to discontinue or taper medication should be made at three- to six-month intervals.

Usual dosage range: 2 g to 4 g daily, intravaginally, depending on the severity of the condition.

Treated patients with an intact uterus should be monitored closely for signs of endometrial cancer and appropriate diagnostic measures should be taken to rule out malignancy in the event of persistent or recurring abnormal vaginal bleeding.

INFORMATION FOR AUTHORS

Editorial policies

The requirements for manuscripts submitted to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY conform to the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" established by the International Committee of Medical Journal Editors and published in *Annals of Internal Medicine* 1988;108:258-65. Certain requirements unique to our JOURNAL are provided in Information for Authors, published in each issue of the JOURNAL, and in more detail in the *Guide to Writing for the American Journal of Obstetrics and Gynecology*. The latter may be obtained from The C.V. Mosby Company or the Editors on request.

Manuscript submission. Manuscripts should be submitted to one of the three Editors as follows:

1. **Dr. Brewer**—all manuscripts originating from the southeastern quadrant of the United States or Canada and those presented before one of the official sponsoring societies, except the Society for Gynecologic Investigation and The Society of Perinatal Obstetricians.

2. **Dr. Zuspan**—manuscripts from the northeastern quadrant of the United States and from Japan, Israel, Italy, and England, manuscripts written for Clinical Opinion and Current Development, and Letters to the Editors. Dr. Zuspan is responsible for manuscripts from The Society of Perinatal Obstetricians. Manuscripts from The Society of Perinatal Obstetricians should be submitted to Dr. Donald R. Coustan, Department of Obstetrics and Gynecology, Women and Infants Hospital of Rhode Island, 101 Dudley St., Providence, RI 02905.

3. **Dr. Quilligan**—manuscripts from the north central states (including Ohio), states west of the Mississippi River, Hawaii, Alaska, and abroad (except Japan, Israel, Italy, and England). Dr. Quilligan is responsible for manuscripts from the Society for Gynecologic Investigation. Manuscripts from the Society for Gynecologic Investigation should be submitted to Dr. Roger A. Lobo, Women's Hospital, 1240 North Mission Road, Room 1M2, Los Angeles, CA 90033.

Author's designation of reviewers. When authors submit their manuscripts, they may provide the names and addresses of three reviewers for consideration by the Editors.

Copyright statement. The specified copyright statement that follows the Information for Authors in each issue of the JOURNAL must be completed, signed by all authors, and submitted with the manuscript. (The Checklist and Copyright Statement may be torn from the JOURNAL or photocopied for submission.) If not completed in full, it will be returned to the author for completion.

Checklist. The checklist that appears with the copyright statement in each issue of the JOURNAL must be fully completed by the author(s) and sent with each submitted manuscript. A more complete description of each item that must be checked is provided under the appropriate heading in the Information for Authors, which is published in each issue of the JOURNAL. If the checklist is not completed in full, the deficiencies will be noted, and the form, as well as the manuscript when necessary, will be returned to the author for completion.

Previous publication. If a report by the same author(s) has been previously published in any medium that deals in any respect whatever with the same patients, same animals, same laboratory experiments, or same data, in part or in full, as those reported in the manuscript being submitted, two reprints of the article or two copies of the manuscript, be it a full-length report or an abstract, must be submitted with the manuscript. The author(s) should inform the Editor of the circumstances of the two reports. This requirement also applies to the submission of a manuscript in which a few different patients, animals, laboratory experiments, or data were added to those reported in a previous publication or in a submitted or

accepted manuscript. Articles previously published in another language will not be considered.

Human and animal experimentation. It is assumed by the Editors that manuscripts emanating from a particular institution are submitted with the approval of the requisite authority. Human experimentation that requires local institutional approval must have this approval *before the experiment is started* and approval must be so indicated in the Methods section of the submitted manuscript. Reports of experiments on animals must *state in the Methods section of the manuscript* that the guidelines for the care and use of the animals *approved by the local institution* were followed.

Authorship. For manuscripts with two or more authors, each author must qualify by having participated actively and sufficiently in the study that is being performed and reported. The inclusion of each author in the authorship list of a report is based only (1) on substantial contributions to (a) concept and design, or analysis and interpretation of data and (b) drafting the manuscript or revising it critically for important intellectual content; and (2) on final approval by each author of the version of the manuscript. Conditions 1 (a and b) and 2 must both be met. Others contributing to the work should be recognized separately in an Acknowledgment. In the covering letter that accompanies the submitted manuscript, it must be confirmed that all authors fulfilled both conditions.

Conflict of interest. Authors are expected to inform the Editor, in a letter accompanying the submitted manuscript, of any commercial association that might pose a conflict of interest, such as ownership, stock holdings, equity interests and consultant activities, or patent-licensing situations. Such information is confidential, is not given to the consultants, and does not play a part in the decision of the quality or timeliness of the manuscript. If the manuscript is accepted, the author and the Editor will determine how best to release the information. The usual and customary listing of sources of support and institutional affiliations on the title page is proper and does not imply a conflict of interest; only where there is a possible conflict of interest is the author(s) expected to inform the Editor.

Disclaimer. Statements and opinions expressed in articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or publisher, and the Editor(s) and publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the publisher guarantees, warrants, or endorses any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

General requirements for preparation of manuscripts

The original and two good-quality photocopies of the manuscript and three sets of glossy prints of illustrations are required.

Manuscripts must be typed double-spaced on one side only of 22 × 28 cm (8½ × 11 inch) white bond paper with 1-inch margins at top, bottom, and sides. Number pages consecutively in the upper right-hand corner in the following order: title page, condensation, abstract, body of text, acknowledgments, references, legends, and tables.

Title page. The title page (page 1) should contain in sequence the title (concise and suitable for indexing purposes); author line with first name, middle initial, and last name of each author and each author's highest academic degree (both MD and PhD are acceptable); city(ies), state(s) in which the study was conducted; divisional, or departmental, and institutional affiliations at the time the study was performed; source(s) of financial support; presented line, if applicable; disclaimers, if any; name, address, and business and home telephone numbers of author to whom requests for reprints should be addressed (if reprints will not be available, it should be so stated); and name, address, and business and home telephone numbers of author responsible for correspondence concerning the manuscript if different from author to whom reprint requests are addressed. At the bottom of the title page supply a short title for the running head not exceeding 52 characters (including word spaces).

Condensation. On page 2 of the manuscript provide a brief, concise condensation, typed double-spaced, that will appear with the title in publication of the Contents pages of the JOURNAL. It should be a single sentence, limited to a maximum of 25 words, delineating the essential point(s) made in the manuscript.

Abstract page and key words/phrases. On manuscript page 3 type the abstract, double-spaced, with the required margins and headed by the title of the article and name(s) of author(s). Abstracts for regular articles, Current Investigation, Clinical Opinion, and Current Development may not exceed 150 words. Abstracts for case reports and brief communications may not exceed 50 words. Below the abstract list 3 to 5 *key words* or short phrases for indexing purposes.

Text. Do not hesitate to write your manuscript in the first-person, active voice if it is more appropriate to the information you wish to convey. The passive voice is generally more effective for describing techniques or observations, since the emphasis is on the "action" rather than on the person performing the action.

Only standard abbreviations are to be used. Consult the *Council of Biology Editors Style Manual* or the AMA's *Manual for Authors and Editors*. Abbreviations in the title are not acceptable. They should be avoided, if possible, in the abstract. In the text they should be kept to a practical minimum. The full term for which an abbreviation stands should precede its first use in the text unless it is a standard unit of measurement.

Either the generic, chemical, or proprietary names of drugs may be used. If the generic or chemical name is used, authors may, if they desire, insert the proprietary name in parentheses after the first mention in the text, with the name of the manufacturer and city and state.

Regular articles are customarily organized into the following sections: an introduction and headings that identify Material and Methods, Results, and Comment. Authors may wish to summarize their findings in a short paragraph at the end of the Comment section. This format may not be appropriate for some types of articles.

In the introduction, state concisely the purpose and rationale for the study and cite only the most pertinent references as background.

In the *Material and Methods* section describe briefly (but in sufficient detail to permit other workers to evaluate and reproduce the results) the plan, patients and/or experimental animals and controls, methods and procedures utilized, and statistical method(s) employed.

In the *Results* section present the detailed findings. Include mentions of all tables and/or figures. Avoid

Estimating length of manuscripts

The length of text material (introduction through Comment section) in regular manuscripts accepted for publication normally ranges from 750 to 4200 words (an average of 2000 words). A 4200-word text can seldom be accepted, especially if tables and figures are included. The average manuscript of 2000 words of text with abstract, 3 tables with captions, 2 figures with legends, and references makes a 5.7-page article in the JOURNAL. The 2000 words of text alone make approximately 8 pages of manuscript typed double-spaced with the required 1-inch margins (approximately 250 words per page). A table or figure that occupies both columns of half a JOURNAL page is equivalent to approximately 500 words in manuscript. Thus, if a greater number of illustrations and tables are used, the length of the text should be adjusted accordingly.

duplication of text and supporting material. Emphasize only your important observations; do not compare your observations with those of others. Such comparisons and comments are reserved for the Comment section.

In the *Comment* section state the importance and significance of your findings but do not repeat the details given in the Results section. Limit your opinions to those strictly indicated by the facts in your report. Compare your findings with those of others. No new data should be presented in this section.

Acknowledgments. Acknowledge only persons who have made substantive contributions to the study.

References. A reasonable number are allowed, except in case reports and brief communications (limited to 2) and in manuscripts for the Current Development section (for which there is no limit). Number references consecutively in the order in which they are mentioned in the text. Use the format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" (Vancouver style) (Ann Intern Med 1988;108:258-65). Journal titles should conform to abbreviations used in *Cumulated Index Medicus.*

Examples (if six or fewer authors, list all; if seven or more authors, list three then et al.):

JOURNAL: Flamm BL, Fischermann E, Quilligan EJ, et al. Vaginal delivery following cesarean section—use of oxytocin augmentation and epidural anesthesia. AM J OBSTET GYNECOL 1984;148:759-63.

BOOKS: James VHT, Folkerd EJ, Bonney RC, Beranek PA, Reed MJ. Factors influencing estrogen production and metabolism in postmenopausal women with endocrine cancer. In: van Herendael HB, Riphagen FE, Goessens L, van der Pas H, eds. The climacteric, an update. Lancaster, England: MTP Press, 1983:29.

Personal communications and unpublished data, if essential, may be used but not as numbered references. If they are used, they are to be referred to, within parentheses, at the appropriate location in the text. If used, the author(s) must obtain written and signed permission for their use from the individual being quoted. This signed permission must accompany the manuscript when it is submitted to the Editor. Abstracts are not acceptable as numbered references.

Illustrations and tables. Illustrations and tables should supplement, not duplicate, the text; presentation of data in either one or the other will suffice.

A reasonable number of halftone and line illustrations will be reproduced without charge, but special arrangements must be made with the Editors for *color illustrations* at a cost of $525 per page (one side).

For *color photographs* submit original transparencies and two sets of unmounted prints on glossy (smooth-surface) paper. Polaroid prints are not acceptable. Color transparencies must have a color balance (consistency in lighting and film speed) that is acceptable to the author and Editors before acceptance for publication. Please note that 35 mm transparencies are enlarged to twice their original size. If it is important to deviate from this standard, please so indicate when the material is submitted. The *top, first author's last name,* and *figure number* must be indicated on the front of each transparency and the back of each print. Consistency in size of illustrations within the article is strongly preferred.

For *black-and-white illustrations* submit three sets of 3×4 inch (minimum) to 5×7 inch (maximum) unmounted, glossy photographic prints. All lettering must be done with commercially available paste-on letters (or numbers) or by a professional; typed or freehand lettering is not acceptable. All lettering must be in proportion to the drawing, graph, or photograph. Original drawings, appropriately done in black India ink, roentgenograms, and other material must be submitted as glossy photographic prints with good black-and-white contrast. Consistency in size within the article is strongly preferred. Any special instructions regarding sizing should be clearly noted.

Do not use paper clips or mar the surface of prints in any way.

Figures must be cited consecutively in the text in Arabic numerals and identified thusly on the back of the print (gummed label with): author(s) name(s), title of article, number, and top marked clearly.

Figures will be returned only on request by the author.

Tables should be typed on separate sheets of paper, one table to a page, and included at the end of the text. They should be numbered in Roman numerals. Each table must be cited in sequence at an appropriate point in the text. Captions should be brief yet indicate clearly the purpose or content of each table, and each column should be precisely defined by headings. Abbreviations and special designations should be explained in a footnote to the table. *If a table or any part thereof has been taken from copyrighted material, a legend to the table must give full credit to the original source.* Special arrangements must be made with the Editors for elaborate tables because of space limitations.

Legends to illustrations. Legends for all figures must be typed double-spaced on paper separate from the text of the

manuscript, and these pages must be numbered in sequence after the references. Titles should be included in the legend; *not* on the print. Original magnifications should be provided. *If an illustration has been taken from copyrighted material, the legend must give full credit to the original source.*

Computer-generated illustrations. *Black-and-white illustrations* submitted must be legible and clearly printed in jet-black ink on heavy coated paper with either a glossy or dull finish. Any patterns or shadings must be dark enough for reproduction and must be distinguishable from each other. Lines, symbols, and letters should be both smooth and complete. The legend for the illustration should not appear on the print. On the back of each print the name of the first author and the figure number should be given and the top indicated. Original individual laser or plotter prints are to be submitted *unmounted* with the manuscript. Laser prints should be full size at 300 dots per inch (DPI) or greater full-page resolution; multiple illustrations on a page cannot be accepted. Dot matrix prints and photographic halftones are not acceptable. *Color illustrations* are acceptable, but special arrangements must be made with the Editors. The colors used must be dark enough and of sufficient contrast for reproduction. With the exception of fluorescent colors, all colors can be reproduced in four-color illustrations. The preparation and submitting of color prints should follow the preceding guidelines for black-and-white computer-generated illustrations.

Permissions. Direct quotations, tables, or illustrations that have appeared in copyrighted material must be accompanied by *written permission* for their use from the copyright owner and original author along with complete information as to source. Photographs of identifiable persons must be accompanied by signed releases or else all recognizable features masked.

Requirements for special sections

Case reports and brief clinical and basic science communications. Limit of 700 words, 2 references. Include abstract of 50 words maximum, 3 to 5 key words/phrases for indexing purposes, and short title. If tables and/or figures are used, an equivalent number of words must be deducted from the total (see "Estimating Length of Manuscript").

Current Investigation. Same requirements as for regular article.

Clinical Opinion. Limit of 3000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Current Development. Limit of 6000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Correspondence. Two types of correspondence will be considered for publication. (1) A Letter to the Editors commenting on an article that has appeared in the JOURNAL should be brief and directly related to the published article. The editorial staff reserves the right to shorten letters if necessary and to make minor editorial alterations without reference to the writer. Letters may be published together with a reply from the original author. If the original author does not respond, a notation indicating "Response declined" will be published. As space for letters is limited, only a selection of letters submitted may be published. (2) A brief case presentation or a short report of a pertinent observation in the form of a Letter to the Editors will be considered for publication. All letters should be typed double-spaced. The original and a good photocopy must be submitted. Letters should be sent to Dr. Zuspan.

Announcements. Announcements of major meetings and other significant activities must be received at least 8 weeks before the desired month of publication. All announcements carry a charge of $60 U.S., and the fee must accompany the request to publish. Information will be limited to title of meeting, date, place, and an address to obtain further information. Send announcements and payment, payable to this JOURNAL, to Kay G. Goehler, Senior Manuscript Editor, Journal Editing, The C.V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318.

Books. Books received will be listed in the JOURNAL. They should be sent to Dr. Gerbie. No books will be returned.

Reprints

Reprints of articles must be obtained from the author. The corresponding author will receive a price schedule and order form at the time of publication. Reprints in quantities must be ordered from the publisher with the author's consent.

Business communications

Communications of a business nature and all advertising communications should be addressed to: Journal Publisher, The C.V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, or call Journal Advertising Production Manager (314) 872-8370.

CHECKLIST AND COPYRIGHT STATEMENT

Both the checklist and the copyright statement forms **must be completed** and sent with each submitted manuscript. If **not** completed, these forms will be returned to the author for completion.

These items appear in each monthly issue of the JOURNAL. A photocopy may be used. An exposition of the requirements given in the checklist is in the Information for Authors, which is published in each issue of the JOURNAL.

CHECKLIST

General

—The original and two copies of the manuscript are submitted.
—The appropriate signed completed checklist and assignment of copyright signed by **all** authors accompany the manuscript.
—Three sets of unmounted glossy photographic prints are submitted, properly numbered and labeled on the back of each print.
—Three sets of computer-generated figures printed on heavy coated paper with either a glossy or dull finish, unmounted, each one on a page, and properly labeled on the back are submitted. None are dot matrix or photographic prints.
—Human experimentation has been approved by the local institution as stated in the Methods section.
—Guidelines for the care and use of animals approved by the institution have been followed as indicated in the Methods section.
—The covering letter with essential information is with the manuscript.
—All elements of the manuscript are typed double-spaced on bond paper with 1-inch margins at top, bottom, and sides.
—All pages are numbered in the following order: title page, condensation, abstract, body of the text, acknowledgments only of persons who have made substantive contributions to the study, references, legends, and tables.
—Signed, written permission from both the copyright holder and the original author for the use of tables, figures, or quotations previously published and their complete references are enclosed with the manuscript.
—Signed, written permission for the use of quotations of personal communications and unpublished data has been obtained from the person(s) being quoted and is enclosed.

Authorship

—In the covering letter that accompanies the submitted manuscript I/we have confirmed that all authors fulfilled both conditions required for authorship.

Conflict of interest

—In the covering letter that accompanies the submitted manuscript the commercial association of the author or of any co-authors that might pose a conflict of interest is described.

Previous publications

—Enclosed with the submitted manuscript are two reprints each of articles the author or co-authors have previously published or have in manuscript form dealing with same patients, same animals, same laboratory experiment, or same data, in part or in full, as those reported in the submitted manuscript. Further explanation is provided in the covering letter that accompanies the submitted manuscript.

Title page

—These elements are given in the following sequence, and are typed double-spaced.
—Title
—Author(s) name(s) and highest academic degree(s)
—City(ies), state(s), and country other than U.S. in which the study was conducted are given
—The name(s) of the institution(s) section(s), division(s), department(s) in which the study was performed is provided and the author(s) institutional affiliation at the time of the study is indicated
—Acknowledgment of financial support is cited
—Name, address, and business and home telephone numbers of author to whom requests for reprints are to be sent
—Reprints will not be available. This has been stated on the title page
—Since the corresponding author is different from the author to whom reprint requests are to be sent, his/her name, address, and business and home telephone numbers have been added
—At the bottom of the page, a running head not exceeding 52 characters (including word spaces) has been typed

Condensation

—On a separate sheet of paper, page 2 of the manuscript, a single sentence limited to 25 words delineating the essential point(s) is typed double-spaced.

Abstract

—The abstract is typed double-spaced with required margins (on page 3) headed by the title and the author(s) name, not exceeding 150 words. For case reports and brief communications the limit of 50 words is not exceeded.
—Three to five key words or short phrases are placed beneath the abstract on page 3.

Tables

—Each table headed by a caption and numbered in Roman numerals is typed double-spaced on a separate page.
—Tables are cited in sequence in the text.

Figures

—Are numbered in Arabic numerals and are cited in numerical sequence in the text.

—Original transparencies of **color photographs** appropriately numbered and identified are submitted along with two sets of unmounted prints on glossy paper, numbered and identified on the back.

References

—Are typed double-spaced.

—Are numbered consecutively in the order they are cited in the text.

—The format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" is used. Examples shown in Information for Authors were followed.

—Abstracts, personal communications, and unpublished work are not used as numbered references but are mentioned in the text with the written approval of the person being quoted and the signed approval is enclosed.

AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY

COPYRIGHT STATEMENT

Must be signed by ALL authors

"The undersigned author(s) transfers all copyright ownership of the manuscript entitled

to The C.V. Mosby Company in the event the work is published. The undersigned author(s) warrants that the article is original; is not under consideration by another publication; and its essential substance, tables, or figures have not been previously published. This restriction does not apply to abstracts or press reports published in connection with scientific meetings. The author(s) confirms the final manuscript has been read and each author's contribution has been approved by the appropriate author."

CONSULTANTS

Consultants for the American Journal of Obstetrics and Gynecology

September 1, 1988—August 31, 1989

The Editors and The C.V. Mosby Company take this opportunity to acknowledge those reviewers who have contributed many hours and much effort in the evalution of manuscripts submitted to the JOURNAL during the past year. Without their interest and help, publication of the JOURNAL would be very difficult indeed. We also continue to seek advice from reviewers and readers alike as regards their overall evaluation of the JOURNAL.

Central hemodynamic assessment of normal term pregnancy

Steven L. Clark, MD, David B. Cotton, MD, Wesley Lee, MD, Clark Bishop, MD, Tracy Hill, MD, James Southwick, MD, James Pivarnik, PhD, Thomas Spillman, PhD, Greggory R. DeVore, MD, Jeffrey Phelan, MD, Gary D. V. Hankins, MD, Thomas J. Benedetti, MD, and Dennis Tolley, PhD

Provo, Utah, Houston and San Antonio, Texas, Los Angeles, California, and Seattle, Washington

Ten carefully screened primiparous patients between 36 and 38 weeks' gestation underwent pulmonary artery catheterization, arterial line placement, and central hemodynamic assessment in the left lateral recumbent position. Studies were repeated in the same patients between 11 and 13 weeks post partum. Compared with the nonpregnant state, there was a significant fall in systemic vascular resistance, pulmonary vascular resistance, colloid oncotic pressure, and colloid oncotic pressure–pulmonary capillary wedge pressure gradient by the late phase of the third trimester ($p < 0.05$). Pregnancy was associated with a significant rise in cardiac output and pulse in all patients ($p < 0.05$). There was no significant change in pulmonary capillary wedge pressure, central venous pressure, left ventricular stroke work index, or mean arterial pressure. Normally the late phase of the third trimester is not associated with hyperdynamic left ventricular function as assessed by the left ventricular stroke work index/pulmonary capillary wedge pressure ratio. (AM J OBSTET GYNECOL 1989;161:1439-42.)

Key words: Pregnancy, pulmonary artery catheter, critical care

During the past decade there has been a rising interest in the hemodynamic assessment of critically ill pregnant patients.[1-11] Whereas much has been documented with regard to the central hemodynamic profile of patients with severe preeclampsia, cardiac disease, and septic shock, interpretation of this information has been hampered by a lack of data that describe the central hemodynamic profile of the "normal" pregnant patient. Early work by both Bader and Ueland[12-14] involved the study of nonuniform patient populations with the use of investigational techniques rarely used in clinical practice today. Thus direct comparisons between their normal populations and recent investigations of critically ill pregnant patients may not be completely valid. This study was designed to define the central hemodynamic profile of a uniform population of normal third-trimester pregnant patients with contemporary clinical methods of hemodynamic assessment.

Material and methods

Ten volunteers were studied. Each met criteria detailed in Table I.

Written informed consent was obtained. The study was approved by the hospital Institutional Review Board and an outside reviewer (pulmonologist/intensivist). Patients were reimbursed $200.00 for participation in each phase (pregnant and nonpregnant) of the study. Four patients who volunteered were excluded before initiation of the study because of borderline anemia, fetal intrauterine growth retardation, or the development of elevated blood pressure before the study. Patients were initially recruited from physicians' offices in Provo, Utah. The study was performed at the Utah Valley Regional Medical Center in Provo.

Each patient underwent pulmonary artery catheterization via the subclavian route and radial arterial line placement. Venous access was established by means of a peripheral heparin lock venous catheter. Baseline hemodynamic assessment was made with patients in the left lateral recumbent position after a 30-minute stabilization period. Cardiac output was measured with

standard thermodilution technique with saline solution at 0° C (Cardiac output computer, American Edwards 18055 A, Santa Ana, Calif.). Reported cardiac outputs represent the mean of three of five independent measurements with high and low values discarded. Central pressures were measured and recorded with a 10-channel physiologic monitor-recorder (Hewlett Packard 7785 B, Waltham, Mass.). Central pressures represent the mean of three consecutive respiratory cycles as measured from the tracing. Monitors were re-zeroed in each position with transducer placement at the level of the left atrium confirmed by simultaneous real-time maternal echocardiography. Studies were repeated in each patient between 11 and 13 weeks post partum.

Statistical analysis was performed with a paired two-tailed Student *t* test.

Results

Table II presents the mean hemodynamic profiles for patients between 36 and 38 weeks' gestation and at 11 to 13 weeks post partum. We found the late phase of the third trimester to be associated with a 43% increase in cardiac output (4.3 ± 0.9 L/min to 6.2 ± 1.0 L/min), a 17% increase in pulse (71 ± 10.0 beats/min to 83 ± 10.0 beats/min), a 21% decline in systemic vascular resistance (1530 ± 520 dyne · cm · sec^{-5} to 1210 ± 266 dyne · cm · sec^{-5}), a 34% decline in pulmonary vascular resistance (119 ± 47 dyne · cm · sec^{-5} to 78 ± 22 dyne · cm · sec^{-5}), a 14% decline in colloid oncotic pressure (20.8 ± 1.0 mm Hg to 18.0 ± 1.5 mm Hg), and a 28% decline in colloid oncotic pressure–pulmonary capillary wedge pressure gradient (14.5 ± 2.5 mm Hg to 10.5 ± 2.7 mm Hg) ($p < 0.05$) (Fig. 1). There was no significant change between nonpregnant and third-trimester values with respect to mean arterial pressure, central venous pressure, pulmonary capillary wedge pressure, or left ventricular stroke work index.

Table I. Study inclusion criteria

1. Primiparous
2. Maternal age < 26 years
3. Singleton vertex fetus
4. Gestational age between 36 and 38 weeks confirmed by ultrasonography
5. No fetal intrauterine growth retardation or anomalies
6. Normal amniotic fluid volume
7. Normal maternal weight for height
8. Normal maternal hematocrit
9. No maternal alcohol, tobacco, or drug use
10. No maternal hypertension, medical illness, or medications

Table II. Central hemodynamic changes

	Nonpregnant	*Pregnant*
Cardiac output (L/min)	4.3 ± 0.9	6.2 ± 1.0
Heart rate (beats/min)	71 ± 10.0	83 ± 10.0
Systemic vascular resistance (dyne · cm · sec^{-5})	1530 ± 520	1210 ± 266
Pulmonary vascular resistance (dyne · cm · sec^{-5})	119 ± 47.0	78 ± 22
Colloid oncotic pressure (mm Hg)	20.8 ± 1.0	18.0 ± 1.5
Colloid oncotic pressure–pulmonary capillary wedge pressure (mm Hg)	14.5 ± 2.5	10.5 ± 2.7
Mean arterial pressure (mm Hg)	86.4 ± 7.5	90.3 ± 5.8
Pulmonary capillary wedge pressure (mm Hg)	6.3 ± 2.1	7.5 ± 1.8
Central venous pressure (mm Hg)	3.7 ± 2.6	3.6 ± 2.5
Left ventricular stroke work index (g · m · m^{-2})	41 ± 8	48 ± 6

Comment

More than 30 years ago Bader et al.[12] first described the hemodynamic profile of pregnant patients. Their study design differed from ours in several respects. First, there was no control for age, parity, smoking, maternal hematocrit, or obesity. Fetal age and appropriate growth were not documented. Further, 4 of 11 patients studied in the late third trimester had a mean arterial pressure ≥105 mm Hg. Cardiac output was assessed with the Fick principle. In subsequent studies by Ueland et al.[13, 14] central hemodynamic assessment was limited to measurement of central venous pressure, and cardiac output was assessed with a dye-dilution technique rarely used in clinical practice today. Thus, in these studies, patient populations were not strictly controlled and hemodynamic assessment was performed with older techniques not suitable for direct comparison with critically ill obstetric patients managed with pulmonary artery catheterization and thermodilution cardiac output assessment.

In the past decade numerous reports have appeared in the medical literature that document the central hemodynamic profiles of pregnant patients with a variety of pathologic conditions including pregnancy-induced hypertension, structural cardiac disease, amniotic fluid embolism, and septic shock.[1-11] Proper interpretation of such data is predicated upon knowledge of normal values. In the absence of such data, investigators heretofore have been forced to make assumptions with regard to what is normal on the basis of either the earlier studies with their methodologic limitations or data collected in nonpregnant subjects. We sought to correct this deficiency by designing a study that involved carefully screened normal pregnant patients and current clinical techniques with each patient serving as her own control during the postpartum period.

We documented a mean rise in cardiac output of 43% by the late phase of the third trimester in the lateral recumbent position ($p < 0.05$), as a result of significant changes in pulse (17%) and stroke volume (27%), the latter secondary to a previously documented increase in intravascular volume during pregnancy.[18] Both figures are in general agreement with measurements obtained by other techniques.[12, 13] We observed a significant fall in systemic vascular resistance (21%) and a more dramatic decrease in pulmonary vascular resistance (34%) ($p < 0.05$). Changes in pulmonary vascular resistance in pregnancy have not previously been described. Such alterations are not surprising and demonstrate increased vascular reactivity in the pulmonary circulation. In contrast, we documented no significant difference in intrinsic left ventricular contractility as assessed by left ventricular stroke work index. Such contractility when corrected for potential differences in Starling forces is assessed by the ratio left ventricular stroke work index/pulmonary capillary wedge pressure (Fig. 2). Thus normal pregnancy is not associated with hyperdynamic left ventricular function. These results confirm earlier observations obtained with noninvasive techniques.[16]

In general, a higher stroke volume (ventricular end-diastolic volume) should be reflected in a higher end-diastolic pressure; this assumption is implicit in the clinical use of the pulmonary capillary wedge pressure as an approximation to left ventricular end-diastolic volume. However, no increase in pulmonary capillary wedge pressure was found during pregnancy, as compared with the nonpregnant state. The explanation for this apparent paradox is ventricular dilatation, which accounts for the well-known increase in cardiac silhouette seen on x-ray film of the chest during pregnancy. The failure of pulmonary capillary wedge pressure or central venous pressure to increase in pregnant patients in the face of marked increases in intravascular volume also reflects the decreases in systemic vascular resistance and pulmonary vascular resistance, which allow both systemic and pulmonary vasculature to accommodate higher volumes at normal vascular pressures.

A pregnancy-associated fall in colloid oncotic pressure has previously been documented, and was con-

firmed by this study. Our documentation of a significant fall in the colloid oncotic pressure–pulmonary capillary wedge pressure gradient implies a greater propensity to pulmonary edema during pregnancy in the presence of any alteration in pulmonary capillary permeability or increase in cardiac preload.

The establishment for the first time of central hemodynamic parameters in the normal term primigravid patient has important research and clinical implications. It is anticipated that such information may facilitate the management of critically ill pregnant patients.

The central hemodynamics of severe preeclampsia

William C. Mabie, MD, Thomas E. Ratts, MD, and Baha M. Sibai, MD
Memphis, Tennessee

Swan-Ganz hemodynamic monitoring in 49 antepartum patients with severe preeclampsia revealed a variable hemodynamic profile. The majority of patients had normal left ventricular filling pressure (8.4 ± 0.2 mm Hg), normal to high cardiac index (4.4 ± 0.1 L · min^{-1} · m^2), and upper normal to moderately elevated systemic vascular resistance (1226 ± 37 dynes · sec · cm^{-5}). Eight patients had pulmonary edema and their findings included high wedge pressure (18 ± 1 mm Hg), upper normal to high cardiac index (4.9 ± 0.5 L · min^{-1} · m^2), and normal systemic vascular resistance (964 ± 50 dynes · sec · cm^{-5}). Left ventricular function was hyperdynamic in 73% of the 49 patients. Patients with chronic hypertension and superimposed preeclampsia were hemodynamically indistinguishable from patients with preeclampsia alone. We conclude that, in general, preeclampsia is a high cardiac output state associated with an inappropriately high peripheral resistance. The normal wedge and central venous pressures suggest central redistribution of intravascular volume if the generally accepted reports of decreased plasma volume in preeclampsia are correct. (Am J Obstet Gynecol 1989;161:1443-8.)

Key words: Preeclampsia, Swan-Ganz catheter, hemodynamic monitoring

The cardiovascular hemodynamics of preeclampsia have been reported to range from a low-output, high-resistance state to a high-output, low-resistance state. Hankins et al.[1] reviewed the six published studies and classified them according to therapy before insertion of the Swan-Ganz catheter. In the group without therapy there was disagreement. Cotton et al.[2] reported a high pulmonary capillary wedge pressure, high cardiac output, and minimally elevated systemic vascular resistance, whereas Groenendijk et al.[3] found a low pulmonary capillary wedge pressure, low cardiac output, and high systemic vascular resistance. In the group with fluid restrictions Benedetti et al.[4] found a normal pulmonary capillary wedge pressure, elevated cardiac output, and elevated systemic vascular resistance, whereas Hankins et al.[1] reported slightly different findings—a low pulmonary capillary wedge pressure, normal cardiac output, and elevated systemic vascular resistance. In the two studies in which there was liberal fluid administration, pulmonary capillary wedge pressure was normal to high, cardiac output was high, and systemic vascular resistance was normal to low in some patients.[5, 6]

Proposed explanations for the differences in the various hemodynamic studies have included: (1) small number of patients in each series (usually ≤10), (2) variable severity and duration of preeclampsia, (3) underlying medical problems such as cardiac or renal disease, and (4) therapeutic interventions before invasive monitoring. In addition, the dynamic fluctuation of the cardiovascular system makes it difficult to control for all the variables that can affect hemodynamics (e.g., gestational age, labor, pain, anxiety, hydralazine, intravenous fluids, analgesics, and anesthesia).

As a practical point, patients are often transferred to a tertiary care center several hours after initial therapy has been started. In addition, the clinical diagnosis of preeclampsia is often suspect, particularly in patients remote from term when underlying renal disease is likely.[7] In light of the heterogeneous circumstances under which these patients arrive at a referral center, we have assessed the hemodynamic profile of 49 patients first seen with severe preeclampsia. The purpose of our study was to determine whether there is a typical hemodynamic profile of patients with severe preeclampsia that requires delivery and to determine the frequency with which patients lie at the extremes of the hemodynamic spectrum.

Patients and methods

The study group consisted of 49 patients with severe preeclampsia who were managed at the E. H. Crump Women's Hospital between January 1, 1986, and March 1, 1988. The study was approved by the Institutional Review Board of the University of Tennessee, Memphis. A total of 38 patients had a clinical diagnosis of preeclampsia and 11 had a clinical diagnosis of chronic hypertension with superimposed preeclampsia. Criteria for entry to the study were (1) singleton pregnancy; (2) severe preeclampsia as evidenced by all three of the

following: nondependent edema, diastolic blood pressure >110 mm Hg on two occasions 30 minutes apart, and 3+ to 4+ proteinuria by urine dipstick; and (3) a clinical decision to deliver.

All patients received intravenous magnesium sulfate given as a 6 gm loading dose over 20 minutes followed by a constant infusion of 2 to 3 gm per hour. Intravenous fluid consisted of 5% dextrose in lactated Ringer's solution adjusted to give a total fluid administration rate of 75 to 100 ml per hour. A total of 22 patients (45%) were in early labor, defined as cervical dilatation <4 cm, and 16 (33%) had received hydralazine within the preceding 7 hours (mean, 4.5 hours) before Swan-Ganz catheter insertion.

After written informed consent was obtained, a 20 gauge catheter (Arrow Corp.) was inserted into a radial artery for continuous blood pressure monitoring. After the administration of 25 to 50 mg of meperidine intravenously and 2 to 3 ml of 1% lidocaine locally, an 8.5F introducer (Arrow Corp.) was inserted into the right internal jugular vein. A 7.5F Swan-Ganz catheter (American Edwards Laboratories) was then positioned in the pulmonary artery and its location was documented by pressure waveform and roentgenogram of the chest. Pressures were measured with disposable transducers (Gould Corp.) with zero reference at the midchest level. Patients were positioned supine with a wedge under the right hip to prevent aortocaval compression. Electrocardiogram, blood pressure, and pulmonary artery pressure were continuously monitored with a multichannel scope (Hewlett-Packard model 78532B). Measurements of pulmonary artery and wedge pressures were obtained at end expiration from a strip chart recorder (Hewlett-Packard model 78572B). Cardiac output was measured by a thermodilution cardiac output computer (Hewlett-Packard model 78552A) with five (10 ml) injections of iced saline solution. The high and low values were discarded and the mean of the three remaining values was recorded. Hemodynamic measurements were made at least 30 minutes after insertion of the catheter to allow the patient to reach a steady state. The Swan-Ganz catheter was removed within 24 hours of insertion to decrease the risk of complications. The measured hemodynamic variables were heart rate, blood pressure, pulmonary artery pressure, pulmonary capillary wedge pressure, central venous pressure, and cardiac output. Computer-derived variables included cardiac index,

stroke volume and index, systemic vascular resistance and index, pulmonary vascular resistance and index, and left and right ventricular stroke work and indices. Values are reported as mean ± SE unless otherwise stated. Data were analyzed by the Student unpaired t test with significance levels taken at $p < 0.05$.

Results

The mean maternal age was 23.6 ± 1 years (range, 15 to 38). The mean gravidity was 2.2 ± 0.3 (range, 1 to 10) and the mean parity was 0.8 ± 0.2 (range, 0 to 6). The mean gestational age was 32.4 ± 0.5 weeks (range, 27 to 40). The mean birth weight was 1700 ± 112 gm; 10 babies (20%) weighed <1000 gm. Nine babies (18.4%) were growth-retarded.

A total of 30 patients (61%) were black. Four patients (8%) had eclampsia and eight patients (16%) had pulmonary edema. There were 27 patients (55%) who were maternal transfers from outside hospitals. A total of 41 (84%) were delivered of infants by cesarean section.

Abnormal laboratory values in the 49 study patients on admission were as follows: hematocrit <33% in 11 patients, serum creatinine >1.0 mg/dl in 12 patients, serum uric acid >6.0 mg/dl in 37 patients, serum alanine aminotransferase >40 U/L in 18 patients, serum albumin <3.2 gm/dl in 30 patients, and 24-hour urine protein >5 gm in 16 patients.

The eight patients with pulmonary edema on admission had clearly elevated pulmonary artery and wedge pressures and were therefore analyzed separately. When patients with pulmonary edema were excluded there was no significant difference in any hemodynamic parameter between patients with preeclampsia and those with chronic hypertension and superimposed preeclampsia. The hemodynamic parameters of the 41 patients without pulmonary edema are shown in Table I.

Although the normal hemodynamic parameters for pregnancy have not been clearly established, we selected the following ranges of normal on the basis of the results of others[3, 5-10]: (1) pulmonary capillary wedge pressure of 6 to 12 mm Hg, (2) cardiac index of 3 to 5 $L \cdot min^{-1} \cdot m^2$, and (3) systemic vascular resistance of 800 to 1200 $dynes \cdot sec \cdot cm^{-5}$. The number and percentage distribution of the study population in each of the categories are shown in Table II. With the use of these parameters 88% of the patients had a normal left ventricular filling pressure with only 7% low and 5% high. A total of 80% of patients had a normal cardiac index and the remaining patients had a high cardiac index. Approximately one half the patients had a normal systemic vascular resistance and the others had an elevated systemic vascular resistance.

The hemodynamic findings in the eight patients with pulmonary edema are shown in Table III. All had elevated wedge pressures, one half had normal and one half had elevated cardiac indices, and all had normal or low systemic vascular resistance. They were a heterogeneous group. Four were obese multiparous women over 30 years of age with chronic hypertension and superimposed preeclampsia whose pulmonary edema was multifactorial. These factors included left ventricular dilatation and hypertrophy, diastolic dysfunction as a result of impaired ventricular relaxation, and volume overload because of salt and water retention during the last weeks of pregnancy. A fifth patient was similar but also had echocardiographic evidence of systolic dysfunction. The sixth patient was a 17-year-old primigravida with worsening preeclampsia managed with escalating dosages of methyldopa and hydralazine in an outside hospital. The other two patients had been given copious amounts of fluid and blood because of oliguria during labor.

Table III. Hemodynamic profile of the eight patients with pulmonary edema

Variable	*Measurement*
Heart rate (beats/min)	106 ± 5
Mean arterial pressure (mm Hg)	136 ± 3
Mean pulmonary artery pressure (mm Hg)	27 ± 2
Pulmonary capillary wedge pressure (mm Hg)	18 ± 1
Central venous pressure (mm Hg)	11 ± 1
Cardiac output (L/min)	10.5 ± 0.6
Cardiac index ($L \cdot min^{-1} \cdot m^2$)	4.9 ± 0.5
Stroke volume (ml)	97 ± 7
Systemic vascular resistance ($dynes \cdot sec \cdot cm^{-5}$)	964 ± 50
Pulmonary vascular resistance ($dynes \cdot sec \cdot cm^{-5}$)	71 ± 9
Left ventricular stroke work index ($gm \cdot m \cdot m^2$)	87 ± 10

Values are mean ± SD.

Ventricular function as shown by the Starling plot of stroke work index versus pulmonary capillary wedge pressure in Fig. 1 was shifted upward and to the left, illustrating hyperdynamic function in 73% of the patients. In the subjects with pulmonary edema, function was normal in four, hyperdynamic in three, and depressed in the one subject who had echocardiographic evidence of systolic dysfunction.

Because our population was heterogeneous, we examined the hemodynamic variables in specific subsets. Sixteen patients treated with hydralazine were compared with 33 untreated patients. No differences in hemodynamics were found. Twenty-two patients in the latent phase of labor were compared to 27 patients not in labor. Small differences were found in heart rate (101 ± 2 versus 91 ± 3 beats/min, respectively, $p < 0.1$) and cardiac index (4.9 ± 0.2 versus 4.2 ± 0.1 $L \cdot min^{-1} \cdot m^2$, $p < 0.01$). Similar comparisons between

Table IV. Comparison of the hemodynamic profile of preeclamptic patients in this study versus the study of Wallenburg et al.

Variable	*Mabie et al. (n = 15)*		*Wallenburg et al. (n = 44)*	
	Median	*Range*	*Median*	*Range*
Heart rate (beats/min)	88	65-110	90	60-130
Mean arterial pressure (mm Hg)	126	100-150	120	95-143
Mean pulmonary artery pressure (mm Hg)	16	8-22	9	3-18
Pulmonary capillary wedge pressure (mm Hg)	8	3-13	4	0-13
Central venous pressure (mm Hg)	5	0-10	1	−2 to 6
Cardiac index ($L \cdot min^{-1} \cdot m^2$)	4.1	3.1-5.2	3	2.0-4.7
Stroke index ($ml \cdot beat \cdot m^2$)	45	33-65	35	20-57
System vascular resistance index ($dynes \cdot sec \cdot cm^{-5} \cdot m^2$)	2416	1660-3310	2970	2100-4585
Pulmonary vascular resistance index ($dynes \cdot sec \cdot cm^{-5}$)	122	62-207	82	25-133

patients received in transfer and those directly admitted did not reveal differences in hemodynamics. Last, we examined a subset of 15 patients from the group of 41 patients without pulmonary edema. The patients were nulliparous, not in labor, without preexisting hypertension, cardiac or renal disease, and had not received therapy other than magnesium sulfate and small amounts of intravenous fluid. Their heart rates (87 ± 3 versus 98 ± 2 beats/min, $p < 0.01$) and cardiac indices (4.1 ± 0.1 versus 4.7 ± 0.1 $L \cdot min^{-1} \cdot m^2$, $p < 0.05$) were slightly but significantly lower than those of the remaining 26 patients. However, there were no differences in their filling pressures (8.9 ± 0.6 versus 7.9 ± 0.4 mm Hg).

Comment

The results of this study demonstrate a spectrum of hemodynamic alterations in severe preeclampsia with the majority of patients having a normal pulmonary capillary wedge pressure, high cardiac output, and normal to moderately elevated systemic vascular resistance. These findings correlate with the physical examination of the patients who usually had tachycardia, bounding pulses, wide pulse pressure, a hyperdynamic precordium, systolic flow murmur, and warm extremities. The hemodynamics of patients with antecedent hypertension were similar to patients without prior hypertension. This observation has been reported by others.[11] There was significant variability in the cardiac output, ranging from 6.0 to 12.1 L/min (3.1 to 6.2 $L \cdot m^{-1} \cdot m^2$ index). The most surprising finding in this study was the normal pulmonary capillary wedge pressure, with only three patients with a low pulmonary capillary wedge pressure. Central venous pressure was also normal or increased in all subjects (normal ranging from 0 to 8 mm Hg).[12-14]

One potentially confounding variable in our study was fluid administration before insertion of the Swan-Ganz catheter. Because 55% of our patients were referred, it was difficult to ascertain fluid intake in them. We examined 34 patients in whom all intravenous fluid intake could be documented. The mean intake was 741 ± 760 ml (mean ± SD) over 10.1 ± 11.4 hours. We also correlated cardiac output with fluid intake for these patients and found no correlation ($r = -0.12$, $p = 0.51$). These observations suggest that, in the majority of patients, fluid administration was not excessive.

The patients with pulmonary edema were a heterogeneous group. They were clearly volume overloaded with high filling pressures and normal to high outputs. Five had preexisting hypertension and had underlying left ventricular hypertrophy with impaired relaxation and marked volume overload. Only one patient had evidence of decreased systolic function of unknown cause. Three patients had iatrogenic pulmonary edema principally as a result of fluid overload. All the patients improved dramatically with diuresis.

Cotton and his colleagues[11] have reported their results with regard to 45 preeclamptic patients in whom the initial hemodynamic measurements were obtained before any intervention other than magnesium sulfate and minimal intravenous fluids. Their results and ours are quite similar (Table I). The main differences are that our patients had lower systolic blood pressure and systemic vascular resistance with higher cardiac output. The differences may be related to intravenous meperidine given before insertion of the Swan-Ganz catheter in our patients. Together these studies which involve 94 subjects, allow a consensus view to emerge with regard to the hemodynamics of severe preeclampsia. Namely, that there is a variable hemodynamic profile with relatively high cardiac outputs and normal filling pressures, which reflect the volume loading of the circulation during pregnancy with inappropriately high systemic vascular resistance superimposed, resulting in hypertension. This variability is not surprising in that a spectrum of cardiac outputs and peripheral resistance is found in virtually every other type of experimental and naturally occurring hypertension.[15, 16] The mechanisms for the varied hemodynamics in hypertension

result from the complex interaction of multiple variables (cardiac output, total peripheral resistance, blood volume, central nervous system integration, and autonomic tone) and remain poorly defined.[16] The failure of the circulation to dilate in the setting of increasing cardiac output appears to be a characteristic feature of preeclampsia. Because resistance is calculated from the mean arterial pressure divided by the output, in a high output state the calculation results in a normal or even low resistance despite the elevated blood pressure.

Our results and those of Cotton et al.[11] contrast with the data reported from The Netherlands by Wallenburg[12] (Table IV). He found a variable pattern with a trend toward a low pulmonary capillary wedge pressure, low cardiac output, and high systemic vascular resistance in 44 untreated nulliparous, preeclamptic patients, whereas a wide range of hemodynamics was found in 22 patients who had received various therapies and were usually referred. He concluded that the untreated patient was significantly volume depleted and that the wide spectrum of hemodynamic findings present in the treated group resulted from prior therapy and the presence of other variables such as labor, multiparity, and preexisting hypertension. However, 15% or more of his untreated group had wedge pressures >8 mm Hg, which suggests a normal central blood volume. In emphasizing the predominant pattern of reduced filling pressures he minimized the variable hemodynamic presentations.

In an effort to obtain a population similar to Wallenburg's untreated group, we found 15 patients who were nulliparous, not in labor, had not received antihypertensives, and did not have a history or evidence of preexisting hypertension, heart, or renal disease. They had received magnesium sulfate and some intravenous fluids before invasive monitoring. Except for the slightly lower heart rates and outputs, the parameters of these 15 patients were not significantly different from those of the remaining 26 without pulmonary edema. The hemodynamic parameters of the 15 patients are listed in Table IV with each parameter presented as median and range in the manner of Wallenberg's data to allow comparison. Our patients tended to have high central pressures, higher outputs, and lower systemic resistances more frequently than did those of Wallenberg, but the range of values were similar.

Studies of plasma volume in preeclamptic patients have shown a 5% to 29% reduction in plasma volume with a mean reduction of 9%.[17] Whereas patients with preeclampsia may have reduced plasma and intravascular volume, the central blood volume as evidenced by central venous pressure and pulmonary capillary wedge pressure is usually normal, which suggests that the vascular capacitance is also reduced. Unfortunately,

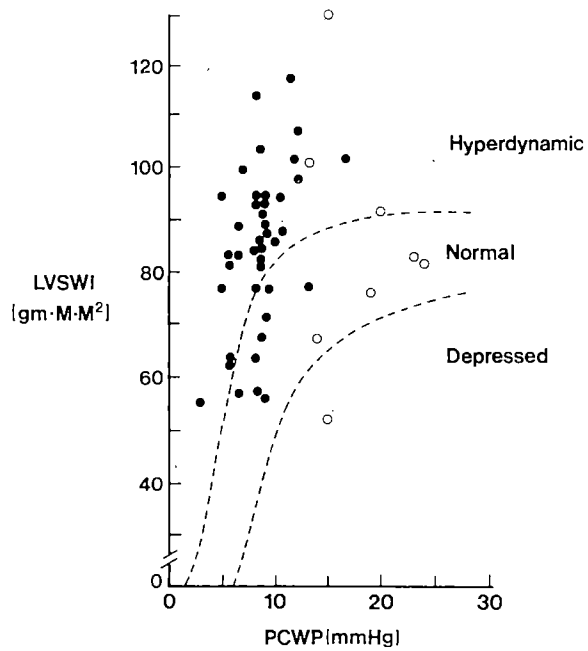

Fig. 1. Left ventricular function curve of left ventricular stroke work index *(LVSWI)* plotted against pulmonary capillary wedge pressure *(PCWP)* in 49 patients with severe preeclampsia. *Solid circles,* No pulmonary edema; *open circles,* eight patients with pulmonary edema.

venoconstriction cannot be easily and accurately assessed clinically. The immediate result of venoconstriction is to shift blood volume centrally from the splanchnic bed, which results in an increase in filling pressure.[18] With continued venoconstriction there is increased transudation of fluid with a decrease in plasma and intravascular volume.[16, 18] What role venoconstriction plays in the spectrum of hemodynamic abnormalities found in preeclampsia remains to be determined. Splanchnic venoconstriction and central relocation of intravascular volume also have been observed in other etiologic types of hypertension.[16] From a therapeutic and practical point of view, many of these patients behave as if they are venoconstricted and are quite susceptible to circulatory congestion and pulmonary edema with fluid administration.

Our study was not designed to determine the best treatment of preeclampsia. The normal pulmonary capillary wedge pressure with normal to elevated cardiac output would imply that neither volume expansion nor diuretic therapy is generally indicated. The findings support the currently used minimal intervention approach of bed rest, magnesium sulfate, and delivery. Attention to fluid balance with input minimally exceeding output can prevent circulatory congestion, especially in patients with left ventricular hypertrophy or chronic renal disease. Most patients with severe preeclampsia can be managed without a Swan-Ganz cath-

eter; however, in certain circumstances hemodynamic monitoring is potentially useful, namely, in sorting out cardiogenic from noncardiogenic pulmonary edema, in management of massive hemorrhage or refractory hypertension, and in induction of epidural anesthesia for cesarean section.

In summary, we have studied the hemodynamics of 49 subjects with severe preeclampsia at a large referral center. Despite a heterogeneous population of referred and nonreferred patients, pretreated and nonpretreated patients, a generally consistent profile emerged. A normal left ventricular filling pressure was present in 88%. A normal to high cardiac output for pregnancy was found with elevated resistances in one half the patients and normal resistances were found in the others. The normal resistances reflected higher cardiac outputs. Our patient population and results are similar to those of Cotton et al. and support the conclusion that, in general, preeclampsia is a normal to high output state with an inappropriately increased systemic resistance, which results in hypertension. The patients with pulmonary edema had either underlying heart disease or iatrogenic fluid overload. Even in patients in whom fluid administration was minimal, filling pressures were not low.

Our study was not designed to test the hypothesis that preeclampsia is a volume contracted state, but rather we wished to determine the central hemodynamics of patients with preeclampsia seen at a tertiary referral center. Because of the normal filling pressures in most and the propensity of pulmonary congestion to develop with fluid administration, we recommend fluid administration not to exceed output with emphasis on current minimal intervention and early delivery. We hope that our study provides insight for future studies of the treatment of preeclampsia.

Major Advances in Human Female Reproduction.

May 10-12, 1990 Universita' Cattolica Rome, Italy

The aim of the symposium is to discuss the physiopathological mechanisms in most important aspects of human female reproduction and provide the recent achievements in this field. The perspectives of new clinical approaches will be discussed.

MAIN TOPICS

Puberty - The follicle - The corpus luteum - Hyperandrogenism

PRACTICE IN THE PERFECT PLACE

Excellent opportunity for BC/BE OB/GYN to join well-established, highly respected practice or to establish solo practice in Saratoga Springs, NY area. Competitive salary guarantee offered. Strong medical staff support and call sharing available.

Located three hours from NYC, Montreal and Boston, and a half-hour from Albany, Saratoga is an historic, close-knit community with lovely neighborhoods, fine restaurants, specialty shops and entertainment including thoroughbred racing and the Saratoga Performing Arts Center. Its proximity to Lake Placid and the Green Mountains of Vermont is ideal for skiers and outdoor enthusiasts.

FEMSTAT PREFILL

(butoconazole nitrate) VAGINAL CREAM 2%

BRIEF SUMMARY

INDICATIONS: FEMSTAT® (butoconazole nitrate) vaginal cream 2.0% is indicated for local treatment of vulvovaginal mycotic infections caused by Candida species. Confirm the diagnosis by KOH smears and/or cultures. FEMSTAT can be used with oral contraceptives and antibiotics. It is effective in non-pregnant women and during the second and third trimesters of pregnancy.

CONTRAINDICATIONS: FEMSTAT is contraindicated in patients hypersensitive to any of the ingredients.

PRECAUTIONS: General: If clinical symptoms persist, repeat microbiological tests to rule out other pathogens and confirm the diagnosis. Discontinue drug if sensitization or irritation occurs.

Information for the Patient: Do not discontinue prematurely during menstruation or because of symptomatic relief.

Carcinogenesis: Animal studies have not been done.

Mutagenesis: Mutagenicity studies were negative.

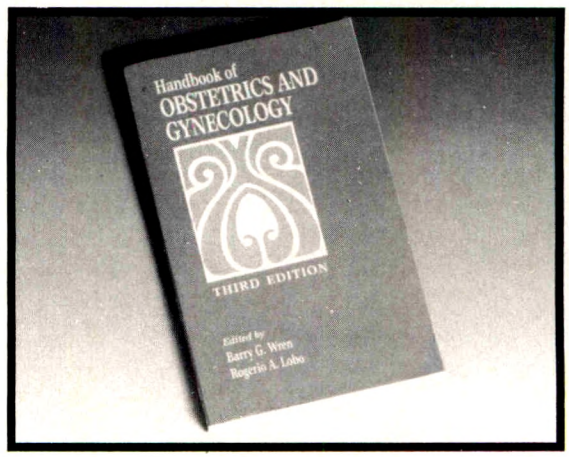
Impairment of Fertility: Animal studies showed no impairment of fertility.

Pregnancy Category C: Adverse effects were noted in animals treated with high oral doses. No studies were done in women during first trimester. Patients in the second or third trimester have shown no adverse effects attributable to the drug.

Nursing Mothers: Use with caution.

Pediatric Use: Safety and efficacy have not been established.

ADVERSE REACTIONS: Vulvar/vaginal burning in 2.3% of patients, vulvar itching in 0.9%, discharge, soreness, swelling, itching of fingers each in 0.2%. Complaints caused 1.6% to discontinue drug.



DOSAGE AND ADMINISTRATION: Non-pregnant Patients: The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for three days. Treatment can be extended for an additional three days if necessary.

Pregnant Patients (second and third trimesters only): The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for six days.

CAUTION:
Federal law prohibits dispensing without prescription.

Cardiovascular changes in early phase of pregnancy

Eleanor L. Capeless, MD, and James F. Clapp, MD
Burlington, Vermont

To assess the magnitude and timing of cardiovascular changes in pregnancy, eight subjects were serially studied before conception and at 8, 16, and 24 weeks' gestation. With the use of M-mode echocardiography, cardiac output, ejection fraction, stroke volume, and end-diastolic volume were calculated from left ventricular dimensions with subjects in the left lateral position. Systemic vascular resistance was calculated with the use of cardiac output and simultaneously obtained measurements of arterial pressure. Cardiac output increased 1 L/min at 8 weeks' gestation, which represented >50% of the total change seen. Cardiac output increased primarily because of stroke volume rather than heart rate. By 8 weeks' gestation, systemic vascular resistance had fallen to 70% of its preconceptional value. Thus when subjects are studied before conception and during the early phase of pregnancy, the majority of the pregnancy-induced changes in these parameters occur during the embryonic period. (AM J OBSTET GYNECOL 1989;161:1449-53.)

Key words: Echocardiography, pregnancy, hemodynamics, cardiac output, systemic vascular resistance

The cardiovascular system undergoes profound alterations during pregnancy. Although the changes in cardiac output, heart rate, and systemic vascular resistance have been well characterized during the latter two thirds of pregnancy,[1-7] the timing and magnitude of these changes during the first trimester remain unknown. In addition, the changes observed during pregnancy have traditionally been compared with postpartum values, but it has not been established when or whether cardiovascular function returns to its preconceptional state. Because measurements were not obtained before pregnancy, previous studies may have underestimated the magnitude of the changes seen in pregnancy.

Our previous observations that basal morning heart rate was significantly elevated at the time of missed menses in a group of recreational runners[8] led us to investigate early cardiovascular changes in the first trimester. The purpose of this study was to document the magnitude and timing of changes in cardiac output, stroke volume, heart rate, mean arterial pressure, and systemic vascular resistance. We hypothesized that the majority of the changes seen in these parameters occur in the first 8 weeks after conception (embryonic period). A longitudinal serial study design in which each subject was studied before conception was used so that comparisons could be based on each subject's preconceptional baseline.

Body fat (%)	17.5	11.7-23.4

Material and methods

Subjects were enrolled before conception and had accurately dated singleton pregnancies. All subjects had positive β–human chorionic gonadotropin determinations within 48 hours of missed menses and an ultrasound examination at 5½ weeks after conception. Pregnancy evaluations were scheduled serially 6 to 8, 14 to 16, and 22 to 24 weeks after conception. These study periods will be referred to as 8, 16, and 24 weeks' gestation. All subjects were initially evaluated within 3 months before conception. All subjects were nonsmoking physically active women with no history of heart disease. Demographic data on age, parity, fitness, and body composition before pregnancy are presented in Table I.

All studies were preceded by an initial 15-minute accommodation to the laboratory environment. At this

time a heart rate monitor and blood pressure cuff were placed and the subject assumed a comfortable left lateral position. Blood pressure was measured every 2 minutes with a mercury manometer that was zeroed at the level of the subject's left ventricle. M-mode echocardiography was performed with the GE 3600 ultrasound machine with a 3.5 MHz transducer. The left parasternal window was used to obtain the long axis view of the heart, which with real-time scanning visualizes the left ventricle, mitral, and aortic valves. The M-mode beam was then positioned just below the tips of the mitral valve leaflets. Measurements of the end-systolic and end-diastolic dimensions were made in accordance with the guidelines published by the American Society of Echocardiography.[9] An additional 5 minutes of imaging preceded the initial measurements in an effort to further accommodate the subject to the study. Heart rate was directly measured during the intervals in which cardiac output was determined. Three or more separate sets of measurements were obtained over 15 minutes with each set measuring three to four cardiac cycles. Thus the values obtained represent the average of 9 to 12 separate cardiac cycles interspersed throughout the respiratory cycle. Over the 15-minute study period, the variability of each set of measurements from the mean cardiac output value averaged 6% with a range from 2% to 17%. In 88% of the studies the variability of successive measurements over the 15-minute study time was <10%.

Left ventricular volumes were calculated from the end-diastolic dimension (EDD) and end-systolic dimension (ESD) in accordance with the formula of Teichholz et al.[10] for a modified prolate ellipsoid. This formula is as follows:

1. End-systolic volume [ESV (ml)] = 7x $(ESD)^3/2.4$ + ESD
2. End-diastolic volume [EDV (ml)] = 7x $(EDD)^3/2.4$ + EDD

Standard equations were used to calculate the following functional parameters:

1. Stroke volume [SV (ml)] = EDV − ESV
2. Cardiac output [CO (ml/min)] = SV × heart rate
3. Ejection fraction [EF (%)] = (SV/EDV) × 100
4. Mean arterial pressure [MAP (mm Hg)] = 2 (diastolic) + systolic/3
5. Systemic vascular resistance [SVR dyne · sec · cm^5] = 80 MAP/CO

Statistical analysis was performed with repeated measures analysis of variance with the Bonferroni correction for multiple comparisons. Significance was set at the 0.05 level.

Results

Eight subjects have completed all study periods. Cardiac output, end-diastolic volume, stroke volume, ejection fraction, heart rate, MAP and systemic vascular resistance are presented in Table II. Stroke volume and heart rate as a function of weeks gestation are presented graphically in Fig. 1. Cardiac output and MAP as a function of gestational age are graphically shown in Fig. 2.

Cardiac output increased 1 L/min by 8 weeks' gestation. This represented a 22% change over preconception values and 57% of the total increase in cardiac output achieved by 24 weeks' gestation. After 24 weeks' gestation, the pattern seen in the subjects was variable and the group mean did not change significantly for the remainder of the pregnancy. Cardiac output is a function of both heart rate and stroke volume (Fig. 1). The increase in stroke volume at 8 weeks' gestation represented a 22% change over preconception values and 78% of the total increase observed by 24 weeks'

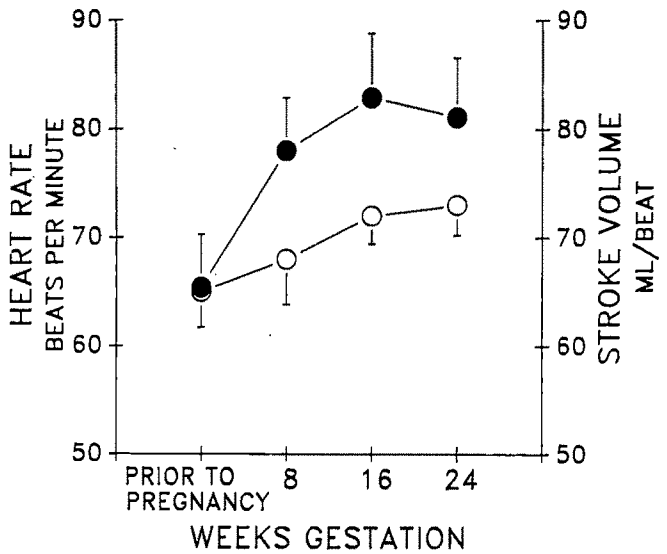

Fig. 1. Stroke volume *(filled circles)* and heart rate *(open circles)* components of cardiac output are presented for four study periods.

gestation. A statistically significant increase in heart rate did not occur until 16 weeks' gestation. This increase represented a 11% change over preconception values and 87% of the total increase observed by 24 weeks' gestation. End-diastolic volume had increased significantly by 8 weeks' gestation and 65% of the total change had occurred by this time. There was no significant change in ejection fraction in any of the study periods.

Systemic vascular resistance fell by 8 weeks' gestation to 30% below preconception values. This early decrease represented 90% of the total change in systemic vascular resistance achieved by 24 weeks' gestation. The components of systemic vascular resistance are presented in Fig. 2. Although mean arterial pressure fell at 8 weeks' gestation, the decrease was not statistically significant until 16 weeks' gestation.

Comment

These data clearly support our original hypothesis that a majority of the pregnancy-induced changes in cardiac output and systemic vascular resistance occur during the embryonic period. The increase in cardiac output can be primarily attributed to an increase in stroke volume rather than in heart rate. The increase in stroke volume was related to an increase in end-diastolic volume as ejection fraction did not change over the study periods. Although we previously had shown that basal morning heart rate increased early in pregnancy,[8] under the conditions of this experiment there was no significant change in heart rate documented.

This is the first report of serial measurements of cardiac output that began before conception. Although the changes in heart rate, blood pressure, and cardiac output during pregnancy have been well documented both by dye dilution[3, 5, 6] and echocardiography,[4, 7] all previous longitudinal studies have started late in the first trimester and have used postpartum values (6 weeks after delivery) to represent preconceptional values. It has been assumed that the women's body returns to its preconceptional state post partum. However, evidence is accumulating that this assumption may be incorrect. Hart et al.[11] have found that multiparous women have larger aortic diameters than those of primiparous women, which suggests that there are alterations that occur during pregnancy that do not revert to the prepregnant baseline. Breast-feeding because of its potential effects on plasma volume,[12] may also influence the rate at which women's cardiovascular systems recover from the metabolic demands of pregnancy. Thus the effects of parity and breast-feeding may have significantly altered the nonpregnancy value. Likewise, our study represents a mixed populace of five nulliparous and three multiparous women. Whereas significant differences were not seen in our study, a larger study sample would be necessary to determine the long-term effects of parity and breast-feeding on the cardiovascular system.

Our data are in agreement and compliment the work of others who characterized cardiovascular changes throughout the second and third trimester of pregnancy. Although all previous reports documented the increase in cardiac output seen during pregnancy, there is disagreement with regard to the relative importance of stroke volume and heart rate in the initiation of this increase. Early serial studies by Walters et al.,[7] Lees et al.,[4] and Ueland et al.[6] that used dye dilution found that cardiac output was already elevated at the time of the first study. They found minimal or no increase in

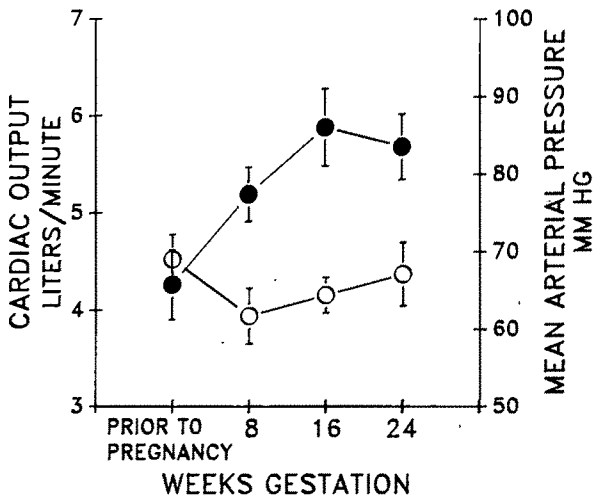

Fig. 2. Cardiac output *(filled circles)* and mean arterial pressure *(open circles)* components of systemic vascular resistance are presented for four study periods.

cardiac output after 20 to 24 weeks' gestation. They demonstrated that the increase in cardiac output resulted from an increase in stroke volume rather than an increase in heart rate. Two echocardiographic studies have serially evaluated cardiac function starting in the first trimester. Katz et al.[5] serially studied 19 women throughout pregnancy. The first evaluation was at the end of the first trimester and a postpartum evaluation was obtained 6 to 12 weeks after delivery. Our findings agree with that of Katz, who found an increase in cardiac output that was a result of an increase in stroke volume, end-diastolic volume, and an increase in heart rate. Mashimi et al.[8] studied seven patients beginning at 11.4 weeks' gestation and compared these values with those obtained 6 to 12 weeks post partum. In contrast with previous investigators, Mashimi concluded that the increases in cardiac output were attributable to changes in heart rate rather than in stroke volume. He failed to observe any change in stroke volume during pregnancy, compared to the postpartum period. In our series, approximately 75% of the increase in stroke volume occurred by the end of the first trimester. Therefore, the relative contribution of stroke volume to the increase in cardiac output could be obscured by the use of the postpartum control value and the timing of the first study period. In addition, there may be different mechanisms operative early in pregnancy to increase cardiac output (end-diastolic volume), which are then augmented by others (heart rate) later in gestation.

M-mode echocardiography is a noninvasive technique to serially follow changes in cardiovascular parameters.[13] The calculation of stroke volume with the Teichholz equation has been validated against angiography-derived stroke volume with a correlation coefficient of $r = 0.97$.[10] When the technique was compared with thermodilution cardiac output, the correlation coefficient was $r = 0.86$.[14] Thus with a normally shaped ventricle and uniform contraction of the ventricular wall, the measurements obtained should accurately reflect left ventricular volumes.[1, 15] During pregnancy the heart is known to change in shape and size and the M-mode technique has not been independently validated. Although the serial nature of this study minimizes the effects of individual variation, the absolute values for cardiac output obtained in this study should not be directly compared with other studies. However, these observations are valid to describe the relative magnitude and timing of cardiovascular changes during early pregnancy.

The magnitude of the changes in cardiac output and systemic vascular resistance that occur in the first trimester are tremendous. The mediators of these changes are unknown. Longo[16] has postulated that maternal blood volume and cardiac output are hormonally controlled with steroidogenesis in the fetal compartment, which influences the maternal environment. The early onset of these changes favor a hormonal mechanism but this may be primarily maternal in origin. The influence of the timing and magnitude of these changes on pregnancy outcome is unknown but represents an area of future study.

The effects of maternal exercise on early pregnancy outcome

James F. Clapp III, MD
Burlington, Vermont

This study was designated to test the hypothesis that vigorous aerobic exercise during both the periconceptional period and early pregnancy increases the incidence of abnormal early pregnancy outcome. Exercise performance was prospectively monitored before and during pregnancy in 47 recreational runners, 40 aerobic dancers, and 28 physically active, fit controls. Pregnancy was diagnosed by an early test for β-subunit human chorionic gonadotropin and viability was confirmed by ultrasonography at 40 days' conceptional age. Spontaneous abortion occurred in 19% of the pregnancies. The incidence was 17% in the runners, 18% in the aerobic dancers, and 25% in the controls. At term, one congenital abnormality was detected in each of the three groups. Late pregnancy events, potentially related to abnormalities of placentation, were limited to two cases of mild pregnancy-induced hypertension. We conclude that, in physically fit women, continuation of these types of aerobic activity at intensities between 50% and 85% of maximum during the periconceptional period and early pregnancy does not appreciably alter early pregnancy outcome. (AM J OBSTET GYNECOL 1989;161:1453-7.)

Key words: Pregnancy, exercise, abortion, congenital abnormality

Both retrospective[1, 2] and prospective[3-6] studies of abortion have documented that the incidence of spontaneous loss is high. Reported frequencies range from as low as 7% to as high as 40% to 60%, depending on the timing and method of pregnancy detection. In studies using standard clinical parameters alone, the overall incidence averages about 15% with distinct increases noted with advancing maternal age and previous early loss. Inclusion of β-subunit human chorionic gonadotropin (β-hCG) testing produces a variable increase in the rate by identifying subclinical losses. In general, the earlier the testing is done, the higher the detection rate and the reported incidence of spontaneous loss.

Approximately one third of these losses are associated with a chromosomal anomaly,[7] and in selected cases specific environmental factors such as subchorionic hemorrhage[8] and defective luteal function[9] have been shown to play a role. The etiologic factors involved in the remainder are poorly understood but are felt to be primarily related to anomalous environmental circumstance. The current study was designed to explore theoretical[10] and epidemiologic[11] concerns that suggested that early wastage should be increased by the cardiovascular, thermal, and hormonal perturbations associated with intense physical activity in early pregnancy.[10-12] Its specific goal was to prospectively test the hypothesis that continuing endurance types of recreational exercise in either the periconceptional period or early pregnancy, or both, increase the incidence of abnormal early pregnancy outcome.

Material and methods

A total of 119 women were studied prospectively for several cycles before conception and then for six additional cycles or throughout subsequent pregnancy. Written informed consent was obtained from each subject before enrollment. All subjects worked outside the

Numeric data presented as mean ± SD.

home, had physically active life-styles, and, on the basis of education and income, were either upper-middle or upper socioeconomic class. All obtained routine obstetric care through private obstetricians not directly involved in the study. The mean age (± SD) was 31 ± 3 years with a range of 25 to 38 years. All were white and in excellent general health. The only historic obstetric risk factor identified was a history of previous spontaneous abortion in 12 (10%) of the subjects. Sixty (50%) were nulligravid, 37 (31%) were primigravid, and 22 (19%) were secundigravid at the time of enrollment.

Ninety women had been either running or aerobic dancing for at least 2 years on a regular basis (three times per week or more) for a minimum of 20 minutes each session at a documented intensity that exceeded 50% of their measured maximum capacity. Forty-nine were recreational runners and 41 were aerobic dancers. Twenty-nine physically active, intermittently athletic women matched for age, weight, percent body fat, and multiple life-style factors served as a control populace. Each control stopped all forms of endurance exercise before attempting conception and did not resume these types of physical activity until after the pregnancy.

In the two exercise groups daily exercise performance was recorded in the field for a minimum of 2 months before conception and throughout the subsequent pregnancy or for an additional six menstrual cycles. The method used to quantitate performance was based on that used to assess both training effect and energy expenditure in the field.[12-14] Briefly, each subject used a portable electrocardiogram telemetry system with memory capability to measure heart rate and the duration of exercise that was recorded at the end of each exercise session in an exercise log. In addition, the relationship between heart rate and exercise intensity (percent of the predetermined maximum oxygen consumption) was determined during graded exercise before conception and every 8 weeks during pregnancy. This information was used to convert the average heart rate during each run to exercise intensity. The product of exercise intensity and the duration of the exercise was averaged weekly and expressed as a duration-intensity index, which was used as the objective measure of each individual's time-specific exercise performance.[14] To allow valid comparison between subjects, the duration-intensity index was normalized and expressed as a percentage of each individual's average exercise performance over the initial 6 weeks of participation.

Maximal oxygen consumption was determined twice before conception in the initial 20 subjects using a constant-speed, progressive-grade, modified Astrand treadmill protocol.[15] There was no evidence of directionality with repeated testing and all second test values were within ±5% of the initial result. Therefore maximal oxygen consumption was determined only once in those that followed. Percent body fat was determined by both hydrodensitometry[16] and six-site skinfold thicknesses[17] in the first 50 subjects. As the mean difference between the two methods was +1.3% with a standard error of ±0.9%, only six-site skinfolds were used in the remainder.

Each subject had conception confirmed by β-hCG assay within 48 hours of missed menses and its viability was documented ultrasonographically between the fortieth and forty-fourth postconceptional day. Bleeding was followed by serial β-hCG assay and one or more ultrasonographic evaluations. At the time of abortion all tissue was examined histologically and, if viability had been recently confirmed, chromosomal analysis was performed. The course of pregnancy, labor, and delivery was independently monitored by study personnel, and all placentas and offspring were carefully examined for evidence of anomalies at the time of delivery. A subject was judged "infertile" if conception could not be documented during the initial six cycles of unprotected intercourse.

The three groups were divided into those who experienced spontaneous abortion and those who were

delivered at term. Within each group, differences in age, history of abortion, gravidity, and exercise performance were sought between those who aborted and those who did not with an unpaired Student t test. In addition, exercise performance, quantitated as the normalized duration-intensity index over various time intervals (the 2 weeks before conception, the first and second lunar months of pregnancy), was examined to see if there was a specific time in the periconceptional period when exercise performance differed in those who did and did not experience early wastage. Then, as the data were virtually identical in the two exercise groups, they were combined and compared with those of the control group, using the χ^2 statistic with Yates' correction, to detect any differences in the incidence of four objective indices of abnormal early pregnancy outcome. They included failure to conceive within 6 months, spontaneous abortion, gross congenital abnormality, and a clinical outcome suggesting anomalous placentation (specifically ectopic pregnancy, placenta previa, abruptio placentae, preterm labor, and pregnancy-induced hypertension). As no real differences were found, a similar comparison was done with the accepted incidence of these outcomes in an overall obstetric populace in an attempt to avoid the possibility of missing a small but significant difference as a result of our sample size (type II interpretive error).

Results

As detailed in Table I, there were no significant differences between the three groups in age, gravidity, preconceptional weight, percent body fat, or maximal oxygen consumption. The relatively low mean percent body fat (populace norms generally are considered to have a normal range of 22% to 28%) and high mean maximum oxygen consumption (populace 90th percentile in the range of 45 ml/kg/min) in the three groups indicate that all subjects were quite fit and in that respect are probably not representative of the obstetric populace at large.

The only significant between-group differences were a history of previous spontaneous abortion and exercise performance before pregnancy. Approximately 15% of the recreational runners and controls had experienced a prior early loss while none of the aerobic dancers had done so.

The level of preconceptional exercise performance, as assessed by the duration-intensity index, was quite varied both between and within groups. Both exercise groups had a mean level of exercise performance that was approximately fourfold that noted in the control group with the runners performing at a level some 17% above that observed in the aerobic dancers. The recreational runners ran an average of 22 miles a week (range 12 to 55), at an average pace of 8 min/mile (range 6 minutes 30 seconds to 9 minutes 50 seconds) and at a mean intensity equal to 68% of maximum capacity range (52% to 83%). The average time devoted by any individual to exercise each week ranged from a low of 1 hour 33 minutes to a high of 6 hours 37 minutes. Participation in aerobic dance averaged slightly more than four sessions a week (range 3 to 11). During each session, subjects worked at an intensity ranging between 20% and 40% of maximum during 25 to 35 minutes of warm-up and cool-down and at 55% to 88% of maximum capacity during the 25- to 30-minute high-intensity, so-called aerobic phase of the workout. This latter phase comprised approximately 70% of most individual's overall performance. In the control group exercise performance was quite erratic with individual frequencies ranging from once every other week to twice weekly. Twenty-one of these individuals only participated in weekend racquet sports in the spring, summer, and fall with a switch to cross-country or downhill skiing in winter. Their exercise performance was estimated from their average pulse rates in the field to have an average weekly duration intensity range between 1400 and 6200. The remaining eight erratically ran or danced aerobic once or twice a week and, on the basis of individual concerns about the impact of exercise on pregnancy, they stopped these activities before attempting conception. Their average duration intensity index was 2104 with a range from 1018 to 3245.

Table II. Spontaneous abortions

Parameter	*Runners*	*Aerobic dancers*	*Controls*

Viable embryo	1 (?)	2	2

There was no within-group relationship between age, gravidity, prior loss, or overall exercise performance level and the occurrence of either early loss or other abnormal early pregnancy outcome.

Conception occurred within six cycles in 97% (115 of 119) of the subjects. The four cases of "infertility" were equally distributed between the groups and not clustered in women who had either extremely high- or low-duration intensity indices before or at the time of conception. One control subject and one recreational runner (24 miles per week in 3 hours) failed to conceive for no apparent reason. One aerobic dancer's husband had a subnormal semen analysis and she had irregular cycles, while another aerobic dancer simply decided to delay conception after a change in life situation.

As shown in Table II, there were no differences in

Table III. Within-group exercise performance*

Group	*Follicular phase*	*Weeks 1-4*	*Weeks 5-8*	*Overall*
Runners (n = 48)	93 ± 15	86 ± 19	80 ± 19	87 ± 19

*All data presented as the percent of the preconceptional duration-intensity index (mean ± SD).

the incidence of spontaneous abortion in the three groups and histologic findings were similar. With the sample size examined, assuming a conservative spontaneous abortion rate in the populace at large of 15%, the probability that an exercise-associated, significant increase in the rate of spontaneous abortion was missed is <1%.

Likewise, histologic, ultrasonic, and chromosomal findings did not suggest that any specific etiologic differences were present between the groups. In the recreational runners there was one early loss, with conception confirmed only by β-hCG assay because no tissue other than decidua was recovered, six blighted ova, and one case in which a fetus was not found but the placental villi were vascularized. In the aerobic dancers there were two early losses with β-hCG confirmation only, three blighted ova, and two cases in which viability was confirmed, followed by embryonic death and abortion. One embryo was a trisomy 15, and in the other case there was ultrasonographic evidence of a subchorionic bleeding that was confirmed histologically. In the control group there was one very early loss with β-hCG confirmation, four blighted ova, and two cases where fetal viability was demonstrated before embryonic death and abortion. In one instance, placentation probably occurred on the septum of a previously undiagnosed subseptate uterus, and in the other, villous vascularity was markedly reduced along with pathologic findings consistent with hemorrhagic endovasculitis.

Over three specific time intervals, there were no significant differences in normalized exercise performance (percent preconceptional duration-intensity index) by the exercising women who aborted versus those who carried pregnancies to term, as shown in Table III. In the follicular phase of the cycle of conception, exercise performance in the runners who eventually aborted averaged (mean ± SD) 88% ± 13% of preconceptional duration-intensity index versus 94% ± 15% in those who carried to term. In the aerobic dancers performance averaged 78% ± 20% of preconceptional duration intensity index in those who eventually aborted versus 88% ± 30% in those who carried to term. In the initial 4 weeks after conception these values were 88% ± 16% and 86% ± 20% in the recreational runners and 78% ± 22% and 84% ± 28% in the aerobic dancers. In the ensuing 4 weeks similar values were 83% ± 17% and 80% ± 19% in the runners and 78% ± 24% and 84% ± 26% in the aerobic dancers.

The three congenital abnormalities diagnosed at birth were not clustered in either group. The single case of trisomy 21 occurred in a control subject. A case of subcoronal hypospadias was noted in the offspring of an aerobic dancer who, with the exception of postconceptional weeks 4 to 8, danced regularly three times each week throughout pregnancy, thereby maintaining her overall performance within 20% of her preconceptional duration-intensity index. A case of digital webbing or partial syndactyly between the second and third toes was noted in the offspring of a runner whose husband and two other relatives have similar anatomic findings.

The incidence of pregnancy events suggesting anomalous placentation was equally sparse. Despite careful monitoring no cases of ectopic pregnancy, placenta previa, abruptio placentae, or clinically diagnosed uteroplacental insufficiency have been observed in either group. There have been two cases of pregnancy-induced hypertension without proteinuria at term. One occurred in a control, the other in an aerobic dancer. The onset of labor occurred before the beginning of the 38th week in 5 cases with an incidence of approximately 5% in both groups.

Comment

These data do not support the initial hypothesis. Rather, they indicate that the continuation of several types of commonly performed antigravitational exercise through the periconceptional period and first trimester is not associated with an increased incidence of spontaneous abortion. Furthermore, although the data are limited, there is no suggestion that the incidence of other abnormal first-trimester events is increased by continuing exercise.

Given the fact that this type of exercise is associated with significant increases in body temperature and regional flow redistribution away from the viscera,[10-12] the interesting question is why. Limited data suggest that

the answer may lie in the extremely early timing of pregnancy-associated changes in maternal physiologic function.[17] Theoretically, early cardiovasular and thermoregulatory changes could have a protective effect by decreasing the flow redistribution requirements or exercise and diminishing the magnitude of its thermal effect. We are currently testing this hypothesis.

Given the large number of women who exercise regularly and plan to continue exercise during pregnancy,[11] these findings are reassuring. However, for several reasons, they may not be generally applicable. First, the fact that all subjects were uncompensated volunteers who had free access to information regarding some of the physiologic changes exercise induced in their bodies, both before and during pregnancy, may have introduced bias into the results as they may indeed not be representative of a more general exercise populace. Second, although the types of exercise were picked for initial study because they should have induced the greatest changes in the maternal internal environment,[10-12] other types of exercise in early pregnancy may be associated with entirely different effects. Third, the study populace was limited to women in excellent overall health and physical condition who had been exercising regularly for several years and their bodies and organ systems were undoubtedly well adapted to the recurrent physiologic stress imposed by exercise. Thus the impact of exercise on early pregnancy outcome might be very different in a group of women who, for example, began an exercise program in the periconceptional period. Fourth, with the exception of spontaneous abortion, the incidence of abnormal outcomes was extremely low. While this is reassuring, the chance of interpretive error is high and further study is warranted.

Oxygen consumption during treadmill exercise before, during, and after pregnancy

James F. Clapp III, MD
Burlington, Vermont

This study was designed to test the hypothesis that the amount of oxygen required to complete a specific treadmill exercise protocol changes during pregnancy as a function of gestational age, weight gain, and an individual's exercise regimen. The amount of oxygen required to complete a three-step, graded workload treadmill protocol was monitored before, every 6 to 8 weeks during, and after a clinically normal, accurately dated, singleton pregnancy in 18 fit, recreational athletes. Nine subjects continued a moderate- to high-intensity exercise regimen and nine did not. The amount of oxygen required to complete each stage of the protocol decreased significantly (6% to 15%) in both groups in early pregnancy. In the women who continued exercise, the amount of oxygen required remained at or significantly below that required before conception for the remainder of the pregnancy and the initial postpartum period. Conversely, in the women who discontinued regular exercise, the amount of oxygen required for each stage rose progressively throughout the remainder of pregnancy at an average rate of 2% per lunar month. It peaked in the thirty-seventh week and remained significantly elevated 7 weeks post partum. However, when the data were corrected for the additional requirement imposed by pregnancy weight gain, net efficiency was increased in both groups throughout pregnancy. These data support three conclusions. First, the efficacy of low- to moderate-intensity treadmill exercise in physically active women is improved in early pregnancy. Second, this increased efficiency is masked later in pregnancy by the effects of weight gain. Third, the degree of efficiency is enhanced throughout pregnancy in women who continue a regular exercise regimen at or above a basic conditioning level. (Am J Obstet Gynecol 1989;161:1458-64.)

Key words: Pregnancy, exercise, oxygen consumption, efficiency

The interaction between the physiologic adaptations to pregnancy and endurance exercise are complex and to date poorly understood.[1, 2] The impact that one may have on the other is unclear since a specific adaptation to one may either oppose or complement the overall physiologic readjustment required by the other.[3, 4] For example, the cardiovascular and metabolic adaptations to pregnancy that occur by the seventh postconceptional week[5, 6] appear to compliment some of the physiologic adaptations produced by endurance training. These pregnancy-induced changes provide a potential physiologic explanation for the anecdotal observation that the competitive performance of world-class athletes may be improved in early pregnancy. This is also supported by one case report that documented an increased exercise efficiency in an individual who maintained her jogging regimen throughout pregnancy.[7] Longitudinal studies, however, of healthy pregnant women, begun after the first trimester, conclude that the efficiency of non-weight-bearing ergometer exercise is either unchanged or decreased[8-10] and that the efficiency of weight-bearing treadmill exercise decreases in rough proportion to the increase in body weight.[8, 10-12]

The current study was designed to examine the impact of pregnancy on the efficiency of weight-bearing exercise in greater detail by serially monitoring the oxygen required to complete a standardized, progressive workload, exercise task before, during, and after pregnancy, controlling for the confounding effects of initial fitness, exercise performance during pregnancy, and weight gain. It was specifically designed to test the hypothesis that the amount of oxygen required to complete a specific weight-bearing exercise task during pregnancy changes as a function of gestational age, maternal weight gain, and an individual's concurrent exercise regimen.

Material and methods

Eighteen women were studied serially before, every 6 to 8 weeks during, and 6 to 8 weeks after a clinically normal, accurately dated, singleton pregnancy. All subjects were breast-feeding without supplementation at

the time of the postpartum study. Written informed consent was obtained from each subject before enrollment. All subjects worked outside the home, had physically active life-styles, and were upper-middle or upper socioeconomic class. All were in excellent health and had maintained a regular antigravitational exercise regimen (running, cross-country skiing, aerobics), consisting of at least three moderate- to high-intensity training sessions (50% to 85% of maximum intensity for a minimum of 30 minutes) per week for ≥2 years before study entry.

In all subjects reported exercise performance was confirmed and quantitated by monitoring individual daily exercise performance for a minimum of 6 weeks before conception and throughout pregnancy by means of standard field techniques described elsewhere.[13] Briefly, maximal oxygen consumption was measured before pregnancy, and the linear relationship between heart rate and oxygen consumption was determined serially before and during pregnancy. This relationship was used to convert the pulse rate during exercise, which was continuously recorded during each field exercise session, to intensity (percent of maximum intensity). The product of this and duration (the duration-intensity index) was used as the quantitative measure of exercise performance.

Nine women maintained their exercise regimens throughout pregnancy at an overall performance level well above 50% of their preconceptional level and form the exercise-continued subgroup. The remaining nine subjects form the exercise-stopped subgroup. On the basis of individual concerns or preference, they either stopped their training regimens completely at the time of conception ($n = 5$) or continued to exercise only intermittently and at low intensity with an overall performance level well below 25% of the preconceptional level ($n = 4$). It should be stressed that subgroup assignment was based on subject preference and was not randomized.

The characteristics of the overall study group and two subgroups are detailed in Table I. The subjects ranged in age from 26 to 35 and approximately two thirds were nulligravid at the time of study entry. Running or jogging was the primary exercise for approximately 60%, while 40% preferred aerobics. Before pregnancy, weekly exercise performance, quantitiated as the duration-intensity index, was similar in the two subgroups. Preconceptional body weights ranged between 53.0 and 64.7 kg.

Fitness was objectively assessed before conception according to AM heart rate, fat mass, and maximum oxygen consumption. The first was recorded with a telemetry device[13] on awaking and before arising. Values ranged between 42 and 59 beats/min in both groups. Body fat was estimated with the sum of six-site skinfolds[5] and ranged between 11.5% and 29.2%. Maximum oxygen consumption was measured directly by means of automated respiratory calorimetry and a constant speed, progressive slope, treadmill protocol.[13] All subjects registered values in the upper 5th percentile. The only significant difference between subgroups was a greater percent of body fat in the controls.

The treadmill protocol always began 90 to 150 minutes after a normal meal and was the first exercise of the day. On arrival the subjects changed into lightweight exercise apparel and then were weighed and fitted with electrocardiogram electrodes and respiratory headgear. The laboratory temperature and relative humidity were maintained between 19° and 21° C and between 30% and 50%, respectively. Each individual's attire was the same for each of her testing sessions.

On each testing occasions, the subjects initially remained at standing rest for 8 minutes while they adapted to the respiratory apparatus and laboratory environment. During the next 7 minutes, measurements of oxygen consumption at standing rest were obtained. Then they began a 36-minute, progressive workload, exercise protocol that was divided into three 12-minute stages. Throughout each progressive stage, the treadmill speed and grade were kept constant, and the initial 5 minutes of data was discarded to be sure

that a new steady state of oxygen consumption had been reached (variability $< \pm 10\%$). The stable oxygen consumption over the last 7 minutes was measured, averaged, and, after subtraction of the oxygen consumption at standing rest, used as the oxygen cost of that workload in later data analysis.

To allow meaningful comparison between individuals, the intensity of the three progressive workloads was standardized at the time of the preconceptional test to require an oxygen consumption equal to approximately 20%, 30%, and 40% of each individual's preconceptional maximum oxygen consumption. Once determined, the same treadmill speed and grades were used for testing the subject during each subsequent session.

Minute ventilation was measured with a pneumotachometer that was calibrated monthly and had a precision of $\pm 3\%$ when compared under actual test conditions with a Tissot apparatus. The oxygen and carbon dioxide content of room air and expired air were measured with applied electrochemistry analyzers, which were calibrated with standard gasses before and after each use. The precision of the entire system for the measurement of oxygen consumption under test conditions was $\pm 5\%$ when compared with concomitant use of a Douglas bag, dry gas meter, and oxygen analyzer.

The initial 10 subjects completed the same protocol twice before pregnancy to assess the biologic variability of the protocol and to determine if a training effect existed. The results of the second testing session ranged from 95% to 107% of the first with a group average of $101\% \pm 3\%$. Thus the biologic variability was no greater than the reproducibility of the measurement and there was no evidence of a training effect.

The oxygen consumption data were analyzed in several ways to detect pregnancy- and exercise-associated changes in efficiency. First, the raw data were analyzed longitudinally without correction for weight gain. Second, the amount of oxygen required to climb vertically at a rate of 5 m/min was calculated from the increase in oxygen consumption produced by a change in treadmill grade at a constant speed. Finally, these data were corrected for the effect of weight gain by use of the longitudinal data gathered by Hanson[14] in subjects who exprienced similar weight gains and completed similar protocols in studies of experimental obesity. Within-group significant changes over time were detected by analysis of variance, repeated measures analysis of variance, and Duncan's multiple range test. Between-group differences at a single time point were detected with Student's unpaired t test. A p value <0.05 was set as the level of significance.

Results

Table II details the longitudinal changes in the amount of oxygen required to perform the progressive treadmill workloads before, during, and after pregnancy in the two subgroups and the overall study populace. The subjects who continued exercise during pregnancy experienced a significant decrease in the oxygen required to complete all three workloads in the seventh and fifteenth weeks of pregnancy, and in the seventh week post partum. At the 20% workload the oxygen requirement remained significantly lower through the thirty-first week. At the various time points and workloads, the group mean was between 6% and 16% below the preconceptional value. The women who discontinued a regular exercise regimen at the beginning of pregnancy experienced a similar decrease in the oxygen requirement in the seventh week of pregnancy that reached significance at the two highest workloads. Thereafter their oxygen requirements rose significantly over time at all workloads at an approximate rate of 3% per lunar month through the thirty-seventh week and reached values that peaked 15% to 18% above those observed preconceptionally. The mean values were significantly higher than the preconceptional ones from the twenty-fifth week onward at the 30% workload, from the thirty-first week onward at the 40% workload, and only during the thirty-seventh week at the 20% workload. At all workloads the postpartum requirement remained significantly higher than the preconceptional one by 6% to 10%. The divergent patterns in the two subgroups offset one another so that the only consistent significant change in the overall study populace was a fall in the oxygen requirement at 7 weeks' gestation. However, when the two subgroups were compared with each other at each time point, significant differences in the absolute change from preconceptional values were present from the fifteenth week onward at all workloads. For the 40% workload, this difference peaked at 170 ml/min in the thirty-first and thirty-seventh weeks and was maintained at that level in the initial postpartum period. Overall, the relative oxygen cost in the women who continued exercise remained 15% to 18% below that of those who did not.

The first portion of Table III presents the longitudinal changes in the calculated oxygen cost of vertical work in the two subgroups. In this calculation, the difference in the oxygen consumption produced by an increase in treadmill grade at a constant speed was simply normalized for each subject to a climbing rate of 5 m/min. Throughout pregnancy and the initial postpartum period, the oxygen requirement of the subjects who continued the exercise regimen remained at or below the preconceptional level. The maximum decrease of 15% was observed in the seventh week, but the values were also significantly lower in the fifteenth and thirty-first weeks despite increases in body weight of 8% and 18%, respectively. The subjects who stopped

their regular exercise regimens also experienced a significant 8% decrease in the oxygen requirement in the seventh week, but this was followed by a significant increase over time in the oxygen requirement through the thirty-seventh week at an approximate rate of 29 ml per lunar month. As a result, the oxygen requirement was significantly higher by 18% to 19% in the thirty-first and thirty-seventh weeks. In both subgroups the value returned to preconceptional levels in the initial pospartum period. Again, the divergent patterns in the two subgroups offset one another so that the only significant longitudinal difference in the overall study populace was a 12% reduction in the oxygen requirement in the seventh week. However, as noted, earlier in the raw workload data, significant between-subgroup differences in the absolute changes from preconceptional values were present at the individual time points from the fifteenth week onward. At the various time points, the relative oxygen cost of climbing at a rate of 5 m/min ranged between 15% and 31% less in the women who continued their training regimens throughout pregnancy.

Significant progressive weight gain was noted throughout pregnancy. This was roughly linear for each subject (R^2 between 0.87 and 0.99). In the exercise-continued and exercise-stopped subgroups, the average rate of increase approximated 1.3 and 1.7 kg per lunar month, respectively. This represented a total weight gain approximating 21% and 27% of preconceptional weight in the two subgroups, which clearly exceeded the percentage increase in oxygen consumption, indicating that the oxygen requirement per kilogram actually decreased. Indeed, the calculated increase in the workload of climbing at the rate of 5 m/min because of weight gain was 61 and 79 kpm/min in the two respective subgroups. To offset this increase in workload, the data were adjusted for the increased oxygen cost attributable to individual weight gain at each time point by a correction factor of −2.6 ml oxygen per kilopond meter per minute. This was calculated directly from data obtained in a study of experimental obesity in which a nearly identical treadmill workload was used before and after similar weight gains and losses.[14] The weight-corrected data are presented in the second portion of Table III. Note that when the effect of pregnancy weight gain is considered the initial significant decrease in the oxygen requirement is maintained in both subgroups throughout pregnancy and the initial postpartum period. The greatest decreases were observed in the third trimester when the values were 37% to 42% lower in the exercise subgroup and 23% to 35% lower in the control subgroup. When the relative change from preconceptional levels in the weight-corrected oxygen requirements of the two subgroups was compared at the various time points of study, the decrease was significantly greater in the exercise subgroup in the seventh, fifteenth, twenty-fourth, and thirty-first weeks. At these time points, the relative decrease in the execise-stopped subgroup was between 33% and 54% of that observed in the exercise-continued subgroup with a peak difference of 104 ml/min in the thirty-first week. No significant difference between subgroups was observed at either 37 weeks or in the seventh week post partum.

Comment

These data support the basic hypothesis in an unambiguous fashion. First, they demonstrate that, in physically fit and active women, there is a consistent (16 of 18 subjects) decrease in the oxygen required to complete a series of progressive, low- to medium-load, antigravitational exercise tasks in the middle of the first

trimester despite a 3% increase in body weight. Furthermore, work efficiency, measured by the decrease in oxygen requirement for the vertical component of the exercise, was clearly increased at this point in pregnancy in both subgroups. Second, they indicate that the continuation of an endurance exercise training regimen during pregnancy significantly modifies the longitudinal change in oxygen required to complete the three workloads throughout pregnancy, as well as the longitudinal change in antigravitational work efficiency. Without adjustment for the effects of pregnancy weight gain, the changes in oxygen requirement were at least 15% less in the exercise-continued subgroup and the longitudinal changes in efficiency were at least 15% less in the exercise-stopped subgroup from the fifteenth week onward. Finally, the data indicate that the magnitude of the decrease in oxygen requirement in the exercise-continued subgroup and the increase in the exercise efficiency in both subgroups is obscured after the fifteenth week by the pregnancy-associated increases in maternal weight. For example, in the thirty-seventh week maternal weight gain should have increased the oxygen requirement for antigravitational work to a level approximately 40% above that observed before pregnancy. The fact that an increase of this magnitude was not observed clearly suggests a marked increase in efficiency that is documented by the weight-corrected data. Thus, when the data are adjusted for weight gain, the increased efficiency seen in the seventh week is maintained throughout the remainder of pregnancy in both subgroups with the improvement being greater in the women who maintained their preconceptional exercise regimens.

These findings and conclusions differ from those reported by others. Hutchinson et al.[11] reported that the oxygen required to run on the flat at 6 mph rose at a rate of 50 ml/month from the third month of pregnancy onward with a value 4 months post partum equivalent to that recorded in the third month. Unfortunately, measurements were not made either before conception or at the time we noted the initial decrease in the oxygen requirement, nor could these data be corrected for the impact of pregnancy weight gain and postpartum weight loss as no vertical work was done. Thus comparison with the present data is difficult. It is interesting, however, to note that the percentage change in weight exceeded the percentage increase in oxygen consumption during pregnancy and that the postpartum oxygen requirement exceeded that recorded in the third month of pregnancy, despite the fact that the subject weighed 1.6 kg less post partum. Both suggest that the weight-corrected oxygen requirement may well have been less during pregnancy, especially early pregnancy.

Knuttegen and Emerson[8] studied 13 pregnant women during treadmill exercise that was roughly equivalent to our 30% workload. The data reported clearly show that the mean oxygen requirement for the group fell post partum in rough proportion to the decrease in weight. In this regard the data from the current study are similar. On the basis of this single finding, however, the authors concluded that the increased stress of treadmill exercise during pregnancy is due to weight gain. In contrast, they noted that only two of the women showed a progressive increase in oxygen requirement for the protocol during pregnancy. This was not discussed further and the longitudinal trends observed in the other 11 women were not described, nor was the relationship between serial weight gain and oxygen requirement addressed. Clearly, it is possible that the weight-corrected oxygen requirement might have decreased over the latter half of pregnancy in 11 of the 13 subjects studied. Blackburn and Calloway[10] used a graded treadmill exercise protocol to study work efficiency serially throughout the latter half of pregnancy and post partum. They concluded that the caloric expenditure for the different workloads increased progressively during the latter half of pregnancy and fell post partum and that the cost per unit weight was unchanged over the time period of study. They also noted that efficiency might actually be increased if one subtracted the resting caloric expenditure, which also rose progressively. Unfortunately, although their data allowed it, they did not pursue the issue of efficiency further by calculating the longitudinal change in the caloric requirement for vertical work. When this is calculated without a correction for weight gain, the caloric requirement to climb at a rate of 8 m/min was decreased by 12% between the twentieth and thirty-sixth weeks of pregnancy when compared with the cost post partum and was no different from the postpartum value between the thirty-seventh and fortieth weeks. Thus their data indicate that work efficiency is improved in pregnancy and are actually in substantial agreement with those obtained in the current study.

Despite these findings, however, it is clear that the oxygen cost of vertical work increases in direct proportion to weight gain and decreases in direct proportion to weight loss in nonpregnant subjects studied serially during changes in either fat mass[14] or weighted load.[15] Thus it appears that there is a fundamental change in the efficiency of uphill walking associated with pregnancy, but the mechanism for this change is unclear. While pregnancy-associated factors such as the change in the center of gravity and stride length could potentially influence efficiency, the magnitude of the change suggests either a fundamental improvement in contractile efficiency at a cellular level or an unappreciated systematic error in data accrual. Factors favoring the former explanation are speculative at this time but include the increases in metabolic efficiency associated with training and with nutritional and work stress,[16-18]

*Significant difference from preconceptional values.

particularly when heavy physical activity and nutritional stress are combined in pregnancy.[18] The most likely factors to cause a systematic error would be the presence of a training effect, an anaerobic metabolic component, or a marked oxygen debt. The first is quite unlikely because we found no evidence to support a training effect in our initial replicate studies nor have others seen it at similar intensities.[8, 10, 14] The second, although possible, is unlikely for several reasons. First, these were serial studies in very fit subjects and the workloads were light to moderate. Second, in earlier studies in similar women, lactate levels actually fell with exercise of slightly greater intensity than this during mid and late pregnancy.[13] Finally, a pregnancy-associated increase in oxygen debt is a real possibility noted or considered by others.[9, 10] This, however, was not measured in the current study for several reasons. First, the study design, with three progressive workloads without separate recoveries, did not allow us to measure it for each workload independently. Second, there is no evidence that the oxygen debt accrued at the very beginning of muscular activity is increased further by a change in exercise intensity of this magnitude. Third, in the current study we assessed changes in efficiency from the change in the difference in oxygen consumption produced by a change in grade. Any potential oxygen debt should not influence this measurement. Thus an increase in oxygen debt also appears to be an unlikely explanation.

As we only determined maximum oxygen consumption before pregnancy (human subject safety concerns), one must consider whether a pregnancy-associated increase or decrease in an individual's maximum oxygen consumption would in and of itself influence the oxygen required to perform a set, progressive load, treadmill exercise task. Training and detraining data in pregnancy[19] suggest that the associated increases and decreases in maximum oxygen consumption are reflected by changes in the relative oxygen requirement for a standard task (percent of maximum oxygen consumption). There is no evidence, however, that a change in maximum oxygen consumption significantly influences the absolute oxygen requirement for a standard task (milliliters per minute).[20] Thus exercise performance should influence perceived exertion, heart rate, etc., but should not affect the absolute oxygen requirement. In the current study we assumed that changes in maximum oxygen consumption would not change the absolute oxygen requirement and used maximum oxygen consumption only as a means to standardize the relative preconceptional oxygen requirements (intensity) for the progressive workload task between individuals. Because of differences in weight and efficiency, the actual individual absolute oxygen requirements and tasks were quite different. Once set, each individual's progressive workload task did not change in the subsequent testing periods. While it is likely that maximum oxygen consumption and therefore the relative oxygen requirement (percent of maximum) changed during pregnancy as a function of exercise performance, in and of itself, this should not have influenced the absolute oxygen requirement for performing the identical progressive workload task.[20] The latter would be influenced by weight[15, 16] and the other efficiency-related factors discussed above.

In summary, the data obtained in this prospective, serial study of a fairly uniform, physically fit populace support the initial hypothesis. They indicate that in this populace the efficiency of low- to moderate-intensity exercise is increased throughout pregnancy and that the increase is enhanced in women who choose to continue their training regimens throughout pregnancy. Review of several earlier studies suggests that these findings also may apply to less physically active groups of women. Currently, the mechanism responsible for the pregnancy-associated change in efficiency is not understood.

Exercise prescription in pregnancy: Weight-bearing versus non-weight-bearing exercise

Raul Artal, MD, Damon I. Masaki, MD, Nazareth Khodiguian, PhD, Yitzhak Romem, MD, Susan E. Rutherford, MD, and Robert A. Wiswell, PhD

Los Angeles, California

Bicycle ergometry (non-weight-bearing exercise) and treadmill (weight-bearing exercise) were compared to assess physiologic responses to similar work loads. A total of 22 subjects at 29.3 ± 1.6 (±SEM) weeks' gestation who performed non-weight-bearing exercise were compared with 15 similarly fit subjects at 26.1 ± 2.3 weeks' gestation who performed weight-bearing exercise at three submaximal levels. Measurements by indirect calorimetry indicate preferential carbohydrate use during non-weight-bearing exercise at submaximal levels. (Am J Obstet Gynecol 1989;161:1464-9.)

Key words: Exercise prescription in pregnancy

Exercise is routinely prescribed because of various clinical conditions in nonpregnant patients. Recently, exercise has been proposed as adjunctive therapy for gestational diabetes.[1] It appears that exercise facilitates the use of glucose uptake by postreceptor mechanisms that regulate glucose transport and intracellular glucose metabolism.[2, 3] Because gestational diabetes is a disease of glucose intolerance, therapeutic modalities to overcome this resistance and improve glucose metabolism may be preferred rather than insulin administration. If exercise can successfully maintain normoglycemia and avert the use of insulin in patients with gestational diabetes, this could reduce maternal and infant morbidity and avoid complications related with insulin therapy.

Exercise prescription requires knowledge of poten-

tial risks, general physical condition, and work capacity to estimate the training intensity necessary to induce conditioning or desired effects. To establish the safety of exercise therapy in gestational diabetes a pilot study was performed.[4] We investigated the effects of mild treadmill exercise on normal mothers and their infants as well as pregnancies complicated by gestational diabetes and reported no immediate adverse effects.

Exercise prescription in the treatment of gestational diabetes is investigational. Therefore exercise studies on substrate use during pregnancy are needed. One method to assess substrate use is indirect calorimetry through determinations of the respiratory exchange ratio (R). R is a respiratory variable that reflects the ratio between carbon dioxide output (VCO_2) and oxygen uptake (VO_2) and provides information on the proportion of substrate derived from various foodstuffs.[5,6] If carbohydrates are completely oxidized to CO_2 and water (H_2O), one volume of CO_2 is produced for each volume of O_2 consumed. Hence an R value of 1.0 would indicate that only carbohydrates are being used ($C_6H_{12}O_6 + 6\ O_2 \rightarrow 6\ CO_2 + 6\ H_2O$; $R = VCO_2/VO_2 = 6/6 = 1.0$). An R value of 0.7 would indicate that fats are being burned. Any value between 0.7 and 1.0 would reflect the relative proportion of carbohydrate and fat being used.

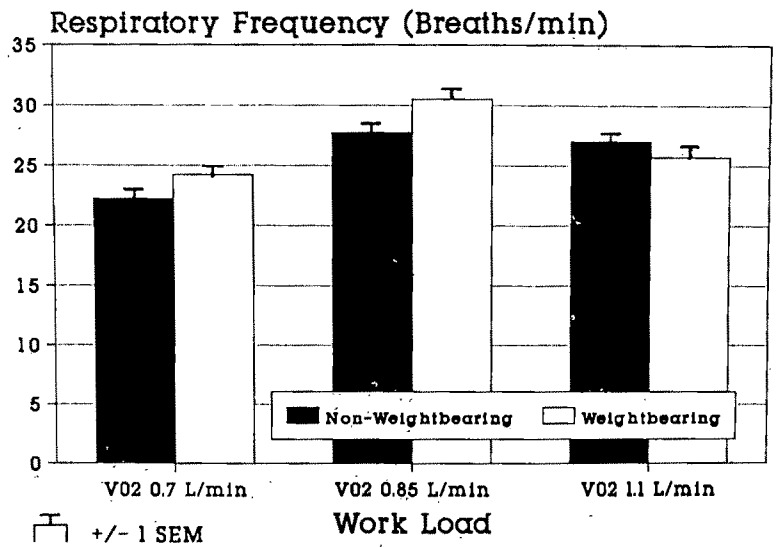

Fig. 5. Respiratory frequency (breaths/min) during non-weight-bearing (bicycle ergometry) and weight-bearing (treadmill) exercise at incremental work loads.

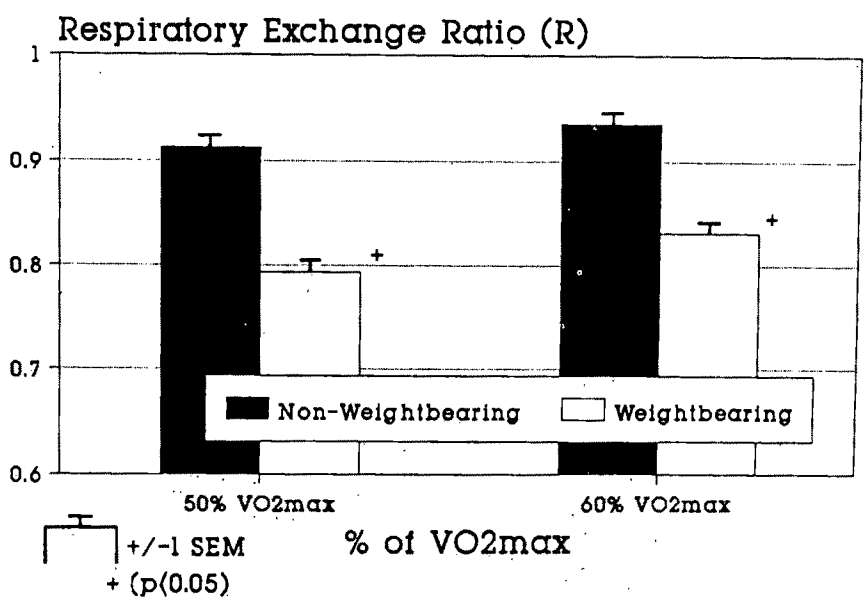

Fig. 6. Respiratory exchange ratio at 50% and 60% of the individual VO_2max.

The objective of this study was to compare different exercise regimens and responses between non-weight-bearing exercise such as bicycle ergometry and weight-bearing exercise such as the treadmill in persons with uncomplicated pregnancies.

Material and methods

A total of 37 healthy pregnant subjects were studied after informed consent was obtained. The subject characteristics are summarized in Table I. On the basis of an intake questionnaire, both groups were found to be of similar low-to-average levels of fitness judged by their regular physical activities and later confirmed by similar maximal O_2 uptake (VO_2max) stress test. A total of 22 subjects performed bicycle ergometry exercise and 15 subjects performed treadmill exercise. The participants were not randomly assigned in the study; group assignment was not stratified but rather was based on date of entry into the study. Bicycle ergometry exercise involved work loads of 25, 50, and 75 W with steady state achieved in 7 minutes with 5-minute rest periods between stages. To achieve VO_2max an initial work load of 75 W with increasing increments of 25 W every 2 minutes was performed. A modified Balke protocol was used in the treadmill group.[7] The intensity of exercise was started at 2.5 mph at 0% eleva-

tion and was increased 2% every minute until exhaustion. Similar submaximal levels of exercise were performed by both groups. For the purpose of analysis, the levels of exercise were quantitated by the level of VO_2 by arbitrarily chosen increasing work loads. The data were grouped by incremental work loads of $VO_2 = 0.7 \pm 0.05$ L/min, $VO_2 = 0.85 \pm 0.05$ L/min, and $VO_2 = 1.1 \pm 0.05$ L/min. In addition, to obtain uniform standardized data independent of weight and level of fitness, the R data were then grouped and analyzed at points that corresponded with the 50% and 60% of the individual VO_2max (see Fig. 6).

VCO_2, VO_2, ventilatory parameters, and maternal heart rate were measured at each work load. The Beckman Metabolic Measurement Cart (model MMC) with open circuit spirometry was used for all measurements. The equipment was calibrated daily before the experiments were started. Indirect calorimetry was used to derive R.[5]

Fetal heart rate (FHR) and uterine activity were continuously monitored before and after exercise with a Corometrics fetal monitor (model 140). FHR and uterine activity were also monitored during exercise when technically feasible. Unpaired Student *t* test analysis with the use of MR-TOD (Medical Research–Time Oriented Data base, Seattle, Wash.) for statistical significance were performed with α equal to 0.05.

This investigation was approved by the University of Southern California School of Medicine Human Research Committee.

Results

Table I presents the subject characteristics of both the non-weight-bearing and weight-bearing exercise groups. No statistical differences were found between the subject characteristics at rest.

Figs. 1 to 5 summarize maternal heart rate response, R values, VCO_2, and ventilatory parameters (tidal volume and respiratory frequency). Maternal heart rate responses were similar in both groups. The R values were significantly higher during non-weight-bearing exercise than during weight-bearing exercise. This difference was consistent at all preset submaximal levels of exercise (Fig. 2) and at 50% and 60% of the individual VO_2max (Fig. 6). VO_2 levels were similar at each submaximal work load by study design. Inasmuch as R is derived from the ratio of the VCO_2 to VO_2, the higher R values reflect elevated VCO_2 as seen in Figs. 2 and 3. Ventilatory parameters were similar in both groups at each submaximal work load.

FHR monitoring showed good reactivity and rare uterine contractions before, during, and after exercise.

Comment

Comparative physiologic studies between weight-bearing and non-weight-bearing exercise have not been previously conducted in pregnancy. A similar respiratory tidal volume while pedaling the bicycle ergometer at the same VO_2 and while walking on the treadmill were reported in prior studies in nonpregnant subjects.[8,9] Similarly, in our study at submaximal work loads the tidal volumes were not statistically different. In our study, bicycle ergometry induced hyperventilation only at VO_2max, as compared with walking.

The use of the R value to assess energy use is valid if no ventilatory abnormalities exist such as hyperventilation, which would increase VCO_2 and therefore increase the R value. Such differences in ventilation were noticed in our study only at VO_2max.

The significantly higher R values in the non-weight-bearing exercise group during exercise may reflect preferential carbohydrate use over lipids during non-weight-bearing mild exercise in comparison with weight-bearing mild exercise in pregnancy. This observation in our study was independent of the fitness level and weight as reflected by similar VO_2max/kg values in the two groups as summarized in Table I and Fig. 6.

Theoretically, during prolonged exercise higher lactate values could be associated with an elevation in R. The lactate is buffered by sodium bicarbonate and results in excess CO_2 formation that is independent of fuel metabolism.[10] Elevated lactate production during bicycle ergometry that leads to metabolic acidosis could explain the higher R values. This is unlikely to occur in brief exercise sessions as performed by our subjects.

One potential clinical application of this finding is its use as an alternative therapeutic modality to gestational diabetes. Because gestational diabetes appears to be a state of impaired glucose use, noninsulin intervention would be advantageous. The preferential carbohydrate use during brief non-weight-bearing exercise in comparison with weight-bearing exercise during pregnancy requires further investigation. This preferential use of carbohydrates may be a result of the anaerobic component of this type of non-weight-bearing exercise.

Recognition of potential risks is essential when exercise is prescribed. Comparative studies such as this one allow an assessment of physiologic responses. The risks involved with exercise in pregnancy in previously sedentary obese individuals include soft tissue musculoskeletal injuries.[11] The anatomic changes of pregnancy that include laxity of joints and ligaments, coupled with a continuous shift in the center of gravity and increasing weight, place sedentary persons at higher risk for injuries (primarily in weight-bearing activities) during exercise. Thus certain types of exertion such as weight-bearing exercise may not be suitable for this type of subject. This body weight and the change in the point of gravity have a much smaller effect on bicycle ergometer performance and therefore less risk of injury is involved.

Should exercise become a therapeutic modality for women with gestational diabetes or in the otherwise normal sedentary person, it appears from these preliminary studies that non-weight-bearing exercise such as bicycle ergometry may be the preferred form of exercise to be prescribed.

Human fetal behavioral states after vibratory stimulation

Robert Gagnon, MD, Cora Hunse, RN, and John Foreman, PEng
London, Ontario, Canada

A total of 14 healthy pregnant women between 37 and 41 weeks' gestational age were studied to determine the effects of a 5-second external vibratory stimulus (100 Hz, square wave) on human fetal behavioral states. Fetal behavioral state observations were made with simultaneous recordings of fetal heart rate, gross fetal body movements, and fetal eye movement between 8:30 AM and 4:00 PM. During the first episode of behavioral state 1F (quiet sleep state) ≥10 minutes duration on two consecutive half days, the vibratory stimulus was placed on the surface of the maternal abdomen over the fetal head. Each fetus received one 5-second vibratory stimulus during either the first or second half day of observation. The time at which the instrument was applied but no vibratory stimulus was administered was considered as the control period. All women were then observed for 2 hours after the control period and after stimulation. A transition period from a quiet sleep state to a stable active sleep state (state 2F, rapid eye movement sleep) averaged ≤3 minutes after stimulation, as compared with 23 minutes after the control period. These changes in fetal behavioral states persisted for 20 minutes after vibratory stimulation. There also was an immediate and sustained increase in long-term fetal heart rate variability, the number of fetal heart rate accelerations and gross fetal body movement during the first 20 minutes after stimulus, without changes in basal fetal heart rate. We hypothesize that changes in fetal behavior seen after application of low frequency vibratory stimulus are more physiologic than the profound changes in fetal heart rate and gross fetal body movement previously described after vibratory acoustic stimulation with an electronic artificial larynx. (AM J OBSTET GYNECOL 1989;161:1470-6.)

Key words: Human fetal behavior, sound and vibration, fetal heart rate

Healthy human fetuses undergo rest-activity cycles that are usually related to different behavioral states.[1] It is believed that human fetuses may change from a state of sleep to a state of wakefulness as a result of vibratory acoustic stimulation.[2, 3] Recently, low-frequency vibration as a source of external stimulation has been suggested as the cause of the increase in fetal heart rate (FHR) reactivity[4] and as a possible means to decrease the length of nonstress tests.

The aim of this study was to investigate the effect of an external vibratory stimulus on fetal behavioral states in a group of healthy human fetuses at term.

Patients and methods

Patients. Informed consent was obtained from 16 pregnant women between 37 and 41 weeks' gestational age. All remained in good health and had normal term deliveries that confirmed gestational age and the good health of the fetuses studied. The average gestational age at delivery was 40.5 ± 0.4 weeks (SEM). The average weight of the fetuses at birth was 3664 ± 141 gm (SEM). No Apgar score was <8 at 5 minutes. Umbilical cord blood arterial samples were obtained at birth in all fetuses. The mean umbilical arterial P_{O_2} was 17.1 ± 1.2 mm Hg, the P_{CO_2} was 54.1 ± 2.0 mm Hg, and the pH was 7.28 ± 0.01. Two (12.5%) women were delivered of infants by cesarean section because of cephalopelvic disproportion. All fetuses were in vertex presentation at the time of delivery.

Experimental design. The women received a standardized 800 kcal breakfast or lunch at 8:00 AM or 12:00 PM, respectively. All studies began 30 minutes later at 8:30 AM or 12:30 PM and were conducted in a quiet room with the patients either sitting upright in bed or resting in a lateral recumbent position. Women were asked not to smoke for ≥4 hours before the studies. Smoking or food intake by patients or observers was not permitted during the studies.

The external vibratory stimulus used in this study was generated with a Model 4810 minishaker (Bruel and Kjaer, Copenhagen, Denmark) matched with a minishaker power amplifier (Department of Mechnical Engineering, University of Western Ontario, London, Ontario, Canada), firmly applied on the maternal abdomen. The signal was generated with the output of a Fast Fourier Transform analyzer (Model SP-20, Sig-

nology, Campbell, Calif.) and adjusted to generate a square wave of 100 Hz during 5 seconds. During a pilot study in our laboratories (Gagnon et al. Unpublished observations), this type of stimulus was associated with a more consistent fetal response than a sine wave of the same frequency or higher frequencies. The surface of the minishaker in contact with the maternal abdomen was 9.6 cm^2, which was approximately twice the moving surface of the Model 5C electronic artificial larynx (4.9 cm^2; Western Electric, New York, N. Y.). The surface of the instrument vibrated at a fundamental frequency of 100 Hz with multiple harmonics up to at least 5000 Hz.[4] The maximum force of vibration was 48 dB at 100 Hz, equivalent to an absolute force of 4.35×10^{-3} N.[4] A similar spectrum of vibration (maximum force of 45 dB at 100 Hz) is produced by the electronic artificial larynx.[5]

All patients were acclimatized by touching the surface of the activated minishaker with their hand before the studies began. Women were studied continuously for 3½ hours on each of 2 half days. Fetal behavioral state observations were made with simultaneous recordings of FHR, gross fetal body movement, and fetal eye movement between 8:30 AM and 4:00 PM. During the first episode of behavioral state 1F (FHR, pattern A; gross fetal body movement, incidental; fetal eye movement, absent)[1] on each consecutive half day, the minishaker was placed on the surface of the maternal abdomen over the fetal head. The device was applied only after the fetus has been in state 1F for 10 minutes. This technique allowed us to synchronize all fetuses in the same behavioral state (quiet sleep state) for the same length of observation (10 minutes) just before both the stimulus and the control were applied. Each fetus received one 5-second vibratory stimulus during either the first or second half day of observation. Patients were informed that the stimulus might or might not be activated during the two times that the instrument was placed on the abdomen. The choice of whether to stimulate the abdomen during the first or second episode of state 1F was made from random number tables. The time at which the instrument was applied but no vibratory stimulus was administered was considered as the control period. All women were observed for 2 hours after the control period and stimulation.

One healthy fetus did not show evidence of any episode of state 1F after 3 hours of continuous observation, and fetal eye movements could not be adequately visualized in another fetus. These two study participants were excluded from further analysis.

FHR measurement. FHR was recorded with a Hewlett Packard Model 8040 A external monitor (Hewlett Packard GMBH, Boeblinger, Federal Republic of Germany) with a compact transducer and was analyzed on-line by a Sage II microprocessor (Sage Technology, Reno, Nev.) as previously described.[2,6] During analysis, a baseline was fitted to the heart rate record and FHR accelerations ≥10 beats/min for ≥15 seconds above the baseline were automatically detected. For each 10-minute interval, the basal FHR (beats/min), the number of FHR accelerations, the total gained beats (total area of FHR accelerations above the baseline), and the mean minute range (milliseconds) were calculated on-line.

Measurement of fetal activity. Fetal breathing movement and gross fetal body movement were measured with a real-time ADR ultrasound scanner (Model 2130, Advanced Diagnostic Research Corp., Tempe, Ariz.) and were analyzed on-line in 10-minute intervals with a PDP 11/34 minicomputer as previously described.[7] Individual gross fetal body movement and fetal breathing movement were identified on a video monitor and coded with an event marker. With the use of this technique, the agreement between observers to detect fetal breathing movement and gross fetal body movement is 94%.[7] The 3.5 MHz transducer was positioned over the maternal abdomen to permit continuous observation of a longitudinal cross-section of fetal chest and abdominal wall echoes.[7]

Measurement of fetal eye movement. A second real-time ultrasound scanner (Model SAL-30A, Toshiba Corp., Shimoishi, Japan) was used to identify fetal eye movement. The 3.5 MHz transducer was positioned on the maternal abdomen so that an oblique cross-section of the fetal face was obtained.[8] In such a section one of the fetal eyes can be seen as a sonolucent globe, behind which lies a wedge-shaped echo-rich area. Fetal eye movement can be detected easily in the real-time image as small movements in the periphery of the sonolucent area and in the retroocular echo-rich area.[8] Individual fetal eye movements were identified on a second video monitor adjusted to magnify the size of the real-time image approximately eight times and the movements were coded with an event marker. The interobserver agreement to detect fetal eye movement with real-time image is reported to be 90%.[8]

Measurement of fetal behavioral states. FHR tracing, gross fetal body movement, fetal breathing movement, fetal eye movement, and failed time were recorded on an eight-channel chart recorder (Model 7, Grass Instrument Co., Quincy, Mass.). Electrical signals from the analog output of the HP 8040A external monitor and the two event markers were processed by means of a common mode rejection preamplifier (Model 7, P51 IJ, Grass Instrument Co.). The paper speed was adjusted at 25 mm/min for off-line analysis of fetal behavioral states.

Data analysis. The basal FHR, the number of FHR accelerations ≥10 beats/min for ≥15 seconds above the baseline, the total gained beats, and the mean minute range were determined for successive 10-minute intervals. Portions of records that could not be analyzed

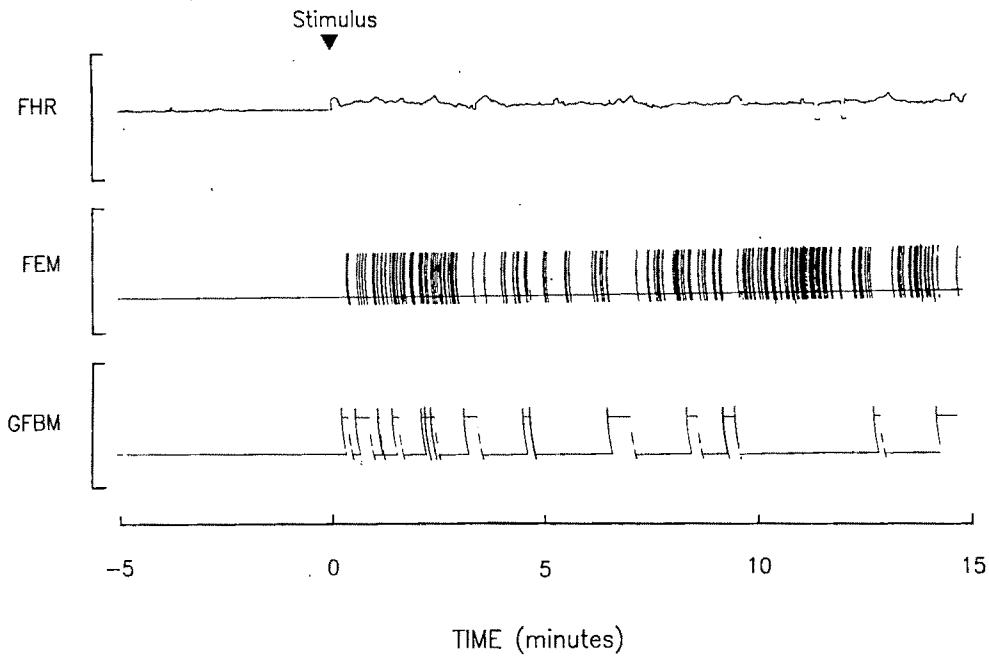

Fig. 1. Typical example of transition from state 1F (quiet sleep state) to state 2F (rapid eye movement sleep state) after 5-second external vibratory stimulation *(arrow)* in healthy term human fetus. (*FHR*, fetal heart rate; *FEM*, fetal eye movements; *GFBM*, gross fetal body movements).

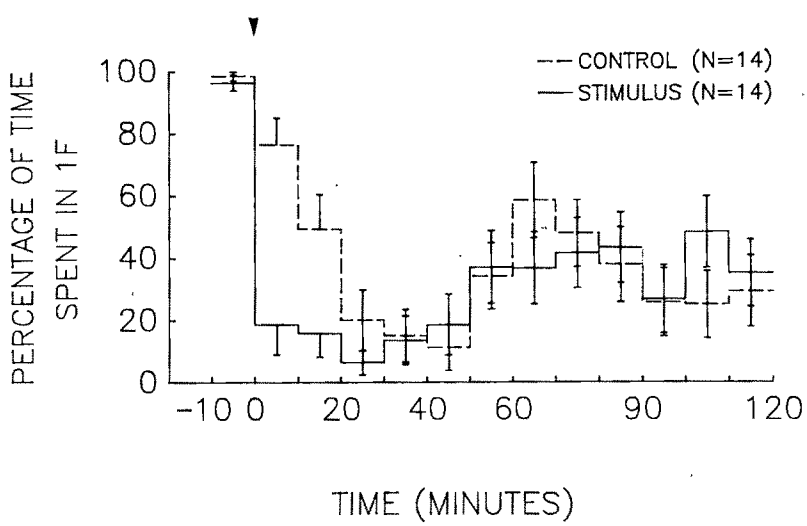

Fig. 2. Mean incidence of coincidence 1F (±SEM) was plotted in 10-minute intervals before and after stimulation (——) or control (- - - -).

because of FHR signal loss of >30% or patient interruption were not included. These portions made up 5.0% of the total study time.

Measurements of the percentage of time spent making gross fetal body movements, the percentage of time spent making breathing movements, and the frequency distribution of breath-to-breath intervals were calculated for each 10-minute interval of the 61 hours of total observation time. Portions of movement records that could not be analyzed because of technical problems or patient interruption made up 5.1% of the total study time.

Each of the three fetal behavioral state variables (body movement, eye movement, and FHR pattern) were analyzed separately for condition (parameter for presence or absence of body and eye movement; for heart rate patterns A through D) with the use of a 3-minute moving window advanced in half-minute steps.[1] The result of this procedure was a profile that shows the changes of each variable between its possible con-

ditions (parameters). The three behavioral state variables were then analyzed simultaneously to identify epochs in which the parameters of all three were present in the previously defined combinations.[1] Periods during which the parameters of the behavioral state variables were present in the previously defined combinations were called periods of coincidence 1F to 4F, respectively. To accept the presence of behavioral states, the defined combinations of the behavioral state variables had to persist ≥3 minutes without interruption and transitions from one of the specified combinations to another had to be completed within a maximum of 3 minutes. Portions of fetal eye movement records that could not be analyzed because of technical problems made up 6.0% of the total study time.

Results are presented as means and SE (±SEM). Statistical significance between groups for the 10 minutes before and the 2 hours after the stimulation or the control period was determined by a two-way analysis of variance that compared overall means and each of the 10-minute intervals.[9]

Results

Fetal behavioral states. An example of the changes in fetal behavioral states after external vibratory stimulus is shown in Fig. 1. All fetuses were in state 1F (quiet sleep state) before application of the stimulus or the control period. The mean incidence of coincidence 1F (quiet sleep state) decreased to 18.6% ± 7.5% (SEM) during the first 10 minutes after stimulation, which was significantly lower than 76.4% ± 8.9% after the control period (analysis of variance, $p < 0.01$) (Fig. 2). The percentage of time spent in the quiet sleep state remained below control values up to 20 minutes after the 5-second vibratory stimulus (Fig. 2). The mean incidence of fetal eye movement was 71.4% ± 10.9% during the first 10 minutes after vibratory stimulation and remained above control values (5.0% ± 2.0%) for 20 minutes (analysis of variance, $p < 0.01$) (Fig. 3). Similarly, the mean incidence of coincidence 2F (rapid-eye movement sleep state) increased up to 65.0% ± 11.1% immediately after the stimulus was applied and remained significantly above control values for the first 20 minutes after vibratory stimulation (analysis of variance, $p < 0.01$) (Fig. 3).

In 12 (85.7%) fetuses, fetal behavioral states changed from a quiet (1F) to an active (2F) sleep state immediately after stimulus, two (14.3%) fetuses had isolated FHR accelerations without a shift in behavioral state, and one fetus changed to an indeterminate state characterized by the presence of continuous gross fetal body movement and small-amplitude FHR accelerations. The mean transition time from the time the minishaker was applied on the maternal abdomen to the onset of state 2F (FHR, pattern B; gross fetal body movement, present; fetal eye movement, present) was 3.1 ± 1.5 minutes after stimulation, which was significantly lower than after the control period (23.9 ± 4.0 minutes) ($p < 0.001$) (Fig. 4).

FHR and fetal activity patterns. The mean 10-minute mean minute range was 29.4 ± 4.1 msec before stimulation. After vibratory stimulation, the mean 10-minute mean minute range increased to 54.7 ± 7.0 msec during the first 10 minutes after application of the stimulus and remained above the control value (34.0 ± 4.6 msec) for 20 minutes (analysis of variance, $p < 0.01$). No significant change in the mean basal FHR was found after square wave vibratory stimulation (control value, 135 ± 2 beats/min). Fig. 5 shows that there was an immediate and sustained increase in both the mean number of FHR accelerations and the mean number of gross fetal body movements during the first 20 minutes after vibratory stimulation, as compared with the control period (analysis of variance, both $p < 0.01$).

It is important to note that all biophysical variables including FHR, FHR variability, gross fetal body movement, fetal eye movement, and the time spent in the different behavioral states followed similar patterns in both stimulus and control groups between 20 and 120 minutes after either the control period or application of the stimulus (Figs. 2, 3, and 5). Also, the maximum values in these variables after stimulation was not excessively high, as compared to the maximum values after the control period (Figs. 2, 3, and 5).

Comment

The 5-second external vibratory stimulation (100 Hz, square wave) used in this study was associated with significant changes in human fetal behavioral states at term. There was a transition from a stable quiet sleep state (1F) to a stable active sleep state (rapid eye movement sleep, 2F), within 3 minutes after the application of this stimulus on the surface of the maternal abdomen. These changes in fetal behavioral states persisted for 20 minutes and did not exceed the maximum time spent in an active sleep state after spontaneous transition from state 1F to state 2F after the control period. There also was an immediate and sustained increase in long-term FHR variability and in the number of FHR accelerations and gross fetal body movements during the first 20 minutes after stimulation, without changes in basal FHR, which confirms previous observations.[4]

Behavioral states in healthy term newborns alternate between state 1 (quiet sleep) and state 2 (rapid eye movement sleep).[10, 11] At the time of feedings, there is a shift from state 2 to state 3 (quiet wakefulness) and ultimately to state 4 and state 5 (wakefulness and crying, respectively).[11] The well-organized pattern of these spontaneous and progressive changes in newborns is

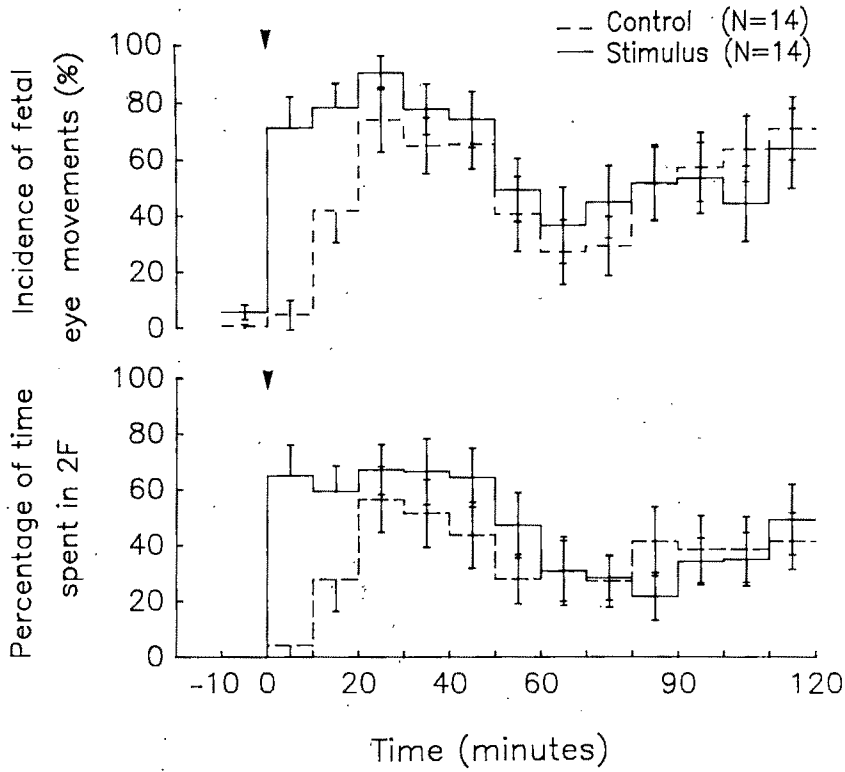

Fig. 3. Mean incidence of fetal eye movements and mean incidence of coincidence 2F were plotted in 10-minute intervals before and after stimulation (——) or control (- - - -).

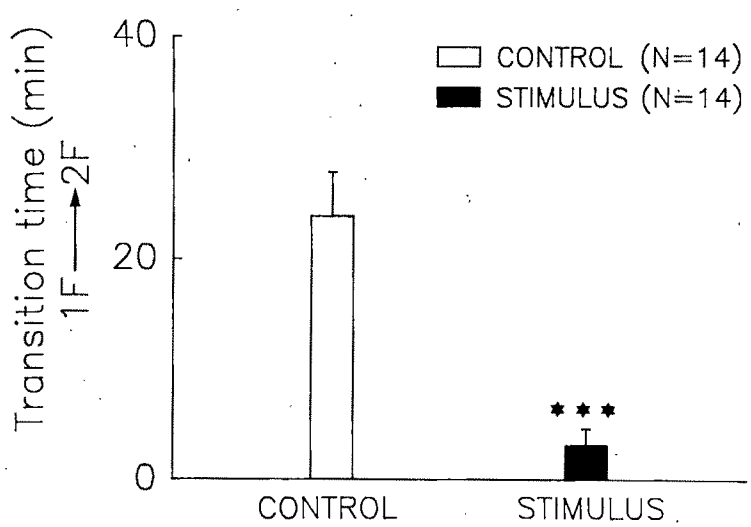

Fig. 4. Mean transition time (±SEM) from time vibratory stimulus *(closed bar)* or control *(open bar)* was applied to onset of state 2F is shown.

believed to reflect the integrity of the central nervous system.[11] Nijhuis et al.,[1] with use of real-time ultrasonography, observed that fetuses of 36 week's gestation had developed states that were, in their organization, fully comparable to the states originally described by Prechtl et al.[10] in neonates. In contrast with the neonates, FHR pattern has been used as a state criteria because it can be easily recorded and four specific patterns can be clearly defined related to the four different fetal behavioral states. FHR pattern B, which is usually seen after vibratory stimulation (Fig. 1), has been defined as a wide oscillation band width with frequent accelerations during fetal movements that occurs during state 2F (rapid eye movement sleep).[1] Clinicians have recognized that the presence of FHR accelerations associated with fetal movements (FHR pattern B, Fig. 1) is a reliable indicator of fetal health.[12]

Hutt et al.,[13] in a series of carefully designed exper-

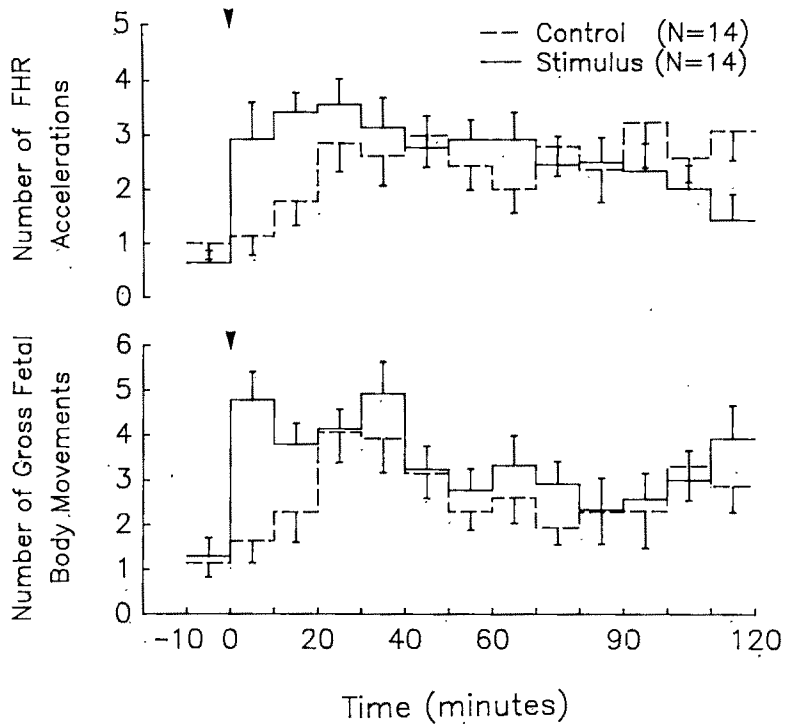

Fig. 5. Mean number of FHR accelerations and mean number of gross fetal body movements were plotted in 10-minute intervals before and after stimulation (——) or control period (- - - -).

iments, reported that acoustic broad-band signals (such as square wave pulses), at an intensity >90 dB sound pressure level could alter behavioral states in the 2- to 3-day-old healthy newborn. Such stimulation applied 10 cm from the newborn's ear during quiet sleep state generally produced a "startle reflex" followed by a period of rapid eye movement sleep state or by waking.[13] In our study, although the stimulus used was vibratory rather than acoustic, similar changes in fetal behavioral states were seen (Figs. 1 and 3). Whether or not such stimulus, after being transmitted through maternal soft tissues, could be perceived as an acoustic stimulation by the fetus remains to be determined. Although not measured in the current study, it is also possible that the pressure applied against the skin by the minishaker is a clinically significant variable that will need to be addressed.

Healthy human fetuses may take as long as 80 minutes to demonstrate activity.[14] To decrease the length of nonstress tests, external vibratory acoustic stimulation with an electronic artificial larynx has been suggested to increase FHR reactivity.[15] However, it has been shown in the pregnant ewe that the fetus might be exposed to extremely high sound pressure levels (135 dB) during stimulation with the electronic artificial larynx.[16] This might explain the excessive FHR and movement responses after stimulation with the electronic artificial larynx, which is believed to reflect a state of fetal wakefulness.[2, 3]

Human term fetuses that were exposed to vibratory stimulation underwent changes in behavioral states from a state of quiet sleep to an active sleep state that were similar to spontaneous changes seen in healthy newborns[11] and were typical of a reactive nonstress test.[12] This contrasted with the frequent occurrence of FHR pattern D (seen in wakefulness) characterized by large FHR accelerations often fused into sustained tachycardia after stimulation with the electronic artificial larynx.[2] Wakefulness state usually does not occur spontaneously after quiet sleep state in healthy term neonates.[11] Therefore it is possible to hypothesize that the changes in fetal behavior seen after low-frequency vibratory stimulation are more physiologic than the profound changes in FHR and fetal movements that occur after stimulation with the electronic artificial larynx.[2, 3]

The mechanisms by which an external source of sound or vibration can alter human fetal behavior are unknown. The clinical efficacy of such stimuli with regard to the prediction of fetal outcome and a decrease in the length of nonstress tests remains to be determined.

We thank Dr. J. Patrick for his interest in this work and Mrs. Maria de Sousa for her excellent technical assistance.

The effect of vibroacoustic stimulation on the nonstress test at gestational ages of thirty-two weeks or less

Maurice L. Druzin, MD, Terri G. Edersheim, MD, J. M. Hutson, MD, and Annette L. Bond, MD

New York, New York

The effect of vibroacoustic stimulation on the nonstress test at gestational ages of ≤32 weeks was studied in 15 patients who underwent a total of 316 nonstress tests starting at 20 to 25 weeks' gestation. There were 168 nonreactive nonstress tests that were followed by 3 seconds of vibroacoustic stimulation. The incidence of reactive nonstress tests after vibroacoustic stimulation was significantly increased after 26 weeks' gestation. This may have clinical applicability and may be related to functional maturation of the fetal auditory system. (Am J Obstet Gynecol 1989;161:1476-8.)

Key words: Vibroacoustic stimulation, nonstress test, preterm delivery

Fetal heart rate (FHR) accelerations have long been known to reflect fetal well-being. Vibratory acoustic stimulation has been used over the years to elicit FHR accelerations in an attempt to decrease the false-abnormal (nonreactive) nonstress test.[1, 2] Studies have shown that FHR accelerations in response to sound may reflect fetal well-being.[3, 4] This increase in heart rate may be related to a change in fetal state. This has recently been described as a startle response of the fetus.[5, 6] Fetal scalp stimulation resulting in FHR acceleration has been correlated with normal acid-base status.[7] Recently, FHR accelerations in response to vibratory acoustic stimulation have been shown to be predictive of fetal pH in labor.[8]

A recent study evaluated fetal accelerations in response to vibratory acoustic stimulation from 26 weeks to term and demonstrated what may be the normal neurodevelopmental status of the fetus.[9] It has been shown that the response to vibratory acoustic stimulation is active as early as 24 weeks' gestation when studied serially from 12 to 32 weeks.[10]

This study was undertaken to determine the effect

of vibratory acoustic stimulation on the fetus in terms of the nonstress test at gestational ages from 20 to 32 weeks.

Material and methods

Fifteen patients underwent 316 nonstress tests starting at 20 to 25 weeks of gestation. Six patients were volunteers with no obstetric risk factors. Nine patients underwent tests for preterm labor ($n = 4$), diabetes ($n = 2$), preeclampsia ($n = 1$), incompetent cervix ($n = 1$), or third-trimester bleeding ($n = 1$). The nonstress test is performed with an external system to monitor fetal movement, uterine contractions, and FHR. Uterine activity and fetal movements are obtained with a tokodynamometer strapped to the abdomen in conjunction with manual palpation of the uterus by the examiner. This method will register the frequency and relative duration but not the actual strength of the contractions. The patient is given an "event marker," with which she can register perceived fetal movements on the strip chart. Thus both the patient and the examiner may record fetal movements. The FHR can be derived from ultrasonographic phonocardiogram, or abdominal wall electrocardiogram signals. Ultrasonography will provide an adequate FHR tracing in up to 95% of the cases, while the success rate of the other two methods has been reported as 40% to 60% of cases.

A nonstress test is considered reactive (normal) if there are two accelerations of the FHR, ≥15 beats/min above the baseline, lasting at least 15 seconds, associated with fetal movement in a 20-minute period.

A nonstress test is considered nonreactive (abnormal) if the above criteria are (1) not met within an initial 20-minute period and (2) not met after vibratory acoustic stimulation is performed in a consecutive 20-minute period.

Vibratory acoustic stimulation was performed by using a single 3-second vibratory acoustic stimulus over the fetal vertex with the use of a Western Electric model 5C electronic artificial larynx. Sound pressure levels of this device measured at 1 m in air averaged 82 dB. Spectral analysis of the artificial larynx shows a fundamental frequency of 80 Hz; harmonics ranging from 20 to 9000 Hz are also observed. The fetal vertex was identified by Leopold maneuvers. In instances where the fetal position was unclear, ultrasonography was used to verify the location of the fetal vertex. FHR response was then observed after vibratory acoustic stimulation and the classification of the nonstress test was then determined.

Results

There were 168 nonreactive nonstress tests that were followed by vibratory acoustic stimulation applied for 3 seconds. The incidence of reactive nonstress tests after vibratory acoustic stimulation was significantly increased after 26 weeks of gestation (Table I). All neonates were appropriate for gestational age (>2800 gm) and all had 5-minute Apgar scores >8. One neonatal death was due to neonatal group B β-hemolytic streptococcal sepsis. There were no congenital anomalies.

Comment

A variety of sound frequencies and levels have been used in fetal vibratory acoustic stimulation to obtain a FHR response. It is thought that lower frequencies may evoke fetal tactile vibrational responses, as well as auditory responses. It is also thought that high frequencies (above 1500 Hz) have minimal vibratory influence and that a response is probably auditory in origin.[11] The study of two anencephalic fetuses revealed that there was no fetal response to vibratory acoustic stimulation in the anencephalic fetuses.[12] These authors therefore concluded that the fetal response to vibratory acoustic stimulation is mediated by auditory mecha-

nisms. This position is supported by other investigators.[10] Our study supports the impression that fetal response to vibratory acoustic stimulation occurs significantly more frequently after 26 weeks' gestation than before that gestational age. Recent studies suggest that there may be a threshold response to vibroacoustic stimulation.[13] Further studies are warranted to confirm this at various gestational ages. This finding may have clinical applicability and may be related to functional maturation of the fetal auditory system.

We acknowledge Audrey Waltner for her assistance.

Effects of low-frequency vibration on human term fetuses

Robert Gagnon, MD, John Foreman, PEng, Cora Hunse, RN, and John Patrick, MD
London, Ontario, Canada

Thirteen healthy pregnant women between 37 and 41 weeks' gestational age were studied to examine effects of a 5-second external vibratory stimulus (100 Hz, square wave) on fetal heart rate, fetal breathing, and gross fetal body movement patterns. All fetuses were stimulated during an episode of low fetal heart rate variability (mean minute range ≤32 milliseconds for ≥5 minutes) lasting at least 5 minutes. There was an immediate and sustained increase in long-term FHR variability, number of FHR accelerations, and gross fetal body movements after stimulation. Fetuses made breathing movements more irregularly after vibratory stimulus. We hypothesize that external low-frequency vibratory stimulus, applied during episodes of low fetal heart rate variability, causes a change from a state of quiet sleep to a state of rapid-eye-movement sleep in healthy term fetuses. (Am J Obstet Gynecol 1989;161:1479-85.)

Key words: Effects of vibration on human fetuses; human fetal behavioral states; proprioceptive fetal sensory receptors

External stimulation of human fetal sensory receptors with sound[1] or vibratory acoustic stimulation[2,3] has been suggested as a method of assessment of human fetal health. Fetal heart rate (FHR) responses to a pure-tone sound stimulus have been reported to be unpredictable and possibly dependent on the behavioral state at the time of the stimulus.[4] Although vibratory acoustic stimulation with an electronic artificial larynx can reproducibly alter FHR and fetal movement patterns during third trimester,[2,5] it is not yet clear whether the stimulus influences human fetuses by auditory or vibrational pathways.

The purpose of this study was to define, in a group of healthy fetuses at term, changes in fetal heart rate, fetal breathing, and gross body movements after a pure external vibratory stimulus applied during an episode of low FHR variability.

Patients and methods

Patients. Informed consent was obtained from 14 pregnant women between 37 and 41 weeks' gestational age. All remained in good health and had normal term deliveries that confirmed gestational age and the good health of fetuses studied. The average gestational age at delivery was 40.6 ± 0.2 weeks (SEM). The average weight of the fetuses at birth was 3765 ± 118 gm. The average 5-minute Apgar score was 9.2 ± 0.1. No Apgar score was <9 at 5 minutes. Umbilical cord blood arterial samples were obtained at birth in 12 of the 14 fetuses. The mean umbilical arterial Po_2 was 16.1 ± 1.2 mm Hg, the Pco_2 was 54.7 ± 3.2 mm Hg, and the pH was 7.27 ± 0.02. Three (21%) women were delivered by cesarean section (two because of failure to progress and one because of a footling breech presentation at the onset of labor). Thirteen fetuses were in vertex presentation and one was in breech position at the time of delivery.

Experimental design. The women received a standardized 800 kcal breakfast or lunch at 8 AM or 12 noon. All studies began 30 minutes later and were conducted in a quiet room with the patients either sitting upright in bed or resting in a lateral recumbent position. Women were asked not to smoke for at least 4 hours before the studies. Smoking or food intake by patients or observers was not permitted during the studies.

The external vibratory stimulus used in this study was generated with a model 4810 minishaker (Bruel and Kjaer, Copenhagen) matched with a minishaker power amplifier (Department of Mechanical Engineering, University of Western Ontario). A real-time, two-channel Fast Fourier Transform analyzer (model SP-20, Signology, Campbell, Calif.) having two input and one output channels was used. The digital output of the built-in signal generator was adjusted to generate a square wave of 100 Hz during 5 seconds. The quality and the amplitude of the signal generated by the Fast Fourier Transform analyzer and received by the minishaker were simultaneously recorded on-line with the two input channels. This procedure allowed us to

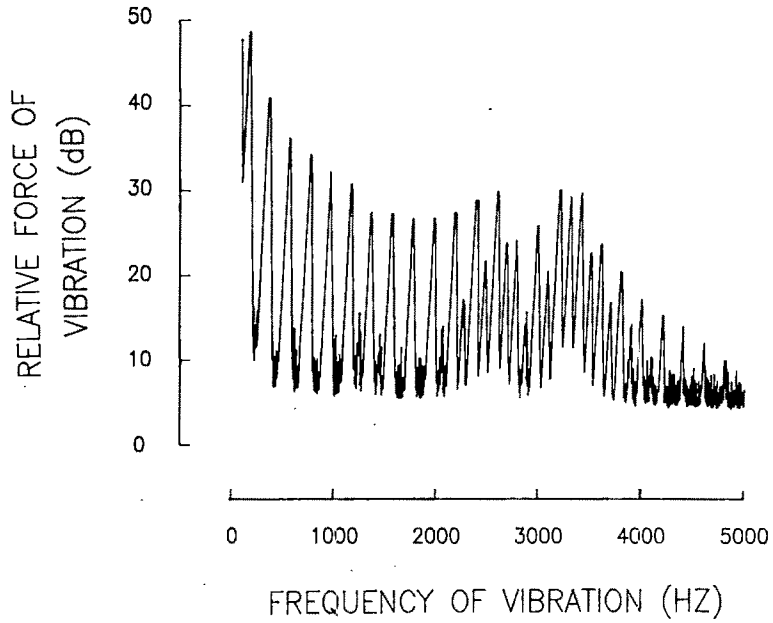

Fig. 1. Relationship between amplitude of vibration (decibels) and frequency of vibration (hertz) produced by minishaker (square wave, 100 Hz).

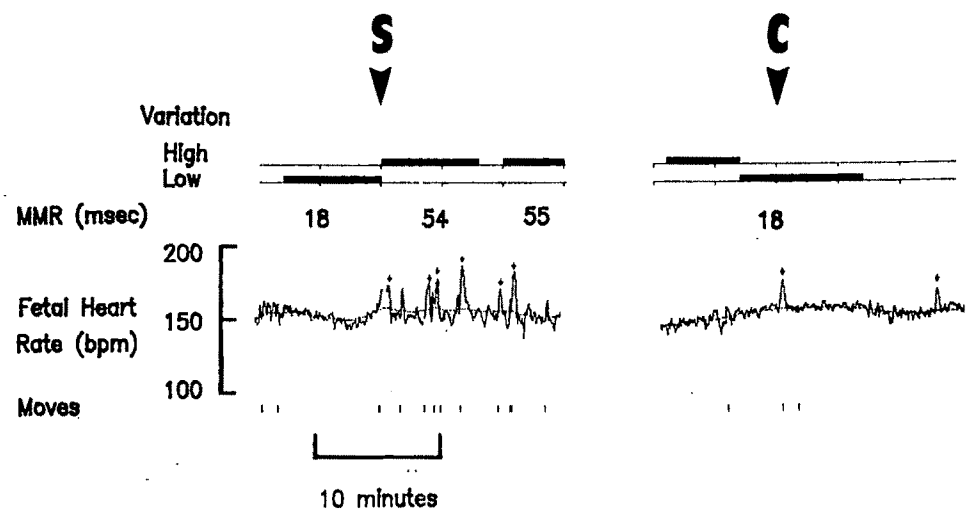

Fig. 2. Example of increase in FHR accelerations and fetal movements after application of a 5-second vibratory stimulus *(S)* during episode of low FHR variability.

apply a reproducible stimulus on the surface of the maternal abdomen.

The surface of the minishaker in contact with the maternal abdomen was 9.6 cm^2, which was approximately twice the moving surface of the electronic artificial larynx (4.9 cm^2). The surface of the instrument vibrated at a fundamental frequency of 100 Hz with multiple harmonics up to 4000 Hz, which are, by definition, the frequency components of a square wave (Fig. 1). The maximum force of vibration was 48 dB at 100 Hz (equivalent to an absolute force of 4.35×10^{-3} N; measurements made on the surface of the source with a model 086B80 impedance hammer, PCB Electronics, Boston; Fig. 1). A similar spectrum of vibration (maximum force of 45 dB at 100 Hz) is produced by the electronic artificial larynx.[6]

All patients had been acclimatized by touching the surface of the activated minishaker with a hand before the beginning of studies. Women were studied continuously for 4 hours. Episodes of low FHR variability (mean minute range of ≤32 milliseconds for ≥5 minutes) were automatically detected on-line by a Sage II microprocessor (Sage Technology, Reno) as previously described.[7,8]

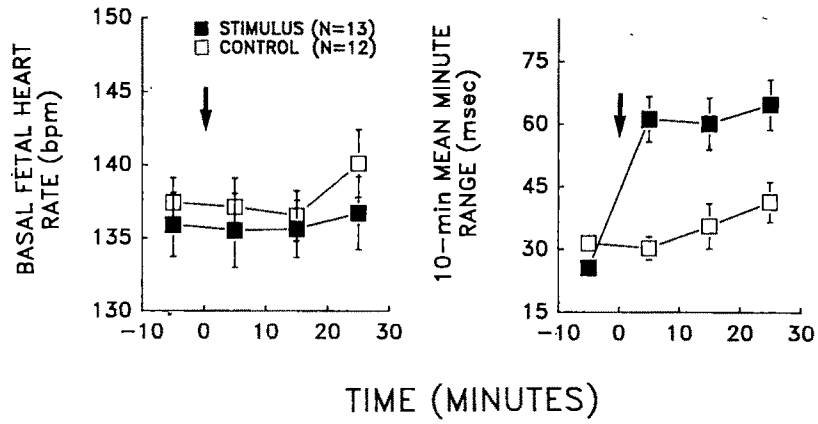

Fig. 3. Mean basal FHR (±SEM) and mean 10-minute mean minute range were plotted in 10-minute intervals before and after stimulus *(solid squares)* or control *(open squares)*.

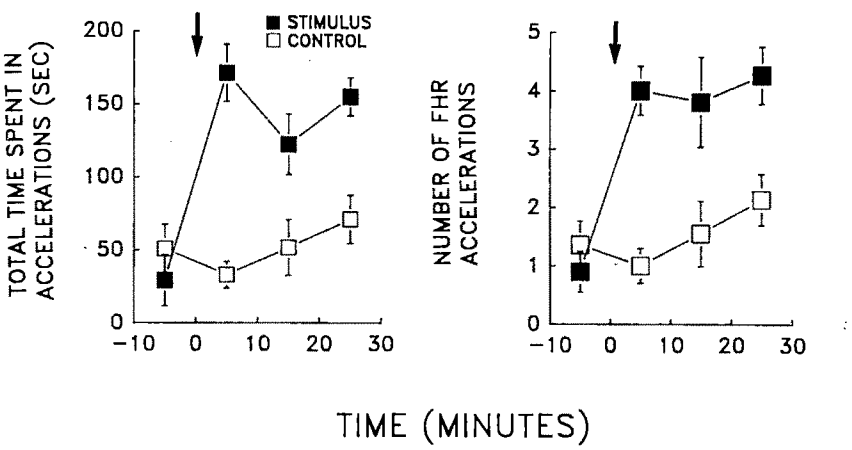

Fig. 4. Mean time spent in accelerations and mean number of FHR accelerations were plotted in 10-minute intervals before and after stimulus *(solid squares)* or control *(open squares)*.

During the first and second episodes of low FHR variability, the minishaker was placed on the surface of the maternal abdomen over the fetal head. Each fetus received one 5-second vibratory stimulus during either the first or second episode of low FHR variability of at least 5 minutes' duration. Patients were informed that the stimulus might or might not be activated during the two times that the instrument was placed on the abdomen. The choice of whether to stimulate the abdomen during the first or second episode of low FHR variability was made from random number tables. The time at which the instrument was applied but no vibratory stimulus was administered was considered the control period. All women received only one stimulus to the abdomen during individual studies and were observed for at least 30 minutes after control and stimulus.

One healthy fetus did not demonstrate any episode of low FHR variability after 4 hours of continuous observation and was excluded from further analysis.

FHR measurements. The FHR was recorded with a Hewlett Packard model 8040A external monitor (Hewlett Packard GmBH, Boeblinger, Federal Republic of Germany) with a compact transducer and analyzed on-line by a Sage II microprocessor (Sage Technology) as previously described.[7,8] During analysis, a baseline was fitted to the heart rate record and episodes of low (mean minute range ≤32 milliseconds for ≥5 minutes) and high (mean minute range >32 milliseconds for ≥5 minutes) FHR variability were recognized and updated automatically every 5 minutes.[8] FHR accelerations of ≥10 beats/min for ≥15 seconds above the baseline were automatically detected.

For each 10-minute interval the basal FHR (beats per minute) and the mean minute range (milliseconds) were calculated.

Measurements of fetal activity. Fetal breathing movements and gross fetal body movements were measured with a real-time ADR ultrasonographic scanner (model 2130, Advanced Diagnostic Research Corp., Tempe, Ariz.) and analyzed on-line in 10-minute intervals with a PDP 11/34 minicomputer (Digital Corp.,

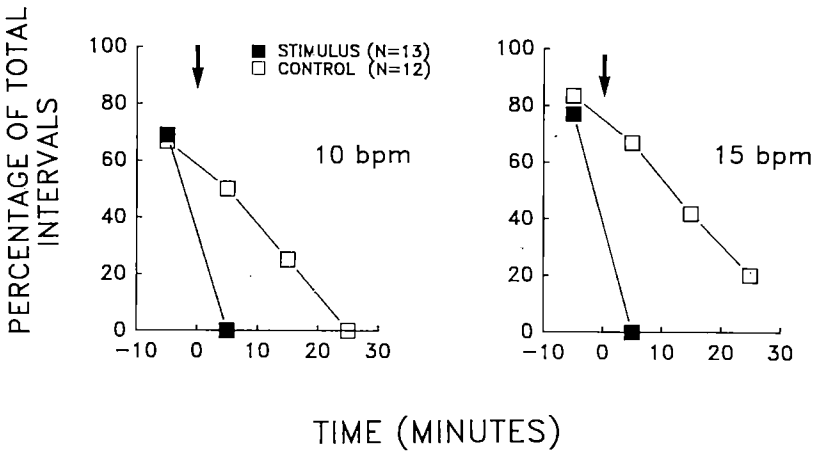

Fig. 5. Percentage of time intervals during which fewer than two FHR accelerations of ≥10 beats/min *(10 bpm)* and of ≥15 beats/min *(15 bpm)* for ≥15 seconds occurred was plotted for all fetuses before and after stimulus *(solid squares)* or control *(open squares)*.

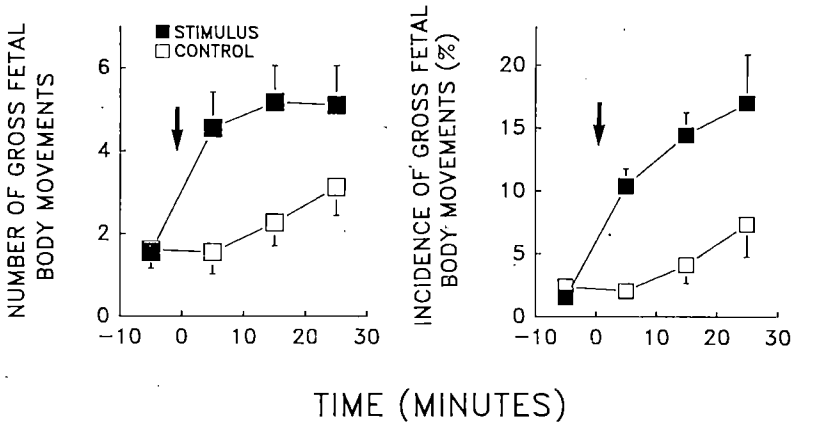

Fig. 6. Mean number and mean incidence of gross fetal body movements were plotted in 10-minute intervals before and after stimulus *(solid squares)* or control *(open squares)*.

Toronto) as previously described.[9] The transducer operated at a frequency of 3.5 MHz with an average intensity of 0.045 mW/cm². Individual gross fetal body movements and fetal breathing movements were identified on a video monitor and coded with an event marker. The transducer was positioned over the maternal abdomen to permit continuous observation of a longitudinal cross section of fetal chest and abdominal wall echoes.[9]

Data analysis. The basal FHR, the number of FHR accelerations of ≥10 beats/min for ≥15 seconds above the baseline, the duration and amplitude of individual FHR accelerations, the total time spent in accelerations, and the mean minute range were determined for successive 10-minute intervals. All results are presented as means ± SEM for successive 10-minute intervals during the 10 minutes before and the 30 minutes after stimulus or control. Portions of records that could not be analyzed because of FHR signal loss of >30% or patient interruption were not included. These portions made up 4.0% of total study time.

Measurements of the percentage of time spent making gross fetal body movements, the percentage of time spent making breathing movements, and the frequency distribution of breath-to-breath intervals were calculated for each 10-minute interval of the 25 hours of total observation time. Portions of movement records that could not be analyzed because of technical problems or patient interruption made up 5.0% of total time.

Statistical significance between groups before and after stimulus or control was determined by using a mixed, nested analysis of variance comparing overall means and each of the 10-minute intervals[10] with an HP 9845B microprocessor (Hewlett Packard, Computer Division, Fort Collins, Colo.).

Results

Basal FHR and FHR variability. An example of the FHR response after a pure vibratory stimulus, during an episode of low FHR variability (mean minute range = 18 milliseconds) at 39 weeks, is shown in Fig.

2. The mean 10-minute mean minute range was 25.6 ± 2.3 milliseconds before stimulus. After vibratory stimulation, the mean 10-minute mean minute range increased to 61.2 ± 5.4 milliseconds during the first 10 minutes after stimulus and remained above control for 30 minutes (analysis of variance, $p < 0.001$) (Fig. 3). No significant change in the mean basal FHR was found after square-wave vibratory stimulation (Fig. 3).

Characteristics of FHR accelerations. The mean total time spent in accelerations per 10 minutes was 29 ± 14 seconds before stimulus and increased to 149 ± 14 seconds during the 30 minutes after stimulation compared with 52 ± 11 seconds after control (analysis of variance, $p < 0.001$) (Fig. 4). Similarly, there was an immediate and sustained increase in the number of FHR accelerations from 0.9 ± 0.4 during the 10 minutes before stimulus to 4.0 ± 0.4 after vibratory stimulus (analysis of variance, $p < 0.001$) (Fig. 4). No significant change was found in the mean amplitude or the mean duration of FHR accelerations after either stimulus or control (34.4 ± 5.1 beats/min and 37 ± 5 seconds, respectively). It was important that all fetuses (100%) had more than two FHR accelerations during the first 10 minutes after vibratory stimulation with either 10 or 15 beats/min for acceleration amplitudes compared with 50% and 35%, respectively, after control (Fig. 5). This suggested that at least 50% of the fetal responses were due to vibratory stimulus compared with control.

Gross fetal body movements. Fig. 6 demonstrates that there was an immediate and sustained increase in both number and incidence of gross fetal body movements from 1.6 ± 0.3 and 1.5% ± 0.8% before stimulus to 5.0 ± 1.5 and 13.9% ± 1.9% during the 30 minutes after vibratory stimulus (analysis of variance, both $p < 0.001$).

Fetal breathing movements. Fetuses made breathing movements 26.9% ± 8.0% of the time during the 10 minutes before vibratory stimulation, and the incidence of breathing movements was not significantly altered by stimulus compared with control.

Fig. 7 demonstrates a histogram plot of the mean percentage of total breath-to-breath intervals in successive 0.5-second increments in 12 fetuses during the 10 minutes before control ($n = 11$) or stimulus ($n = 12$) (Fig. 7, *A*) and in the same fetuses during the 30 minutes after control or stimulus (Fig. 7, *B*). There was a skewed distribution of breath-to-breath intervals with a peak at 1.0 to 1.5 seconds before and after control (Fig. 7, *A* and *B*). However, during the 30 minutes after stimulus, there was a broad distribution of breath-to-breath intervals at 0.5 to 1.5 seconds without a well-defined peak (Fig. 7, *B*). This suggested that fetuses were breathing more irregularly after square-wave vibratory stimulation.

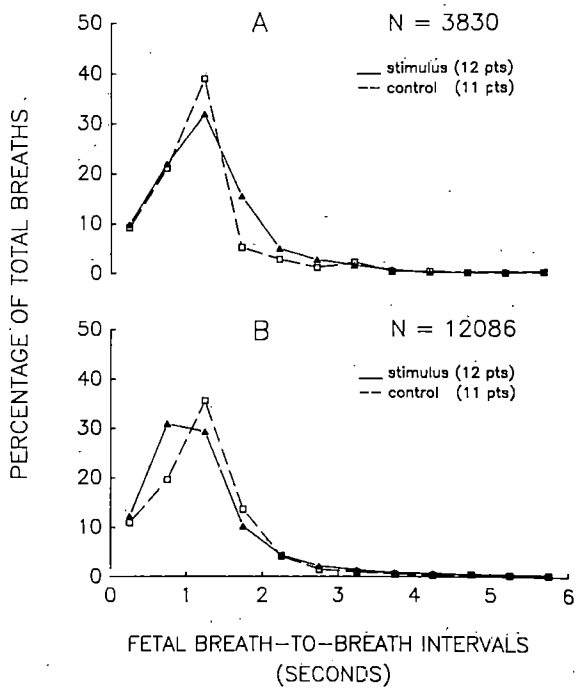

Fig. 7. Fetal breath-to-breath intervals were measured, and histograms of mean percentage of total breath-to-breath intervals in 0.5-second increments were plotted for 12 fetuses during 10 minutes before **(A)** and 30 minutes after **(B)** stimulus (——) or control (- - - -). There was a broad distribution of breath-to-breath intervals at 0.5 to 1.5 seconds without a well-defined peak after stimulus.

Comment

The results indicated that, in a group of healthy term fetuses, the patterns in the FHR and fetal movement were significantly altered after a 5-second external vibratory stimulus (100 Hz, square wave) applied during an episode of low FHR variability. There was an immediate and sustained increase in long-term FHR variability, number of FHR accelerations, and gross fetal body movements. Analysis of fetal breathing intervals demonstrated a broader distribution of breath-to-breath intervals after stimulus. No significant change was found in the basal FHR or the characteristics of FHR accelerations.

In humans, Meissner's and pacinian corpuscles (fundamental frequency response beween 80 and 150 Hz) are thought to be the primary vibration-sensitive receptors and are related to proprioceptive sensation. In healthy term newborns, proprioceptive reflexes can be elicited mainly in behavioral state 1 (quiet sleep)[11]; auditory response is best obtained in state 2 (rapid-eye-movement sleep) and state 3 (quiet wakefulness).[12] Nociceptive reflexes, elicited after stimuli such as tickling, scratching of the skin, and Babinski reflex, are state independent.[11] Finally, auditory responses at high intensity (above 95 dB) are state independent.[13]

During a pilot study in our laboratories (Gagnon R,

et al., unpublished observations), no fetal response was found with the same vibratory stimulus during episodes of high FHR variability associated with FHR accelerations. Also, no response was found at frequencies above 150 Hz. This suggested that vibratory (best stimulated in quiet sleep) rather than auditory (best stimulated in active sleep, fundamental frequency response 2000 Hz) sensory receptors were stimulated in the present study. Proprioceptive reflexes, which are best obtained in quiet sleep state in newborns,[11] might therefore also be present in healthy term fetuses.

There is evidence that the nature of the stimulus may be important in obtaining a response in the human fetus and newborn. The spectral component of a square wave is the superposition of multiple odd harmonics of a pure tone sine wave[14] (Fig. 1). Hutt et al.[13] measured instantaneous heart rate and electromyographic responses in upper and lower limbs to acoustic stimulation in term newborns. The best heart rate and electromyographic responses occurred after a square-wave stimulus of 125 Hz, 75 dB. No consistent response was seen with a sine wave or at frequencies above 500 Hz.[13] Bernstein et al.[15] measured vibrotactile sensitivity thresholds from two profoundly deaf children, to sine-wave and square-wave vibratory stimuli, at frequencies between 20 and 160 Hz. The deaf children had the same sensitivity thresholds only to square-wave vibratory stimulus, when compared with a group of children with normal hearing.[16] The authors suggested that square-wave vibrotactile stimulation may be potentially useful to assess neurologic function in profoundly deaf children.[15] The lack of any correlation between congenital deafness and the FHR response to vibrotactile stimulation[16] also supports this suggestion.

Similarly, we recently reported more consistent FHR and fetal body movement responses after square-wave vibratory stimulus (100 Hz, 48 dB) than after sine-wave stimulus of the same intensity (Gagnon R., et al., unpublished observations). This indicated that, as in newborns[13] and children,[15] the type of stimulus (square wave vs. sine wave) used might be important to predict human fetal sensory responses to low-frequency vibration.

The lack of any increase in basal FHR and duration of FHR accelerations after vibratory stimulus contrasted with the sustained increase in basal FHR and large FHR accelerations (which we believe to be wakefulness) after vibratory acoustic stimulation with the electronic artificial larynx. This suggested that the acoustic and vibratory components[6] of the electronic artificial larynx are important to elicit fetal responses to a mixed vibratory acoustic stimulus.[5-7]

Current data demonstrated an immediate increase in FHR variability, FHR accelerations, and fetal movements after vibratory stimulus. Fetuses also breathed more irregularly. Both FHR and fetal activity patterns were similar to rapid-eye-movement sleep in newborns[17, 18] and to state 2F in healthy term fetuses.[19] These observations would be compatible with the hypothesis that fetuses have been changed from a state of quiet sleep to a state of rapid-eye-movement sleep as a result of low-frequency, square-wave vibratory stimulation. It is not possible to determine whether the higher frequencies (>1500 Hz) of the square-wave vibratory stimulus could be transmitted as an "auditory stimulus" available to the fetus. In the near future, using a miniaturized hydrophone to record intrauterine sound pressure level at the time of vibratory stimulation, we hope to be able to answer that question.

Although human fetal responses to sound and vibration are potentially useful to assess fetal health[2, 3] and, perhaps, fetal neurologic function,[5] it remains to be determined if human fetuses, during such stimuli, are exposed to higher intensities of sound or vibration than measured in air.[6]

If clinicians wish to shorten nonstress testing times to be certain that FHR accelerations and fetal movements are occurring, pure vibration applied during quiet periods might be preferable to the electronic artificial larynx, which causes a prolonged fetal tachycardia[7] and shortens nonstress testing by only 4½ minutes.[2] Determination of long-term neurobehavioral development after repeated stimuli with the electronic artificial larynx also is important before the electronic artificial larynx is suggested for use in clinical practice.

We thank Mrs. Maria de Sousa for her excellent technical assistance.

Nifedipine pharmacokinetics during preterm labor tocolysis

James E. Ferguson II, MD,[a] Thomas Schutz, BA,[a] Robert Pershe, BS,[c] David K. Stevenson, MD,[b] and Terrence Blaschke, MD[c]
Stanford, California

Nifedipine, a calcium entry blocker, has known relaxing effects on the myometrium. Thirteen women in preterm labor received nifedipine for tocolysis. Blood samples obtained serially during treatment and at the time of delivery were assayed for maternal and neonatal nifedipine concentrations. The peak concentration of nifedipine during sublingual therapy ranged from 23.4 to 197.9 ng/ml and reflected substantial interpatient variability. The mean (±SD) measurable trough value in patients who received 20 mg of nifedipine orally every 6 hours was 7.2 ± 5.5 ng/ml. The maternal mean half-life of nifedipine was 81 minutes (range 49 to 137 minutes). At delivery, neonatal nifedipine levels were nondetectable in 6 of the 11 neonates available for study; in 5, values ranged from 29.5 to 1.8 ng/ml. From these results we conclude that both sublingual and oral nifedipine treatment results in variable but usually measurable maternal plasma concentrations and that placental transfer of nifedipine occurs. (AM J OBSTET GYNECOL 1989;161:1485-90.)

Key words: Preterm labor, nifedipine, pharmacokinetics, calcium entry blockers

Preterm labor continues to complicate a significant number of pregnancies and contributes substantially to perinatal morbidity and mortality.[1] Although a variety of pharmacologic agents are currently used to treat preterm labor, only the β-adrenergic agent ritodrine has a Food and Drug Administration–labeled indication for such treatment.[2] The use of β-adrenergic agents can be associated with undesirable side effects.[2] Because of these potential side effects, we were prompted to study an alternate tocolytic agent.

Calcium entry blockers, by virtue of their relaxing effects on the myometrium, show promise. Preliminary studies with nifedipine have suggested that the drug can inhibit labor while producing few apparent side effects.[3-5]

Although the pharmacokinetics of nifedipine have been studied in healthy subjects[6,7] and in patients with various cardiovascular disorders,[8] there are no data available for pregnant women. Because of the clinical interest in nifedipine as a tocolytic agent, we sought to

define maternal peak values and the half-life of nifedipine and to determine if placental transfer of nifedipine occurs in patients undergoing preterm labor tocolysis.

Material and methods

Patients with preterm labor occurring between 20 and 36 completed weeks of gestation were eligible for enrollment into the study. Informed consent, as approved by the Stanford University Committee for the Protection of Human Subjects in Research, was obtained from each patient. Preterm labor was defined as regular uterine contractions with a documented change in cervical dilatation or effacement after 20 weeks but before 36 completed weeks' gestational age. Patients with these maternal factors were excluded: prior recent tocolytic exposure, diabetes, hyperthyroidism, cardiac disease, severe preeclampsia-eclampsia, abruptio placentae, chorioamnionitis, multiple gestation, hydramnios, and cervical dilatation >4 cm. Fetal distress, suspected intrauterine growth retardation, a dead fetus, or a fetal anomaly incompatible with life constituted fetal factors for exclusion.

The pharmacokinetic investigations in the present study were performed in a group of patients who were already part of an ongoing prospective, randomized clinical trial comparing nifedipine and ritodrine tocolysis. Patients selected by the randomization process to receive nifedipine gave additional informed consent for the extra phlebotomies required for the pharmacokinetic studies. An intravenous infusion of 5% dextrose in lactated Ringer's solution at 100 ml/hr was administered to all patients after an initial 200 ml fluid bolus. Nifedipine tocolysis was initiated with a 10 mg capsule given sublingually; patients were instructed to bite the capsule between their molars and, if possible, to avoid swallowing to facilitate sublingual absorption. If uterine contractions persisted after 20 minutes, a similar dose was given. This pattern was repeated, if needed, up to a maximal total dose of 40 mg administered sublingually during the first hour of treatment. If sublingual tocolysis abolished the uterine activity, then oral therapy with 20 mg of nifedipine was initiated 6 hours after the last sublingual capsule. This dose was repeated at 4- to 6-hour intervals or, if continuation of tocolysis was clinically indicated, occasionally at more frequent intervals. Tocolysis was attempted for 48 hours when glucocorticoids were administered to patients with ruptured membranes and through 36 completed weeks of gestation when the membranes were intact. If delivery was delayed beyond these intervals, tocolysis was considered "successful." Before and at 12 hours of treatment, an electrocardiogram was obtained on each patient. Throughout the initial 24-hour period of treatment, patients remained in the left lateral decubitus position and received nothing by mouth, except for sips of water with oral nifedipine.

Fluid intake was limited to 2400 ml/24 hours, and records of total intake and urine output were made. Maternal blood pressure, pulse and respiratory rate, fetal heart rate, and uterine activity were recorded at frequent intervals. Serial laboratory evaluations were performed, and the use of amniocentesis and steroid administration followed our standard practice as previously described.[3]

To facilitate blood sampling, a heparin lock was placed in each patient participating in the pharmacokinetic studies. The heparin lock was maintained with 1:1000 sodium heparin solution and flushed at regular intervals. Five milliliters of blood was obtained before the first sublingual nifedipine dose and 20 minutes after each sublingual dose given (before each subsequent sublingual dose). After the last sublingual dose, blood was obtained on an hourly basis until the first oral dose. These samples were used for a basis to determine the half-life of the drug. Patients receiving oral nifedipine had blood samples for nifedipine levels obtained at 4- to 6-hour intervals (immediately before each subsequent oral dose) during the initial 24 hours of treatment. Occasionally (for instance, at the time of discharge from the hospital or when a patient was seen on an outpatient basis), blood was drawn for trough concentrations after the initial 24-hour study interval. Additionally, maternal and neonatal samples were obtained at the time of delivery, and neonatal sampling was repeated at 12 and 24 hours of life. In one patient blood samples (maternal and neonatal) were drawn only at the time of delivery, not during initial sublingual or oral tocolysis. Blood samples were transferred to heparinized screw-top vials wrapped with aluminum foil (to protect against light degradation) and placed in a refrigerator. Within 24 hours, the samples were centrifuged and the plasma was placed in cold storage (−20° C) until assayed.

Plasma nifedipine concentrations were measured by high-performance liquid chromotography with ultraviolet detection by means of a minor modification of the method developed by Raemsch and Sommer.[7] The system consisted of a Waters model 6000A pump with an IBM 9505 autosampler and a Spectra-Physics 4290 integrator. A 15 cm Waters NovaPak C_{18} column was used and a Waters model 441 ultraviolet absorbance detector was operated at 254 nm and AUFS (absorbance units full scale) 0.005. The mobile phase was 55% methanol and 45% 0.05 mol/L monobasic potassium phosphate (pH 3.0 by addition of 85% phosphoric acid). The flow rate was 1.0 ml/min. Extraction of 1.0 ml of plasma, 100 ng of the internal standard (nitrendipine), and 500 μl of 1 mol/L sodium hydroxide was done with 7.5 ml of ethyl ether and hexane (1:1, vol/vol).

The aqueous phase was frozen in a dry ice–acetone bath, and the organic layer was separated and evaporated at 37° C under a vacuum. The residue was reconstituted with 200 μl of the mobile phase and 100 μl was injected onto the chromatograph. All extraction and chromatographic procedures were performed under yellow light to prevent the photodegradation of nifedipine.

A set of nifedipine standards was run along with each set of unknown samples. Normalized peak area ratios, derived from the standard curve, were used to calculate nifedipine concentrations in the unknowns. In general, the lower limit of the nifedipine assay was 5 ng/ml; however, in some cases, if the background noise in the chromatogram was <30% of the nifedipine signal, plasma concentrations of 1 to 2 ng/ml could be detected. The half-life of nifedipine was estimated by fitting the postpeak plasma concentration-versus-time data to a monoexponential function, by means of a weighted nonlinear regression analysis.[10]

Results

Demographic data that relate to the study patients are depicted in Table I. None of the patients had a prior history or current evidence of hepatic impairment. The mean (±SD) peak concentration of nifedipine in the 12 patients in whom blood samples were drawn during sublingual therapy was 96.7 ± 45.3 ng/ml (range 23.4 to 197.9 ng/ml). Plasma concentrations from the study subjects obtained during sublingual dosing are presented in Fig. 1. Subjects generally had increasing plasma concentrations after each successive dose of sublingual nifedipine. Several patients (Nos. 3, 5, and 7), however, demonstrated nearly equal or lower values with each additional sublingual dose. The half-life (mean ± SD) of nifedipine, calculated from plasma concentrations obtained hourly after the last sublingual dose but before the first oral dose, was 81 ± 26 minutes (range 49 to 137 minutes).

Sublingual tocolysis was effective in 11 of 13 patients and they were subsequently treated with oral nifedipine. In 10 of these 11 patients trough values were determined routinely during the initial 24-hour study period. An every-6-hour oral dosing schedule was followed in 9 patients. Blood for the determination of the 6-hour trough values during the initial 24 hours of treatment was therefore obtained in 27 instances. Measurable values were detected in 24 samples; the mean (±SD) for these values was 7.2 ± 5.5 ng/ml (n = 24). The levels ranged between 1.5 and 21 ng/ml. Some drug accumulation seemed to occur in the remaining patient, who received her first oral dose 5 hours after the last sublingual dose, then an oral dose 5 hours later, followed by three oral doses at 4-hour intervals. The oral trough plasma concentrations for blood samples obtained during the 5-hour and subsequent 4-hour intervals from this patient were 34, 44, 48, and 57 ng/ml. Additionally, four of the nine patients who were receiving 20 mg of nifedipine orally every 6 hours had a single trough plasma concentration determined between 2 and 21 days after the initial pharmacokinetic studies. The values obtained 2 to 21 days later were 5.9, 6.0, 7.0, and 5.7 ng/ml, compared with the corresponding initial average 6-hour trough values of 5.4, 3.9, 6.0, and 5.0 ng/ml.

Neonatal and corresponding maternal nifedipine levels at the time of delivery are shown in Table II. In patients 1, 7, and 8, tocolysis failed and delivery occurred within 2, 5, and 3 hours, respectively, of the last maternal nifedipine dose. In the remaining 10 patients, nifedipine was discontinued either because the gestation had been prolonged ≥48 hours in patients with ruptured membranes or beyond 36 weeks in patients with intact membranes or, in one instance, because a patient wished to withdraw from the study. As shown, delivery occurred at various intervals after the last nifedipine dose. The disposition of nifedipine could be determined in the neonate of patient 1 and neonatal levels at 12 and 24 hours of life were 13.6 and 10.4 ng/ml, respectively, indicating a half-life of 26.5 hours. In the remaining 10 infants available for study, neonatal nifedipine concentrations at 12 and 24 hours of life were nondetectable in six and not obtained in four neonates. The calculated fetal/maternal ratios for patients 1, 3, 4, and 13 were 0.63, 0, 1.3, and 0.75, respectively.

Comment

To our knowledge, neither the disposition of nifedipine in pregnant women nor the concentration of drug in neonates at the time of delivery has been previously reported. We have demonstrated that both sublingual and oral nifedipine administration results in variable but usually measurable maternal blood levels in patients receiving this drug for preterm labor tocolysis. Our results are consistent with previous studies in healthy

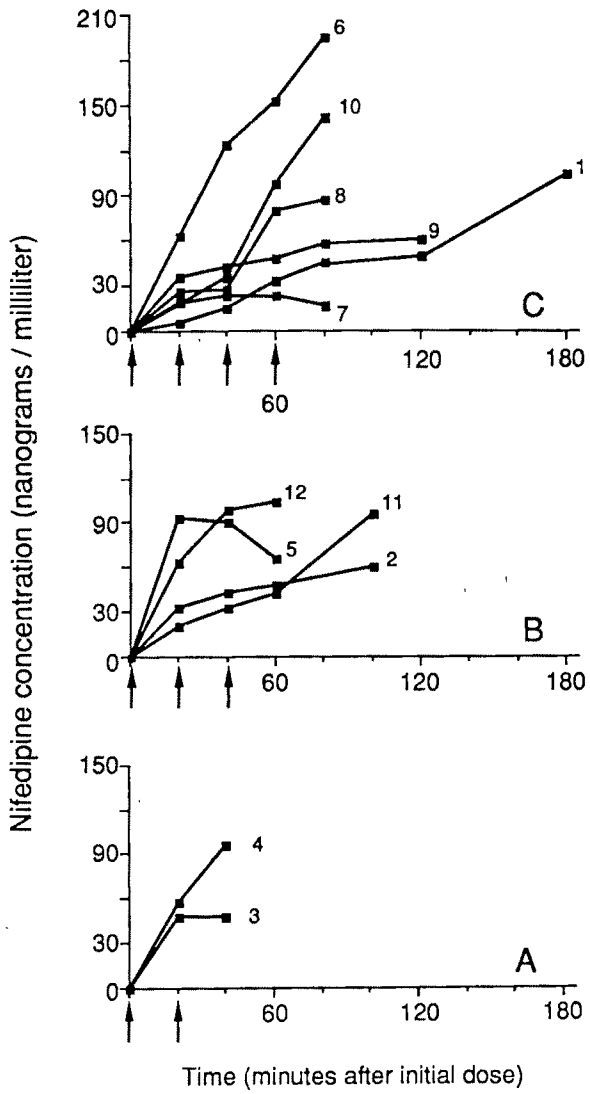

Fig. 1. Nifedipine concentrations for 12 patients receiving two, three, and four sublingual doses, respectively, as shown in panels *A*, *B*, and *C*. *Arrows* indicate approximate times of sublingual 10 mg nifedipine administration. Each curve ends at the corresponding patient's maximum measured concentration, excepting the curves labeled *3*, *5*, and *7*, which are unique in that concentrations remained the same or even fell during serial administration of the drug (these curves end at the first measurement after the final sublingual dose).

volunteers and patients with hypertension, which likewise demonstrated extreme interpatient variability in pharmacokinetic parameters including half-life, magnitude and timing of peak plasma concentrations, and trough levels.[6-8] In these studies the interpatient variability existed irrespective of whether the drug was administered intravenously, orally (capsules or tablets), sublingually, or rectally.

Although the exact cause of the large interpatient variations in measured peak plasma concentrations after sublingual administration among the patients in this study and other studies of nonpregnant patients is unknown, variations may be attributed to differences in the site and rate of absorption, extent of first-pass hepatic extraction, and rate of metabolism. It is generally accepted by investigators that sublingual nifedipine absorption occurs and is rapid[7]; nonetheless, some controversy exists concerning the efficiency of nifedipine absorption through the buccal mucosa when compared with absorption from the stomach and intestine. Indeed, McAllister[11] suggested that sublingual absorption of nifedipine may be limited and that active absorption may occur only after patients swallow and the drug reaches the stomach. If so, interpatient differences in the length of time a "sublingual" dose is held in the mouth before swallowing may, by potentially delaying absorption, also contribute to the observed variability. Although nearly all of a swallowed dose is thought to be absorbed in the stomach and small intestine, Nakashima et al.[12] suggested that patients with "fast" and "slow" absorption exist and that they differentially absorb nifedipine in the stomach and small intestine, respectively, accounting for further differences in the timing and magnitude of peak plasma concentrations. Additionally, Kleinbloesem et al.[13] have identified the existence of an oxidative polymorphism regulating the metabolism of nifedipine. The majority of patients have been phenotypically classified as "rapid metabolizers"; approximately 20% are thought to be "slow metabolizers." The differing rates of metabolism could also compound the interindividual differences reported.

Direct comparison of pharmacokinetic parameters with other studies is difficult because pregnant women have not been previously studied and because differing dosages and routes of administration have been used in prior studies. Although the physiologic changes of pregnancy could have affected the absorption, distribution, metabolism, and excretion of nifedipine, the pharmacokinetic parameters we observed were similar when compared with those of nonpregnant patients. There are few data on the pharmacokinetics of nifedipine after sublingual administration. Raemsch and Sommer[7] administered a single 10 mg dose of nifedipine sublingually to 10 fasting patients. Although this group of investigators also noted marked differences in individual plasma levels, the mean plasma concentration-versus-time curves generated are remarkably similar when compared with the profiles obtained from patients in this study. Drug half-life has been previously determined after single intravenous bolus and single oral dose exposure in healthy volunteers. Kleinbloesem et al.[6] noted a mean half-life of 1.7 ± 0.4 hours in six male volunteers who had intravenously received nifedipine, 0.015 mg/kg of body weight and a half-life of the same order for this same group of volunteers when a 20 mg capsule of nifedipine

was given orally in the crossover phase of the study. Raemsch and Sommer,[7] using similar methods, reported a half-life after intravenous treatment of 1.26 ± 0.55 hours in seven volunteers and approximately 2½ hours after oral administration. The maternal half-life of 1.35 ± 0.43 hours that we observed when postpeak plasma concentration-versus-time data were evaluated after successive 10 mg sublingual doses of two to four nifedipine capsules does not differ greatly from others reported, even though the dose, route of administration, and physiologic milieu were different. The neonatal half-life was quite long; however, comparative data are not available. Immature neonatal hepatic detoxification mechanisms may be responsible for this finding. Raemsch and Sommer[7] noted a mean nifedipine level of 17 ng/ml at 6 hours in five fasting volunteers who received 20 mg of nifedipine orally. This value is somewhat greater than the mean trough value of 7.2 ng/ml we obtained in nine patients receiving 20 mg of nifedipine orally every 6 hours.

We further demonstrated that there are no time-dependent changes in plasma trough concentrations in patients continuing the same oral dose of nifedipine for up to 21 days after the initial study period. This finding is in agreement with previous reports. Raemsch and Sommer[7] studied nine male and female volunteers on an oral dosing regimen with 10 mg of nifedipine three times daily. They noted no change in the mean maximum or trough concentrations of nifedipine when concentrations on day 7 were compared with those of day 1. In this study involving pregnant women, there was also no apparent cumulative effect of nifedipine when administered orally in 20 mg doses every 6 hours. Because of the frequent need to administer oral tocolytic agents over a prolonged period of time, it is clinically useful to know this drug apparently may be given every 6 hours without fear of a cumulative effect.

This study represents the initial documentation that nifedipine undergoes transplacental passage. The transplacental passage of verapamil has recently been reviewed.[14] Given the similarities between these two calcium entry blockers, we were not surprised that nifedipine was detected in the fetal-neonatal circulation. Although substantial cord blood levels were noted in two patients in whom tocolysis failed and delivery occurred within 3 hours after a maternal nifedipine dose, neonatal nifedipine levels were ≤6 ng/ml in all instances in which ≥5 hours had elapsed since the most recent maternal nifedipine dose. As expected, the highest neonatal levels were found in newborns of mothers who had received the last dose of nifedipine in closest proximity to the time of delivery. Because neonatal nifedipine concentrations and fetal maternal ratios have not been previously determined in humans, only animal data are available for comparison. Harake et al.[15] infused 5 and 10 $\mu g \cdot kg^{-1} \cdot min^{-1}$ of nifedipine to eight pregnant ewes. Fetal and maternal nifedipine levels (mean ± SEM) during the 5 $\mu g \cdot kg^{-1} \cdot min^{-1}$ infusion rate were 29 ± 5 and 110 ± 12 ng/ml. After the 10 μg infusion rate the respective values were 91 ± 8 and 267 ± 35 ng/ml. Individual fetal/maternal ratios were not enumerated; however, the mean fetal/maternal ratios during the 5 and 10 μg infusion rates were 0.3 and 0.4, respectively. Although the limitations in comparing transplacental passage in an animal model to that in the human are well known, the overlapping range for

the plasma concentrations (at the 5 μg infusion rate) and the fetal/maternal ratios is interesting to note.

In summary, we have demonstrated that both sublingual and oral nifedipine treatment result in variable but usually measurable maternal plasma concentrations and that placental transfer of nifedipine occurs.

We thank Marion I. Brown, MS, and the labor and delivery nurses at Stanford for their able assistance with this study.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1989 issues from the Publisher, at a cost of $56.00 ($79.00 international) for Vol. 160 (January-June) and Vol. 161 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C.V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146-3318, USA; phone (800) 325-4177, ext. 351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Prediction of hematocrit decline after intravascular fetal transfusion

Scott N. MacGregor, DO, Michael L. Socol, MD, Bruce W. Pielet, MD, John S. Sholl, MD, and Richard K. Silver, MD

Chicago and Evanston, Illinois

Fetal blood sampling and intravascular transfusion via cordocentesis allow more precise fetal evaluation and treatment in isoimmunized pregnancies. However, the timing of repeat transfusion has remained empiric. In this report we review our experience with fetal transfusions in isoimmunized pregnancies to evaluate the ability to predict fetal hematocrit decline and thereby determine the optimum timing for repeat transfusions. Between March 1986 and March 1988, 60 intravascular fetal transfusions were performed in 20 patients. Fetal transfusions were excluded from analysis if blood samples were unable to be obtained before and after transfusion, as well as at the beginning of the next transfusion or birth. Fifty-three procedures were analyzed. Two equations were used to predict the fetal hematocrit at the subsequent transfusion. The difference between observed and predicted hematocrits at the beginning of a subsequent transfusion or birth was −0.9% ± 5.8% with equation 2, which was the more accurate formula in the majority of fetuses. Prediction of fetal hematocrit decline may be used to determine the optimum timing of repeat transfusion. (AM J OBSTET GYNECOL 1989;161:1491-3.)

Key words: Fetal transfusion, isoimmunization, cordocentesis, fetal therapy

Fetal blood sampling and intravascular transfusion via cordocentesis allow more precise fetal evaluation and treatment in pregnancies complicated by blood group isoimmunization.[1-3] Fetal transfusion volume is determined by the severity of anemia, and the adequacy of therapy can be assessed by the posttransfusion fetal hematocrit. Despite these improvements in the management of the severely isoimmunized fetus, the timing of repeat transfusion has remained empiric. In this report we review our experience with fetal transfusions in isoimmunized pregnancies to evaluate the ability to predict fetal hematocrit decline and thereby determine the optimum timing for repeat transfusions.

Material and methods

Between March 1986 and March 1988, 60 intravascular fetal transfusions were performed in 20 patients with gestational ages between 21 and 35 weeks. Ultrasonography-guided intravascular transfusions were performed with methods previously described with a few modifications.[3] A detachable needle guide is no longer used and maternal administration of sedatives has been replaced by the intravenous infusion of pancuronium bromide (0.05 to 0.1 mg/kg) to the fetus after needle tip placement into the umbilical vein.

Transfusions were performed with cytomegalovirus-negative, frozen, washed, packed red blood cells cross-matched against maternal blood. Transfusion volumes ranged from 30 to 110 ml. Three minutes after completion of the transfusion, fetal blood was sampled for the posttransfusion hematocrit with the first 0.5 to 1.0 ml aliquot of this sample being discarded. The needle was left within the umbilical vessel during this period of donor-fetal blood mixing to avoid needle replacement. The desired fetal hematocrit after transfusion was approximately 45%, on the basis of the upper limits of normal fetal hematocrit between 26 and 30 weeks' gestation.[4] In those fetuses transfused either before 26 weeks' gestation or after 30 weeks' gestation, the desired posttransfusion hematocrit was slightly <45% or >45%, respectively. The pretransfusion and posttransfusion fetal hematocrits, as well as that of the donor blood, were determined with a Coulter S-IV or S-VI electronic cell counter (Coulter Electronics Inc., Hialeah, Fla.).

Fetal transfusions were excluded from analysis if blood samples were unable to be obtained after transfusion, as well as at the beginning of the next transfusion or birth. Fifty-three procedures were analyzed. Seventeen of the 20 patients were rhesus sensitized and 47 of the 53 transfusions were performed in these pregnancies. Kell, c, and E isoimmunization each complicated one pregnancy and the remaining six transfu-

sions were performed in these patients. Gestational age assessment was based on menstrual dates and early ultrasonographic examinations. Fetal weight was estimated by ultrasonography-derived growth parameters obtained at each transfusion.[5, 6]

Two transfusion intervals were indentified: interval 1 between the first and second transfusions (n = 20) and interval 2 between subsequent transfusions or birth (n = 33). The hematocrit of either the fetal blood sample obtained at the beginning of the next transfusion or the umbilical cord blood sample obtained at birth was predicted with the following equations:

$$\text{Hct pred} = \text{Hct f} - \text{i} \times (\text{EFW1/EFW2}) \times (120 - \text{Days})/120 \quad \text{(Equation 1)}$$

$$\text{Hct pred} = \text{Hct f} \times (\text{EFW1/EFW2}) \times (120 - \text{Days})/120 \quad \text{(Equation 2)}$$

where Hct pred is the predicted hematocrit at the subsequent transfusion or birth, Hct f − i is the final hematocrit minus the initial hematocrit at the index transfusion, Hct f is the final hematocrit at the index transfusion, EFW1 is the ultrasonographically estimated fetal weight at the index transfusion, EFW2 is the ultrasonographically estimated fetal weight at the subsequent transfusion, and days is the number of days between the index and subsequent transfusion or birth. These equations assume that donor red blood cell survival in the fetal circulation is 120 days. In addition, equation 1 assumes that between the first and second transfusions few, if any, of the fetal red blood cells will survive.

The observed and predicted hematocrits at the beginning of a subsequent transfusion or birth were compared. Hematocrits were predicted with both equations 1 and 2 for the interval 1 transfusions. Since only two (6%) of the interval 2 transfusions had >10% fetal red blood cells (determined by Kleihauer-Betke testing) remaining at the subsequent transfusion or birth, hematocrits were predicted with only equation 2 for the interval 2 transfusions.

Interval 1 transfusions were further divided into those with presence versus absence of fetal hydrops and fetal red blood cells ≤10% versus >10% at the subsequent transfusion or birth. Observed and predicted hematocrits also were compared in these subgroups. Comparisons were performed with the paired t test with statistical significance assumed at $p < 0.05$.

Results

Gestational age distribution at the time of transfusion is summarized in Table I. The mean interval between subsequent transfusion or birth was 16.0 ± 6.4 days; the mean intervals in the interval 1 and interval 2 groups were 12.5 ± 3.9 and 17.7 ± 6.7 days, respectively.

The differences between observed and predicted hematocrits at the beginning of a subsequent transfusion or birth are shown in Table II. The mean differences for interval 1 transfusions were 9.8% ± 9.3% with equation 1 and −3.6% ± 7.8% with equation 2. For interval 2 and all (interval 1 plus interval 2) transfusions, the mean differences were only 0.5% ± 3.5% and −0.9% ± 5.8%, respectively, with equation 2. The

predicted hematocrits were only significantly different from those observed only for the interval 1 transfusions when equation 1 was used. The mean decline in hematocrit per day between subsequent transfusion or birth was 1.3% ± 1.1%; the mean declines in hematocrit per day for the interval 1 and interval 2 groups were 1.5% ± 1.6% and 1.2% ± 0.6%, respectively.

Comparisons of the differences between observed and predicted hematocrits among the interval 1 subgroups are summarized in Table III. If fetal hydrops was present at the initial transfusion or ≤10% fetal red blood cells remained at the subsequent transfusion or birth, equation 1 and equation 2 were comparable. Otherwise, equation 2 more accurately predicted the subsequent hematocrit.

Comment

Prediction of fetal hematocrit decline after intravascular transfusion is subject to systematic errors as well as variation among different fetuses. For example, a previous case report suggested that life span of transfused adult cells may be shorter in the isoimmunized fetus (approximately 100 days) than in adults (approximately 120 days).[7] Further studies are required to confirm this observation. Additionally, estimation of fetal weight by ultrasonographic parameters may introduce error. Finally, the severity of the fetal hemolytic anemia is variable even in those fetuses with similar blood group isoimmunization. The assumption that few fetal red blood cells survive after the first transfusion (equation 1) may be correct only in the most severely affected fetuses. Indeed, half of the fetuses in the interval 1 subgroup had >10% fetal red blood cells at subsequent transfusion or birth by Kleihauer-Betke testing. Despite difficulties involving interpretation and standardization observed with this test, it is considered sensitive to 0.01.

Our data suggest that the simple formulas evaluated help to predict the decline in fetal hematocrit and determine the optimum timing of repeat transfusion. This is most evident in interval 2 because by this time the fetal red blood cells have essentially all been replaced by donor red blood cells in the fetal circulation. Consequently, the decline in fetal hematocrit is dependent on the life span of the transfused blood cells and the rate of fetal growth rather than the hemolysis that is secondary to isoimmunization. The interval between first and second transfusions (interval 1) is more problematic because of the unpredictable hemolysis of the remaining fetal red blood cells. In those fetuses with more severe hemolytic anemia few fetal red blood cells will survive the transfusion interval. However, because the rate of hemolysis of the remaining fetal red blood cells is variable and cannot be controlled for, it will always be more difficult to predict the hematocrit decline in interval 1 than in interval 2. Nonetheless, these simple formulas offer an alternative to empiric decision making.

Effect of acute intravascular volume expansion on human fetal prostaglandin concentrations

Carl P. Weiner, MD,[a] and Jean E. Robillard, MD[b]
Iowa City, Iowa

Direct fetal intravascular transfusion is well tolerated by the human fetus. However, the rapid transfusion of high-hematocrit blood should increase vessel distention and the flow shear force. Each is known to stimulate the release of prostacyclin. We measured prostaglandins E_2 and $F_{2\alpha}$ and the stable metabolite of prostacyclin, 6-keto-prostaglandin $F_{1\alpha}$, by radioimmunoassay before, at the estimated midway point of, and at the completion of 40 umbilical venous transfusions performed because of immune hemolytic anemia. Umbilical venous pressures corrected for amniotic fluid pressure were measured at similar intervals during nine of the procedures. The mean (±SEM) length of gestation at transfusion was 29 ± 1 week, opening hematocrit 23% ± 1%, and total volume of 70% hematocrit red blood cells transfused 83 ± 5 ml. 6-Keto-prostaglandin $F_{1\alpha}$ was the principal circulating fetal prostanoid and its concentration was unrelated to gestational age. Intravenous transfusion was associated with an 84% increase in 6-keto-prostaglandin $F_{1\alpha}$ ($p = 0.03$) and a 68% increase in prostaglandin E_2 ($p < 0.05$). The rise for each strongly correlated with the rise in the fetal umbilical venous pressure (6-keto-prostaglandin $F_{1\alpha}$, $r = 0.94$, $p = 0.0005$; prostaglandin E_2, $r = 0.81$, $p < 0.03$). We conclude that 6-keto-prostaglandin $F_{1\alpha}$ is the principal circulating prostaglandin in the human fetus and that the release of venodilator prostaglandins may be one reason the human fetus can tolerate a large increase in intravascular volume without obvious sequelae. (AM J OBSTET GYNECOL 1989;161:1494-7.)

Key words: Cordocentesis, human, fetus, prostaglandins, intravascular transfusion, anemia

The most frequently performed therapeutic fetal procedure is an intravascular transfusion to treat immune hemolytic anemia. Though transfusion is an effective treatment for anemia, its effects on fetal homeostasis are not well documented. We have previously demonstrated that arginine vasopressin is reduced in the anemic fetus before transfusion[1] and that atrial natriuretic factor and umbilical venous pressure are greatly elevated in the fetus with immune hydrops.[2, 3] These observations suggest that the anemic fetus is in a state of relative hypervolemia. Thus it was surprising to observe that the fetal umbilical venous pressure increased only modestly during intravascular transfusion despite sometimes doubling the estimated fetal-placental intravascular volume.[4, 5] The placenta likely contributes to stability as a high-capacitance unit, but other factors may be involved. A variety of fetal tissues from humans and sheep are capable of producing large quantities of prostacyclin and prostaglandin E_2 (PGE_2).[6-9] Each can stimulate vasodilation at appropriate concentrations[10, 11] and is released in response to an increase in shear force and perfusion pressure occurring simultaneously with vessel distention.[12] Such changes might accompany a rapid infusion of packed red blood cells and trigger the release of prostacyclin and PGE_2. In support of this possibility, we have observed that the umbilical artery systolic/diastolic ratio, resistance index, and pulsatility index decline after transfusion.[13] Others have noted a similar acute decline in Doppler-determined resistance of the renal, cerebral, and femoral arteries after transfusion.[14] Thus we hypothesized that the fetus actively enhances vascular capacitance during intravascular transfusion by the release of vasodilator prostanoids. To test this hypothesis, we measured the stable metabolite of prostacyclin (6-keto-prostaglandin $F_{1\alpha}$, 6-keto-$PGF_{1\alpha}$), PGE_2, and prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) before, during, and after completing the transfusion.

Material and methods

This investigation was approved by the University Institutional Human Subjects Committee. Eighteen anemic fetuses underwent a total of 40 intravascular transfusions. Intravascular transfusions were performed as described previously[13] with a 5 MHz sector transducer (model 3600, General Electric, Ran-

cho Mirage, Calif.), an attached needle guide (CIVCO Inc., Kalona, Iowa), and a 22-gauge needle (Beckton-Dickinson, Rutherford, N.J.). Each fetus received pancuronium (0.3 mg/kg estimated fetal weight intravenously) for neuromuscular blockade and furosemide (4 mg/kg intravenously in two divided doses). The packed red blood cells were prepared from fresh type O-negative blood compatible with both mother and fetus, rendered buffy coat poor, irradiated, washed twice in normal saline solution, and resuspended in saline solution to yield a hematocrit of 70%. Adequate blood was infused over a 15- to 30-minute interval to give a closing hematocrit between 45% and 50%. Only the umbilical vein was used for transfusion and blood sampling. Blood specimens for hematocrit, venous blood gas parameters, 6-keto-$PGF_{1\alpha}$, PGE_2 and $PGF_{2\alpha}$ were aspirated before, at the estimated midway point of, and immediately after completing the transfusion. During nine of the procedures, the fetal umbilical venous pressure was recorded at the same sampling intervals. The interval between repeat transfusions was at least 3 weeks.

The fetal umbilical venous pressure was measured by connecting a saline solution–filled tube to a solid-state pressure transducer (Sorenson Transpac II, no. 468626-04, supplied by Abbott Critical Care Systems, North Chicago) and pressure monitor (no. 78833B, Hewlett-Packard, Houston). The transducer was placed at the level of the fetal heart as determined during the preceding ultrasonographic examination. The identity of the vessel was confirmed by observing both the lack of a pulsatile pressure waveform on the monitor screen and the direction the infusate flowed on ultrasonography. At the conclusion of the procedure, the needle was withdrawn from the vein into the amniotic cavity where the amniotic fluid pressure was recorded. There was neither maternal perception nor sonographic evidence of uterine activity during the time the pressure measurements were made. The reported umbilical venous pressures reflect subtraction of the amniotic fluid pressure from the umbilical venous pressure.

The heparinized specimen, which provided a sample for both the blood gas measurements and the prostaglandins, was placed directly onto wet ice. Blood gas values were measured immediately with automated equipment (model 1312, Instrumentation Laboratory, Pittsburgh). The pH, P_{CO_2} (millimeters of mercury), and P_{O_2} (millimeters of mercury) were measured directly. Base deficit (milliequivalents per liter), bicarbonate (milliequivalents per liter), and oxygen saturation (percent) were calculated by means of standard nomograms.

The heparinized plasma sample was then quickly acidified with citric acid and the prostaglandins were isolated with a C_{18} solid-phase column (Bond Elut, Analytichem International, Harbor City, Calif.) with ethyl acetate used as the eluting solvent. Once prostanoids are extracted, their concentration remains stable. Recovery of tritiated prostaglandins was as follows: 6-keto-$PGF_{1\alpha}$, 71.8% ± 1.7%; PGE_2, 75.1% ± 1.1%; and $PGF_{2\alpha}$, 8.30% ± 2.8%. The samples were taken to dryness and reconstituted in a mobile phase (water/acetonitrite/benzene/acetic acid, 772:225:2:1), clarified by microfiltration, and injected into the high-pressure liquid chromatography system (Waters free fatty acid HP column, 3.9 mm × 15 cm). Recovery of tritiated prostaglandin by high-pressure liquid chromatography was: 6-keto-$PGF_{1\alpha}$, 72.8% ± 0.3%; PGE_2, 71.6% ± 1.1%; $PGF_{2\alpha}$, 66.7% ± 0.6%. Fractions containing each of the respective prostaglandins were taken to dryness with argon and stored at −20° C until assayed at multiple volumes by highly specific and sensitive radioimmunoassays performed by the University of Iowa Cardiovascular Research Center Core Laboratory.[15-17]

All results are reported as the mean ± 1 SEM. Because of the small sample volumes, not all of the prostanoids could be measured for each transfusion. Adequate specimen to measure 6-keto-$PGF_{1\alpha}$ and $PGF_{2\alpha}$ at each of the three sampling intervals was available in 19 procedures and PGE_2 in 22 procedures. The effect of transfusion on the study parameters at each sampling interval was compared with a repetitive measures analysis of variance. When significant differences were identified, Scheffé's test was applied. The relationship between the change in concentration of the three prostanoids during transfusion and gestational age, baseline hematocrit, change in hematocrit, and change in umbilical venous pressure was investigated by least-squares multiple linear regression analyses. Differences yielding $p \leq 0.05$ were considered significant.

Results

There were no procedure-related complications and all fetuses have since been delivered uneventfully. The effects of intravascular tranfusion on the various study parameters are summarized in Table I.

The mean length of gestation at transfusion was 29 ± 1 week (range 21 to 35 weeks). The opening hematocrit ranged from 5.5% to 34%, and the total volume of packed red blood cells infused ranged from 25 to 160 ml.

Levels of both 6-keto-$PGF_{1\alpha}$ and PGE_2 rose significantly during the course of the transfusion ($p < 0.04$ for each). $PGF_{2\alpha}$ remained stable. The three prostanoids also were measured in aliquots obtained from four of the units of blood used for a transfusion. In all samples the concentrations of 6-keto-$PGF_{1\alpha}$, PGE_2, and $PGF_{2\alpha}$ were less than the baseline concentrations and usually less than half. The umbilical venous pressure rose approximately 50% during the transfusion

($p < 0.0001$). Though there were considerable differences in the patterns of umbilical venous pressure responses by the eight different fetuses ($p < 0.01$), in most who began the transfusion with an umbilical pressure in the normal range, the pressure remained within the normal limits (<10 mm Hg).

The magnitude of the increase in 6-keto-$PGF_{1\alpha}$ and PGE_2 was unrelated to either gestational age, initial or change in hematocrit, or total volume of packed red blood cells infused. However, the increase in 6-keto-$PGF_{1\alpha}$ did correlate with the increase in PGE_2 ($r = 0.67$, $p = 0.003$) and each of these venodilator prostanoids correlated strongly with the change in the umbilical venous pressure that occurred during transfusion (6-keto-$PGF_{1\alpha}$; $r = 0.94$, $p = 0.0005$; PGE_2, $r = 0.81$, $p < 0.03$). The change in umbilical venous pressure was unrelated to either the total volume infused ($r = 0.20$, $p = 0.54$) or the change in hematocrit ($r = 0.38$, $p = 0.25$).

Comment

The rapid expansion of fetal intravascular volume by intravenous transfusion of high-hematocrit blood has numerous effects on fetal homeostasis other than correcting the anemia. We have previously demonstrated that, when preceded by the administration of pancuronium and furosemide, acute fetal volume expansion with packed red blood cells (1) stimulates the release of atrial natriuretic factor[2] and (2) increases umbilical venous pressure modestly[4] despite in some instances almost doubling the total fetal-placental intravascular volume.[5] There are several potential explanations why the increase in umbilical venous pressure is not more dramatic after fetal volume expansion. First, the placenta may act as a low-pressure, high-capacity reservoir. Second, atrial natriuretic factor produces vascular smooth muscle relaxation. Third, the fetal vasculature is capable of synthesizing and releasing a high concentration of PGE_2 and 6-keto-$PGF_{1\alpha}$.[6-9] Each can produce vasodilation in a variety of vessel beds. The rapid infusion of packed red blood cells increases both the flow rate and the shear force, which in some systems can stimulate the release of these prostanoids.[12] Further, PGE_2 itself can stimulate prostacyclin release.[18] This release would complement the action of atrial natriuretic factor and increase the systemic capacitance by venodilation.

This study documents that, similar to the human abortus,[6] 6-keto-$PGF_{1\alpha}$ is the principal circulating prostanoid in the anemic fetus. It also demonstrates that intravascular transfusion stimulates a significant rise in the concentration of 6-keto-$PGF_{1\alpha}$ and PGE_2 that is directly proportional to the rise in the fetal umbilical venous blood pressure. The release of these agents, which can produce systemic and placental vasodilation,[10, 11] may explain the acute decline in Doppler-determined placental, trunk, renal, and cerebral resistance that occurs after intravascular transfusion.[13, 14] Though a pharmacologic concentration of PGE_2 produces umbilical artery constriction in vitro,[15] the decline in the umbilical artery systolic/diastolic ratio with transfusion[13] would suggest that constriction is not a factor in the circumstances studied. Hypoxia[19] and acidosis[20] are unlikely explanations for their release since P_{O_2} and pH remained fairly constant. $PGF_{2\alpha}$ declined during transfusion by an amount not inconsistent with dilution.

This investigation used specific and sensitive radioimmunoassays although indomethacin was not used during sample collection. The measured levels are high but not dissimilar to those in prior studies of fetal prostaglandins. It has been suggested that high plasma con-

centrations especially of 6-keto-$PGF_{1\alpha}$ result from interfering plasma substances and that the 6-keto-$PGF_{1\alpha}$ would be much lower if measured by another method such as mass spectrography.[22] However, the present study was longitudinal in design and there was little prostaglandin-like material in the transfused packed red blood cells. Thus the increases in 6-keto-$PGF_{1\alpha}$ and PGE_2 are unlikely to be solely an artifact of the assay.

These findings have clinical application. One common problem either during or after transfusion is uterine irritability. If the release of prostacyclin and PGE_2 is an important adaptive mechanism for fetal adjustment to volume expansion, it would be unwise to use prostaglandin synthetase inhibitors either prophylactically before or therapeutically after transfusion.

In conclusion, the human fetus responds to a variety of stimuli as early as 0.5 of gestation. In this study intravascular transfusion stimulated the release of venodilator prostanoids, which may help stabilize the umbilical venous pressure.

The effect of intravascular transfusion on umbilical venous pressure in anemic fetuses with and without hydrops

Carl P. Weiner, MD, Gay D. Pelzer, RN, Joni Heilskov, RN, Katharine D. Wenstrom, MD, and Roger A. Williamson, MD

Iowa City, Iowa

Human fetal umbilical venous pressure was measured during 20 intravascular transfusions performed for treatment of hemolytic anemia. The mean (±1 SEM) gestational age at the time of transfusion was 29.3 ± 1 weeks and the mean beginning hematocrit was 27% ± 2%. The mean volume of infused packed red blood cells (70% hematocrit) was 90.3 ± 7 ml. The mean hematocrit at completion of the procedure was 48% ± 1%. In nonhydropic fetuses umbilical venous pressure rose progressively from 6.7 ± 1 mm Hg at the start of transfusion to 10.9 ± 1 mm Hg at the completion of transfusion ($p < 0.002$). However, most fetuses who began the infusion with a normal umbilical venous pressure ended the transfusion with a normal umbilical venous pressure (<10 mm Hg). Fetuses with immune hydrops ($n = 2$) had elevated umbilical venous pressure values before the initiation of transfusion therapy when compared with the first transfusion of nonhydropic fetuses (12.5 ± 0.5 vs. 5.7 ± 1 mm Hg, $p = 0.01$). However, the umbilical venous pressure measurements declined into the normal range within 24 hours of the first transfusion; this normalization was too rapid to be explained by the reversal of liver hypertrophy or portal hypertension. There was no demonstrable relationship between the rise in umbilical venous pressure and either the gestational age, the volume transfused, or the rise in hematocrit. This study demonstrated: (1) In terms of the umbilical venous pressure, direct intravenous infusion of the human anemic fetus is well tolerated; (2) the elevated umbilical venous pressure associated with immune hydrops can correct rapidly with red blood cell replacement. (Am J Obstet Gynecol 1989;161:1498-501.)

Key words: Cordocentesis, rhesus disease, umbilical venous pressure

The fetal response to intravascular transfusion provides valuable information concerning both the ontogeny and the function of mechanisms involved with volume regulation and the cause(s) of hydrops fetalis. It also provides information necesary for the development of optimal methods of transfusion.

There are presently two forms of fetal intravascular transfusion—direct and exchange. The advantage of a direct transfusion is that it is faster. By reducing the time for operator error, the overall morbidity also should be reduced. However, concern has been expressed that direct transfusion might lead to volume overload and cardiac decompensation in an already stressed fetus.[1] The observations that arginine vasopressin is lower in the anemic fetus than in controls[2] and atrial natriuretic factor is very high in the fetus with immune hydrops[3] suggest that the anemic fetus has an expanded intravascular volume. On the other hand, we have previously reported that intravascular transfusion stimulates the release of atrial natriuretic factor[3] and vasodilator prostanoids.[4] Each could result in increased venous capacitance. This would be consistent with observations from our and other fetal therapy units that Doppler-measured resistance to blood flow in the umbilical, renal (Mari G, Moise K, Kirshon B, Carpenter RJ. Unpublished observations), femoral, and cerebral arteries declines transiently after intravascular transfusion.[5, 6] The effect of intravascular transfusion on the umbilical venous pressure of the anemic human fetus has not previously been reported. We hypothesized that a combination of high placental capacity and the activation of fetal venodilator mechanisms such as atrial natriuretic factor and prostaglandin release would stabilize the umbilical venous pressure during the infusion of large volumes of blood. To test this hypothesis, we measured umbilical venous pressure before, at the estimated midway point of, and after completion of the transfusion.

Material and methods

Eight fetuses undergoing 20 intravascular transfusions for treatment of anemia as a result of isoimmunization were studied. Two of the 8 (25%) were hy-

*$p < 0.05$, compared with baseline value.

dropic at the time of the first transfusion. Our method for intravascular transfusion has been described previously in detail.[5] For each procedure we used a 22-gauge spinal needle (Beckton-Dickinson, Rutherford, N.J.) and a 5 MHz sector transducer (model 3600, General Electric, Rancho Mirage, Calif.) with an attached needle guide (CIVCO, Kalona, Iowa). All fetuses received pancuronium (0.3 mg.kg estimated fetal weight intravenously) for neuromuscular blockade and furosemide (4 mg/kg intravenously in two divided doses) to dilate capacitance vessels.[7] Transfusion therapy was initiated when the fetal hematocrit declined below 30%. After the first procedure, a repeat transfusion was performed at 3- to 4-week intervals until the final transfusion was performed at 34 to 35 weeks, if appropriate. Our goal was a term delivery. The packed red blood cells were prepared from fresh type O, negative blood compatible with both mother and fetus, rendered buffy coat-poor, irradiated, washed twice with 0.9% sodium chloride, and resuspended in 0.9% sodium chloride to yield a hematocrit of 70%. Blood was infused into the nonhydropic fetus over 15 to 30 minutes to produce a closing hematocrit of 45% to 50%. The hydropic fetuses described here were managed differently at the beginning of therapy. During the first transfusion, the hematocrit increased only to 25%; 24 hours later the hematocrit had increased to 45% to 50%.

The hematocrit and fetal umbilical vein blood gas parameters were measured before, at the estimated midway point of, and at the end of the transfusion. After the required blood specimens had been obtained, the needle was connected to a saline solution–filled tube attached to a solid-state pressure transducer (Sorenson Transpac II, No. 46862-04, supplied by Abbott Critical Care Systems, North Chicago, Ill.) and pressure monitor (No. 78833B, Hewlett-Packard, Houston). The transducer was placed at the level of the fetal heart as determined during the preceding ultrasonographic examination. The needle was purged briefly to clear the shaft of blood, and the pressure was recorded at its nadir. This process took approximately 30 seconds. The identity of the vessel punctured was confirmed to be the umbilical vein by observations of both the flow direction of the injected saline solution and the lack of a pulsatile pressure waveform on the monitor screen. At the conclusion of the transfusion, the needle was withdrawn from the vein into the amniotic cavity. The nadir pressure was recorded. There was neither maternal perception nor sonographic evidence of a uterine contraction during the time any of the pressure measurements were recorded. The umbilical venous pressure reported in this article reflects subtraction of the amniotic fluid pressure from the umbilical venous pressure.

A complete blood count was performed on blood anticoagulated with 1% ethylenediaminetetraacetic acid with a Technicon H-1 analyzer (Technicon, Tarreytown, N.Y.). Venous blood gas measurements were performed with blood anticoagulated with heparin on a Blood Gas Manager No. 1312 (Instrumentation Laboratory, Lexington, Mass.). The pH, Pco_2 (millimeters of mercury), and Po_2 (millimeters of mercury) were measured directly. The base excess (milliequivalents per liter), bicarbonate (milliequivalents per liter), and oxygen saturation (percent) wre calculated by use of standard nomograms.

The results are presented as the mean ± 1 SEM. The three values for baseline umbilical venous pressure, hematocrit, and posttransfusion umbilical venous pressure were compared with a repetitive measures analysis of variance. When significant differences were identified, Scheffé's test was applied. Differences in discrete variables between nonhydropic and hydropic fetuses were tested for significance with an independent t test. The relationship between the baseline umbilical venous pressure and gestational age and between the change in umbilical venous pressure and gestational age, total volume infused, and change in hematocrit were tested by least-squares regression. A $p \leq 0.05$ was considered to represent a significant difference.

Results

There were no complications associated with any of the 20 procedures. The mean gestation at transfusion was 29.3 ± 1 weeks (range 21.5 to 34.5) and the mean beginning hematocrit was 27% ± 2% (range 5% to 37%). There was no demonstrable relationship between the beginning umbilical venous pressure and gestational age ($r = 0.10$; $p = 0.68$). The mean volume of packed red blood cells infused was 90.3 ± 7 ml (range

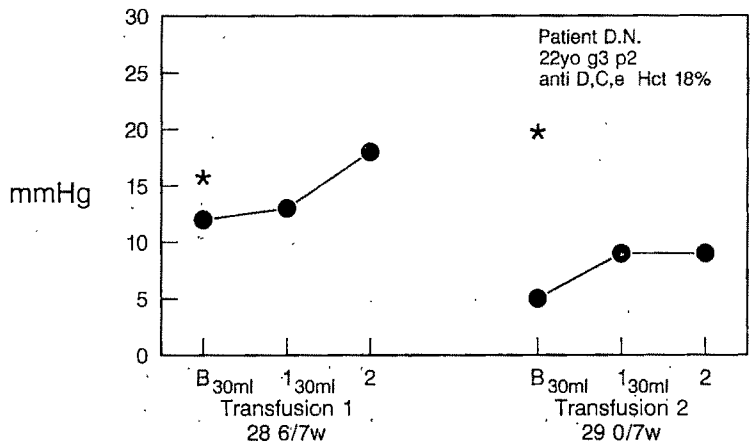

Fig. 1. Effect of intravascular transfusion on umbilical venous pressure in fetus with hydrops. *Asterisks* indicate amniotic fluid pressure. Umbilical venous pressure (in millimeters of mercury) corrected for amniotic fluid pressure is indicated by *solid circles*. Normal umbilical venous pressure is <10 mm Hg.

35 to 120). Umbilical venous pressure values with paired amniotic fluid pressure values at all three sampling times were available for 15 procedures.

The baseline umbilical venous pressure exclusive of hydropic fetuses (6.7 ± 1 mm Hg) was within normal limits (2 SD ≥ 10 mm Hg[8]). The umbilical venous pressure rose significantly ($p < 0.002$) during transfusion, reaching a level just above the normal range (10.9 ± 1 mm Hg) (Table I). The increase observed for the umbilical venous pressure during transfusion was similar in fetuses undergoing the first transfusion as opposed to a subsequent transfusion (4 ± 2 vs 4.3 ± 1 mm Hg). Most fetuses who began the transfusion with a normal umbilical venous pressure still had a normal umbilical venous pressure at the end of the procedure. The baseline umbilical venous pressure of the two fetuses that were hydropic at the time of first transfusion was significantly elevated (12.5 ± 0.5 mm Hg) compared with all nonhydropic fetuses undergoing their first transfusion (5.7 ± 1 mm Hg, $p = 0.01$, two-tail t test). The umbilical venous pressures of these two hydropic fetuses responded differently during the transfusion when compared with those of the nonhydropic fetuses. In one fetus previously described,[8] the umbilical venous pressure normalized *during* the first transfusion and remained normal thereafter. The umbilical venous pressure of the second fetus rose during the first transfusion but was normal by the time of the second transfusion 1 day later (Fig. 1). The hydrops itself resolved far more slowly.

There was no relationship observed between the rise in umbilical venous pressure during transfusion and either gestational age ($r = 0.14$, $p = 0.72$), the volume of packed red blood cells infused ($r = 0.21$, $p = 0.57$), or the change in hematocrit achieved by transfusion ($r = 0.36$, $p = 0.25$).

Comment

Blood returning through the umbilical vein passes via the ductus venosus into the inferior vena cava where it streams preferentially through the foramen ovale into the left atrium.[9] We assume that the umbilical venous pressure is an approximation of the fetal central venous pressure, which also may be sensitive to left-sided cardiac alterations. Our present and prior experience[8] measuring the umbilical venous pressures of fetuses with a variety of problems supports this assumption. Fetuses with elevated umbilical venous pressures had pathologic conditions consistent with cardiac failure, hepatosplenomegaly, or acute bradycardia.

Direct intravascular transfusion significantly increased the umbilical venous pressure, though most pressures were still within the normal range at the completion of the transfusion. Thus, despite a preexisting, relative increase in fetal intravascular volume before transfusion,[2, 3] acute volume expansion was well tolerated by the fetus. The finding that umbilical venous pressure rose during transfusion is similar to our animal investigation,[10] where there was a 50% rise in the central venous pressure of the sheep fetus that had been rendered anemic by phlebotomy and then transfused 24 hours later. The magnitude of the volume expansion should not be underestimated. With a mean transfused volume of almost 100 ml in nonhydropic fetuses, we often doubled the estimated fetal intravascular volume during the course of this study.[10] The tolerance of the fetus to volume expansion likely reflects both a high placental capacitance and other adaptive fetal mechanisms.[3, 4] We presently have little information concerning the length of time the umbilical venous pressure remains elevated after the transfusion. In two fetuses studied after the preparation of this manuscript, the needle was left in place pending a final

blood count. The umbilical venous pressure had already begun to decline by the time the result was received 5 to 10 minutes later. The umbilical venous pressures of all fetuses repetitively studied here had returned to the baseline value by the next transfusion 3 weeks later. These findings, however, may be applicable only to the fetus who is transfused by a procedure consisting of pancuronium, furosemide, and 70% hematocrit blood and whose closing hematocrit is between 45% and 52%.

The two fetuses with immune hydrops studied at the time transfusion therapy was initiated each had an elevated umbilical venous pressure that corrected far too rapidly with transfusion for us to conclude that the hydrops resulted solely from hepatic parenchymal hypertrophy and resulting portal hypertension. This observation was unexpected and would seem at odds with the prevailing opinion that portal hypertension and hypoalbuminemia that are secondary to hepatoerythropoiesis are important in the genesis of hydrops.[12, 13] Thus it seems likely that hypoxic myocardial dysfunction led to increased umbilical venous pressure in these two fetuses. In this circumstance intravascular transfusion would have a positive inotropic effect by increasing the fetal oxygen-carrying capacity. This might explain prior clinical studies reporting an increase in the survival rate of hydropic fetuses treated by intravascular transfusion rather than intraabdominal transfusion, where red blood cell absorption from the peritoneal cavity can be delayed.[14]

On the basis of results in these two fetuses, no conclusion can be made concerning the appropriate method for intravascular transfusion. However, these observations suggest that fetal vascular overload can be prevented by monitoring the umbilical venous pressure. In conclusion, though direct fetal intravenous transfusion, as described here, significantly raises the umbilical venous pressure, the pressure remains within clinically acceptable norms.

Addendum

We have now examined 16 fetuses undergoing 40 intravascular transfusions as described. The results are virtually identical.

Duplex Doppler ultrasonographic evaluation of the fetal renal artery in normal and abnormal fetuses

J. C. Veille, MD, and C. Kanaan, MD
Cleveland, Ohio

Using duplex Doppler ultrasonography in asymmetrically grown fetuses with decreased amniotic fluid, we found the renal artery waveform pattern was different from that in the normally grown fetus. Such an abnormal waveform may reflect an increase in vascular resistance within the renal bed in oligohydramnios and intrauterine growth retardation. This would suggest that local mechanisms are operational and may influence renal blood flow in the human fetus with intrauterine growth retardation. (AM J OBSTET GYNECOL 1989;161:1502-7.)

Key words: Duplex Doppler ultrasonography, fetal renal artery, intrauterine growth retardation

Pulsed Doppler ultrasonography with real-time imaging and on-line spectral analysis (duplex imaging) has wide clinical applications in the evaluation of blood flow velocity. Duplex ultrasonographic examination of the kidney has been used to investigate renovascular resistance in patients with renal transplant to noninvasively evaluate the increase in resistance that occurs during acute rejection.[1-5] In patients with episodes of acute renal rejection, the renal arterial diastolic flow velocity is significantly reduced. We hypothesized that in fetuses affected by asymmetric intrauterine growth retardation (IUGR), fetal renal blood flow may similarly be affected as a result of an elevated intravascular resistance, leading to a decrease in renal perfusion and to oligohydramnios.

Material and methods

Patient population. Patients from our clinical practice or from our antenatal testing unit at MacDonald Hospital for Women in Cleveland, Ohio, were asked to participate in this study. Informed consent was obtained as approved by the Institutional Review Board of University Hospitals of Cleveland. None of the normal patients studied was taking any medication at the time of the study except for prenatal vitamins. A total of 22 normal pregnant patients (mean gestational age at the time of the study ± SD = 31.2 ± 4.5 weeks) and 11 pregnant patients who were suspected and were later proved to have asymmetric IUGR of the fetus (mean gestational age at the time of the study, 30.0 ± 3.1 weeks) were studied.

Of the eleven patients with IUGR, three had pregnancy-induced hypertension, two were heavy smokers, one had postdate syndrome, one had intractable nausea and vomiting with no weight gain during her pregnancy, one had gestational diabetes with pregnancy-induced hypertension, and there was no apparent cause for IUGR in three patients. Of the 11 patients with IUGR seven had oligohydramnios, whereas the other four had normal amniotic fluid. It is of interest that the highest values for the systolic/diastolic ratio (S/D) of the fetal renal artery were found in the group with oligohydramnios. Statistical analysis of the waveform was done between these two subgroups of patients with IUGR and is shown in Table I. Among the group of seven patients who had IUGR and oligohydramnios, four had reverse umbilical artery diastolic flow and nonreactive nonstress test results. All four had an emergency cesarean section because of fetal distress, and the neonates' birth weights were <1500 gm (780, 900, 1100, 1400 gm, respectively). All four neonates had respiratory distress syndrome, apnea, bradycardia, jaundice, and difficulty in heat control. The other seven patients had reactive nonstress test results and negative contraction stress test results and were vaginally delivered of infants at 36.8 ± 1.2 weeks. Except for being small for gestational age (SGA) all seven infants did well in the neonatal period.

Instrumentation. All patients had a routine ultrasonographic examination. Measurements of biparietal diameter, femur length, and abdominal circumference were obtained. Placental grading and amniotic fluid determination were noted. The amniotic fluid volume determination was performed with a semiquantitative technique as previously described.[6] The estimated fetal weight was then determined with previously published tables.[7] Birth weights 2 SDs below the mean[8] were con-

sidered to be SGA. Duplex ultrasonographic examinations were performed with a 3 or 5 mHz real-time pulsed-wave Doppler system (UM 8, Advanced Technology, Bothell, Wash.). The Doppler cursor was placed in the lumen of the vessel and the sample volume was kept to a minimal size (1.5 mm).

The wall filter was also kept to minimal settings (50 Hz) to obtain the full Doppler spectrum during diastole. With the use of a foot pedal, the two-dimensional image was intermittently frozen on one screen while the Doppler signal was displayed on the opposite screen. When an adequate waveform was displayed, a hard copy for subsequent analysis was made on a strip-chart recorder set at a speed of 50 mm/sec. Maximum power intensity was previously set by the company to meet the Food and Drug Administration's preenactment level requirements (i.e., I_{SPTA} = 46 mW/cm^2, I_{SPPA} = 65 W/cm^2, and Im = 160 W/cm^2).* Power was further decreased to 10% of its maximum intensity.

*I_{SPTA} = Maximum value of spatial peak temporal average intensity, I_{SPPA} = maximum value of spatial peak pulsed average intensity, Im = spatial peak maximum intensity.

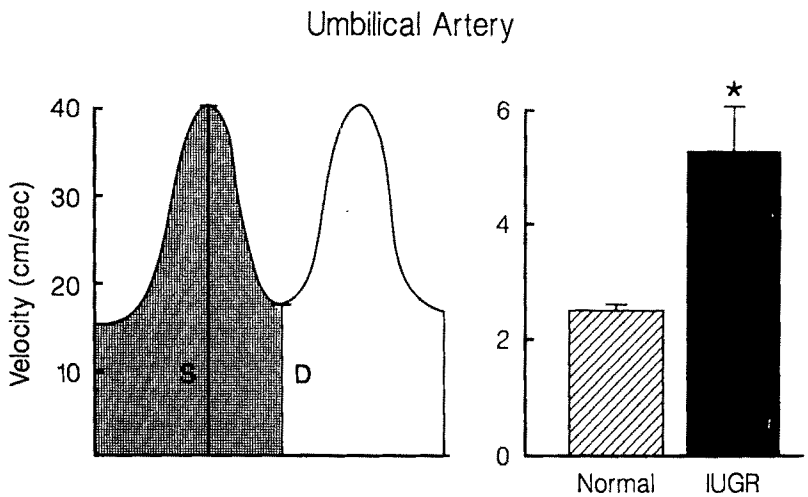

Fig. 3. Summary of umbilical artery S/D ratio. Fetuses affected by IUGR are shown to have significantly higher value. *Denotes p value <0.01.

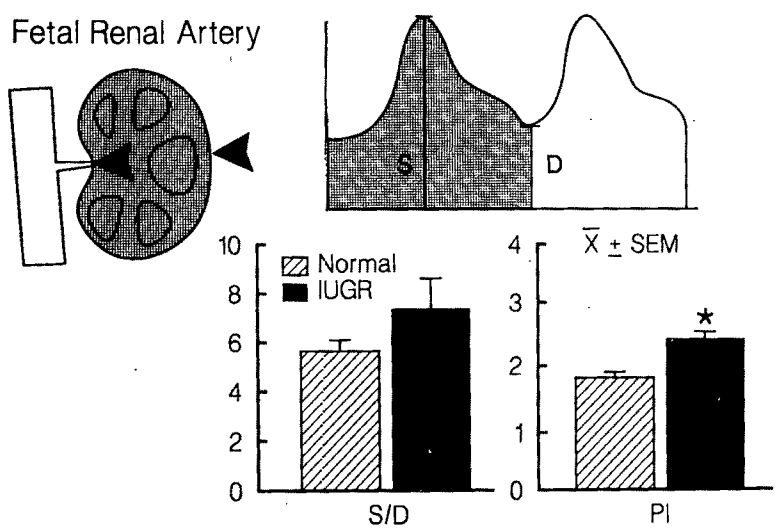

Fig. 4. Summary of fetal renal artery S/D ratio and pulsatility index *(PI)* in normal and IUGR fetuses. No difference in S/D ratio was found. Pulsatility index was significantly elevated in IUGR fetuses. *Denotes p value <0.01.

Duplex examination

Umbilical artery. The placental cord insertion was localized and the umbilical artery identified. The sample volume was placed in the lumen of the vessel and recorded on a strip-chart recorder. Signals were recorded with the fetus in a quiet state and during apnea. Six cycles were calculated for the S/D ratio value and averaged (Fig. 1).

Renal artery. An axial view of the fetus was obtained at the level of the kidneys. The abdominal aorta was identified. Doppler sample volume was placed at the hilus renalis, and then carefully positioned as parallel as possible to the renal vessel to obtain a maximum signal. At times it was necessary to use a larger Doppler sample volume to obtain an adequate waveform. This was then decreased to obtain a signal with the least amount of artifact. Although we could not determine the precise angle of the Doppler beam to the renal artery, repositioning of the transducer and the Doppler sample was accomplished to maximize the waveform signal. The abdominal aorta gave a significantly different signal that helped to differentiate between the two waveforms. A minimum of three consecutive cardiac cycles were analyzed (Fig. 2).

Waveform analysis. The waveforms were analyzed with a digital image processing system (Digisonics, Inc., Houston, Tex.). Each waveform was traced from the hard copy on a tablet digitizer and entered in the com-

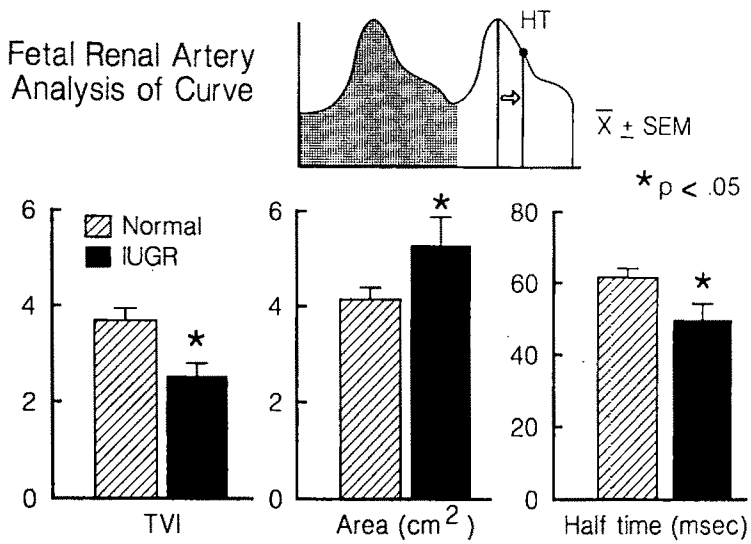

Fig. 5. Time-velocity integral *(TVI)*, area of curve, and half-time of curve between normal and IUGR fetuses. Time-velocity integral and half-time were significantly lower in IUGR fetuses. However, area was significantly higher in IUGR fetuses.

puter program. The systolic and diastolic peak flow velocities were analyzed for both the umbilical artery and the fetal renal artery.

The area under the waveform and the time-velocity integral of the curve were derived by planimetry. The velocity curves were digitalized with the use of the darkest portion of the curve as well as its external contour. The time-velocity integral is derived by the summation of all the different velocity components of the curve (i.e., the variation of the velocity distribution, or the narrow band of frequencies on the spectral display). The area half-time of the traced waveform is the time taken for the Doppler curve to decrease from its peak value to half of its peak value.

Statistical analysis was performed with the nonpaired Student t test with a p value of <0.05 used to reject the null hypothesis. Mean and SEM are reported.

Results

The S/D ratio of the umbilical artery was significantly different in the normal fetuses, as compared with the asymmetrically grown fetuses (2.5 ± 0.11 versus 5.3 ± 0.79, respectively; $p < 0.01$) (Fig. 3). However, the S/D ratio of the waveform for the fetal renal artery was not significantly different between the two groups (5.64 ± 0.45 versus 7.38 ± 1.24, respectively) (Fig. 4). The pulsatility index (i.e., the systolic peak velocity minus the diastolic peak velocity divided by the mean velocity of the waveform) was significantly higher in the abnormal group (1.89 ± 0.08 versus 2.34 ± 0.13; $p < 0.05$) (Fig. 4). Both the time-velocity integral and the area half-time were significantly higher in the normal group, as compared with the abnormally grown fetuses time-velocity integral, 3.69 ± 0.25 versus 2.54 ± 0.26 cm/sec and half-time, 61.5 ± 2.48 versus 49.7 ± 4.59 msec, respectively) (Fig. 5). The total area under the fetal renal artery waveform was significantly larger in the IUGR fetuses (4.15 ± 0.25 versus 5.29 ± 0.59 cm^2, respectively) (Fig. 5).

Comment

Significant differences in the analysis of the umbilical artery and the fetal renal artery waveform were discovered between normally grown fetuses and the fetuses affected by asymmetric IUGR. In the normally grown fetuses the S/D ratio and the pulsatility index of the umbilical artery were found to be significantly higher in the IUGR group. This was largely because of a decrease in the amplitude of the diastolic component of the waveform in the IUGR group. Similar findings have been reported in human pregnancies and agree with our study.[9-11] In fact, a similar decrease in the diastolic component of the umbilical artery waveform has been reported in pregnant ewes after repeated placental embolization through the umbilical artery.[12] With progressive embolization, the end-diastolic velocity waveform progressively decreased and reversed flow was observed before fetal death. This suggests that the abnormal waveform pattern of the umbilical artery is caused by a progressive increase in vascular resistance within the placental bed (Morrow RJ. Unpublished observations).

The S/D ratio of the fetal renal artery was not significantly higher in the IUGR group. With the use of the mean value of the flow velocity curve, the pulsatility index was calculated and found to be significantly el-

evated in the fetuses affected by IUGR. Similarly, significant differences were found when the time-velocity integral and the area half-time of the fetal renal artery waveform were analyzed. This not only indicates that the S/D ratio cannot discriminantly identify impaired fetal renal blood flow, but also suggests that the way the fetal kidney is perfused in the IUGR fetuses is different from that in the normally grown fetus. The majority of the fetuses (4/7) with IUGR and oligohydramnios had signs suggestive of acute fetal hypoxia. It is always possible that the difference between the IUGR and the normally grown fetuses could be explained by the four fetuses with acute hypoxia rather than the growth retardation. Analysis of the data into those with and those without signs of acute fetal hypoxia did not show major differences in the fetal renal waveform between these two groups except for the S/D ratio. Such results suggest that the changes between the IUGR and the normally grown fetuses are mostly a result of the growth retardation process. Similar findings were reported by Rigsby[3, 4] in the renal artery of transplanted kidneys during acute rejection. They speculated that the abnormal renal waveform may be a result of structural, neurogenic, or humoral process mechanism. Experimental work in dog, lamb, and primate fetuses with the use of radioactive microspheres during acute and chronic preparations suggests that both neurogenic and humoral mechanisms are indeed operational and are responsible for local changes in renal blood flow.[12-15] With embolization of the dog's kidneys with microspheres, a good correlation between progressive increase in the renal vascular resistance and decreased organ perfusion was found.[1]

In the instrumented lamb, the renal blood flow has been estimated to be between 2% and 3% of the combined cardiac output during physiologic conditions.[12, 13] During either hypoxemia or hypercapnia, renal blood flow was shown to be reduced by 25% to 50% of the baseline values.[14] Vasoconstriction occurred abruptly when the fetal arterial Po_2 value fell <20 mm Hg. Although the exact mechanism for this decrease in renal blood flow is not clear, it is thought to be mediated by the local action of prostaglandins.[16] In our study the decrease in the time-velocity integral indicates that the quantity of blood perfusing the kidney of the IUGR fetus is decreased but that the decrease found in the area half-time of the renal waveform suggests that the kidney is being perfused at a faster rate. Another possible explanation for the above findings is that there is a significant increase in the vascular resistance distal to the point of measurement. This is in keeping with experimental evidence that vasoconstriction of the renal vascular bed occurs in fetuses with an inappropriate uterine environment. The fact that in our study the total area under the fetal renal artery waveform is higher in the IUGR group may reflect local mechanisms trying to maintain adequate renal perfusion under such circumstances of poor growth.

Our results of an elevated pulsatility index seem paradoxical. If the area of the curve is larger in the IUGR fetuses and the mean value for the curve increases, the pulsatility index should be lower in this group. However, the systolic component of the curve was markedly elevated in this group. The net result was that the difference in the S/D value increased, giving a higher value to the pulsatility index. This would imply that instead of a local vasodilatation on the renal vasculature, the fetal renal blood flow may be maintained by a combination of increase in arterial pressure and intrarenal action of catecholamines, vasopressin, and prostaglandins as previously reported.[17, 18]

It is always possible that technical differences occurred during the sampling of the fetal renal artery waveform. Variability in the Doppler angle could, in turn, affect the shape of the waveform and create significant problems in the interpretation of the data. Although such bias could have occurred because we did not visualize the fetal renal artery per se, we were careful to maintain the Doppler sample volume parallel to the fetal hilus renalis to keep the Doppler angle as close as possible to zero in all views. This study is qualitative in nature as quantification of Doppler echocardiographic data implies that the accurate estimation of the vessel studied can be obtained. Qualitative analysis of the waveform is not angle-dependent and gives an estimate of resistance to flow rather than an estimate of total flow.

Our results suggest that the overall perfusion of the kidney in the fetus affected with IUGR is maintained inasmuch as the diastolic component of the waveform was found to be normal, but the way the kidneys are perfused is different from the normally grown fetus. The oligohydramnios observed in cases of severe IUGR may then be a result of an inability of the kidney to compensate for the decrease in blood flow velocities and increased vascular resistance, which results in an overall decrease in renal blood flow and glomerular filtration rate.[17]

We thank Beth Wilson, RN, for her coordination efforts and Joyce Olson for her assistance in this study.

Intrapartum Doppler velocimetry, amniotic fluid volume, and fetal heart rate as predictors of subsequent fetal distress

I. An initial report

Albert P. Sarno, Jr., MD, MAJ, USA, Myoung Ock Ahn, MD, MPH, Harbinder S. Brar, MD, Jeffrey P. Phelan, MD, and Lawrence D. Platt, MD
Los Angeles, California

This study examines the usefulness of umbilical artery Doppler velocimetry, amniotic fluid volume assessment, and fetal heart rate data in the early intrapartum period as predictors of subsequent fetal distress. A total of 109 patients seen in the latent phase of labor in the labor and delivery area were studied. Both an abnormal initial fetal heart rate and an amniotic fluid index ≤5.0 cm were associated with a significant increase in the incidence of intrapartum fetal distress. Conversely, a systolic/diastolic ratio >3.0 by Doppler ultrasonography was not associated with increased fetal morbidity. Overall, the sensitivities, specificities, and positive predictive values of the fetal heart rate tracing and the amniotic fluid volume assessment were comparable. Doppler systolic/diastolic ratios showed very poor sensitivity and positive predictive value. We conclude that the fetal heart rate tracing or the assessment of amniotic fluid volume in the early intrapartum period are reasonable predictors of subsequent fetal condition. The lack of patients with the absence of or reverse umbilical velocity preclude conclusions with regard to Doppler systolic/diastolic ratios for this purpose. (Am J Obstet Gynecol 1989;161:1508-14.)

Key words: Doppler velocimetry, amniotic fluid volume, fetal heart rate, intrapartum fetal distress

The routine use of intrapartum fetal heart rate (FHR) monitoring has been addressed by the Executive Board of the American College of Obstetricians and Gynecologists.[1] The recently published statement states that intermittent fetal auscultation "is as effective as electronic fetal monitoring in monitoring high risk patients during labor."

However, physicians trained in the era of fetal monitoring may be uncomfortable in following up patients in this manner. In addition, staffing requirements and medical-legal risks are practical issues to be confronted. Therefore studies aimed at further identification of the correct patients for auscultation alone seem indicated.

This information could then be used to triage patients to either continuous intrapartum electronic fetal monitoring or intermittent auscultation. The evaluation, if rapid and easily performed, could be done by the labor and delivery nurse with the results relayed to the physician.

Should the physician prefer to monitor all fetuses with electronic monitoring, this same test may provide information to alert the physician to the increased likelihood of fetal distress. More intensive monitoring and preparations for cesarean delivery may then be indicated. Because most community hospitals do not have 24-hour inhouse obstetric and anesthesia coverage, earlier notification of appropriate personnel may be helpful.

The concept of a "fetal admission test" has been addressed with either the initial FHR monitor strip[2] or the fetal response to acoustic stimulation.[3] Other parameters that may potentially be useful as an admission test include amniotic fluid volume and umbilical artery blood flow as measured by Doppler velocimetry.

This study examines the usefulness and predictive values of Doppler velocimetry, amniotic fluid volume assessment, and FHR patterns early in the course of labor for the subsequent development of intrapartum fetal morbidity.

Material and methods

The study group consisted of 109 patients seen at the labor and delivery unit of Women's Hospital,

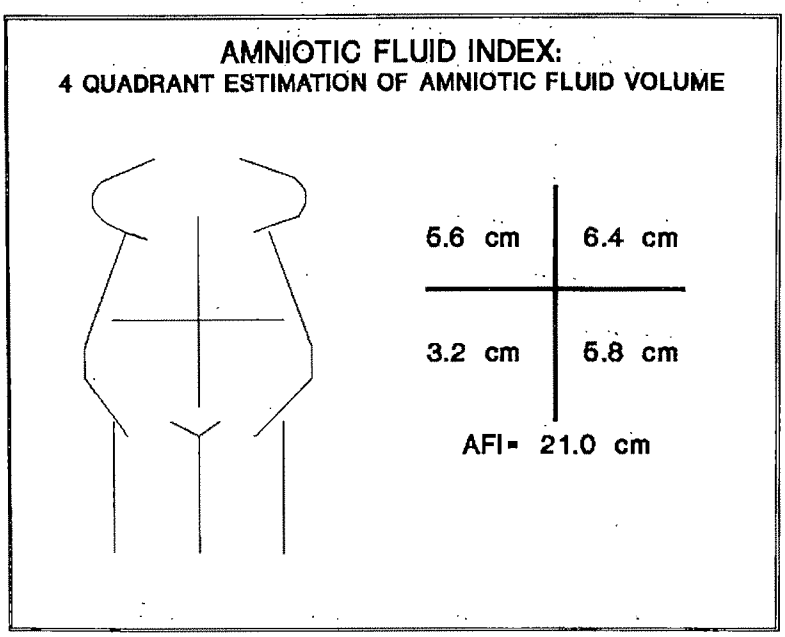

Fig. 1. Schematic representation of four-quadrant estimation of amniotic fluid volume. Greatest vertical diameters of largest pocket of amniotic fluid in each quadrant are summed to form amniotic fluid index. (Hypothetical numbers are shown).

Los Angeles County/University of Southern California Medical Center from August 1, 1987, to December 1, 1987. Inclusion criteria included term or post-term pregnancy (≥36 completed weeks' gestation) as assessed by usual clinical criteria, singleton fetus, vertex presentation, and latent phase of labor. The presence of ruptured membranes was not exclusionary. All patients were evaluated by a single examiner (A. S.).

FHR tracings were examined in both the first and last 40 minutes of monitoring and were evaluated for baseline rate, reactivity, beat-to-beat variability, and the presence of severe variable decelerations, late decelerations, and bradycardia. Severe variable decelerations were graded by the criteria of Kubli et al.[4] Severe variable decelerations and late decelerations were diagnosed only if present with >50% of contractions. Fetal bradycardia was defined as a FHR of 90 beats/min or a decline in heart rate of 40 beats/min from baseline, persisting for 1 minute. FHR reactivity was present if at least a single acceleration of the FHR of 15 beats/min from baseline lasting 15 seconds was noted.[5] Baseline variability was normal if >5 beats/min. For purposes of the study, an abnormal FHR tracing was deemed to be present when any of the following were present: (1) abnormal FHR baseline; (2) decreased baseline variability; (3) absence of reactivity; (4) variable decelerations; (5) late decelerations; or (6) bradycardia.

Real-time ultrasonographic examination was performed with either a General Electric 2600 (Waukesha, Wisc.) or an ADR/ATL Ultramark 4 (Bothell, Wash.) with a 3.5 mHz linear transducer. Amniotic fluid volume was assessed by the amniotic fluid index, which divides the maternal abdomen into four quadrants and measures the greatest verticle diameter of the largest pocket of amniotic fluid in each quadrant and adds the measurements (Fig. 1). An amniotic fluid index >5.0 cm was considered to reflect adequate fluid.[6] The results of the amniotic fluid index were not revealed to the physicians who managed the patient's labor.

Umbilical artery velocimetry was then performed with continuous-wave Doppler ultrasonography (Angioscan III, Unigon Industries, Yonkers, N.Y., or Multigon 500A, Multigon Industries, New York, N.Y.) with a 4 mHz transducer with a power output of 6.5 mW/cm^2 and an effective depth of 8 cm. The umbilical velocity waveform, obtained transabdominally, was recognized by the characteristic signature with the arterial and venous flow in opposite directions (Fig. 2). The screen was frozen and peak systolic to lowest end-diastolic ratios (S/D) were computed. Three different recordings were performed, waveforms were analyzed, and the mean value was calculated for a given patient and used for analysis. The results of the Doppler analyses were not revealed to the physicians who managed the patient's labor. An S/D ratio >3.0 was considered abnormal for term gestation.[7]

Pregnancy outcome was assessed with respect to the incidence of meconium staining, fetal distress that required cesarean delivery, Apgar scores at 1 or 5 minutes <7, birth weight less than the 10th percentile for gestational age, subsequent abnormal FHR patterns, and perinatal mortality. Sensitivity, specificity, and predictive values for fetal distress requiring

cesarean delivery were calculated for each testing modality. Statistical analysis was carried out with the Fisher exact test or χ^2 analysis, and significance was considered at $p < 0.05$.

Results

Table I shows the maternal variables for the entire study population. Equal numbers of patients were first seen with either intact or ruptured membranes. Suspected postdate pregnancy occurred in 31.5% of patients, but most of these had poor clinical dating criteria.

Table II describes pregnancy outcome related to the interpretation of the initial FHR tracing, the amniotic fluid index and Doppler S/D ratio. Of 109 patients, 21 were noted to have abnormalities of the initial FHR tracing, an incidence of 19.3%. Although all indexes of morbidity are higher in the abnormal tracing group, there is a significant increase in fetal distress that requires cesarean delivery (p = 0.0009, RR = 21.6). A total of 17 of 109 patients were found to have oligohydramnios, for an incidence of 15.6%. All indexes of morbidity (except small for gestational age) are increased in the group with oligohydramnios and this reaches statistical significance for fetal distress that requires cesarean delivery (p = 0.047, RR = 5.3) and Apgar score <7 at 1 minute (p = 0.002, RR = 3.3). There was no relationship in the incidence of oligohydramnios to postdate and nonpostdate pregnancies (20.0% and 21.4%, respectively).

Abnormal Doppler flow was found in eight of 109 patients (7.3%). None of these eight patients had the absence of or reverse end-diastolic flow velocity (range of S/D ratios, 3.03 to 6.5). Seven of these eight values were between 3.0 and 3.6, with a single value more significantly elevated at 6.5. An abnormal S/D ratio was not associated with an increase in any index of fetal morbidity. Both fetuses that were small for gestational age had normal S/D ratios. The mean S/D ratio in the group of patients in whom fetal distress developed was 2.26 (range, 1.36 to 2.66), whereas the mean S/D ratio for the group without fetal distress was 2.30 (range, 1.45 to 6.50).

Though equal numbers of patients were seen with intact and ruptured membranes, 5 of 57 patients with intact membranes had oligohydramnios (8.8%), whereas 12 of 52 patients with ruptured membranes had oligohydramnios (23.1%), a significant difference (p = 0.04, χ^2).

Table III shows pregnancy outcome in patients with oligohydramnios in relation to the status of membranes on admission. Morbidity is equal between the two groups, which suggests that oligohydramnios as a result of ruptured membranes has equal significance with preexisting oligohydramnios.

Table IV describes FHR patterns in the last 40 minutes of labor in relation to the results of the initial FHR tracing, amniotic fluid index, and Doppler velocimetry. Patients with abnormal initial FHR patterns had significant increases in the incidence of severe variable decelerations and late decelerations with decreased variability. Patients with oligohydramnios had significant increases in the incidence of baseline tachycardia, loss of reactivity, and bradycardia. An abnormal S/D ratio was associated with a significant increase in the incidence of bradycardia in subsequent labor.

Table V shows the sensitivity, specificity, positive pre-

dictive value, and negative predictive value of the initial FHR, amniotic fluid index, and Doppler velocimetry for subsequent fetal distress that required cesarean delivery.

Comment

The concept of an admission test performed early in the course of labor is attractive because it provides an assessment of current fetal condition and risk. This evaluation would be important even in routine obstetric populations because intrapartum morbidity develops in 10% to 20% of patients at "low risk."[8,9] A fetal admission test may provide a mechanism to triage patients to a "low-risk" or "high-risk" status. Should the patient and her health care provider desire, this may allow intermittent auscultation or intermittent monitoring. Reassuring admission test results may obviate the need for telemetry in the patient who desires to ambulate through the latent phase of labor. Nonreassuring test results would alert the physician to an increased risk of fetal intolerance of labor. Continuous monitoring and physician vigilance may then be indicated.

Diagnostic modalities evaluated thus far include the initial FHR strip and the fetal response to acoustic stimulation. Ingemarrson et al.[2] have studied the usefulness of a short FHR strip in early labor and have found a low rate of intrauterine asphyxia (0.9%) when the tracing was reassuring and a high rate (50%) when the tracing was ominous. In a subsequent study, the same authors evaluated the fetal response to acoustic stimulation and found this technique to be a useful adjunct to the initial FHR strip in the exclusion of fetal compromise in early labor.[3] An ominous FHR strip in association with a nonreactive response to acoustic stimulation was associated with a 75% risk for fetal distress.

Amniotic fluid volume has been found to aid in the assessment of fetal condition in antepartum surveillance.[11] Antepartum oligohydramnios with intact membranes has been associated with postdate pregnancy,[11] intrauterine growth retardation,[12] fetal anomalies,[13] abnormal antepartum FHR patterns,[10] and increased perinatal morbidity and mortality.[11] Therefore, it would seem a logical extension to evaluate amniotic fluid volume in the early intrapartum period as a predictor of subsequent fetal morbidity.

Doppler umbilical artery velocimetry has been used to evaluate high-risk pregnancies. Previous studies by Fleischer et al.,[14] Trudinger et al.,[15] and Brar et al.[16]

have established a relationship between impaired end-diastolic flow velocity, intrauterine growth retardation, and adverse fetal outcome. Abnormal Doppler flow may also be an earlier indicator of fetal compromise than is the nonstress test in intrauterine growth retardation.[17]

Brar et al.[18] have evaluated placental vascular resistance by Doppler S/D ratios in patients with late decelerations and control patients with reactive tracings. Patients with late decelerations had mean S/D ratios significantly higher than those of the control group (4.32 versus 2.32) as well as higher incidences of meconium, cesarean section because of fetal distress, low Apgar scores and admissions to the neonatal intensive care unit. However, the morbidity in this group was largely a result of those patients with late decelerations and elevated S/D ratios as opposed to those with late decelerations and normal S/D ratios. They concluded that Doppler assessment may be an important adjunct during intrapartum monitoring of patients with late decelerations and may help discriminate "false-positive" from "true-positive" late decelerations.

This study suggests that both the initial FHR tracing and amniotic fluid volume assessment may be reasonable choices for an admission test. The sensitivities, specificities, and positive and negative predictive values are comparable, although the FHR strip has somewhat better sensitivity and positive predictive value. The FHR tracing certainly is the most readily available and most physicians are familiar with its interpretation, which makes this technique readily applicable.

However, amniotic fluid volume assessment may provide information not obtainable by evaluation of the FHR strip: the fetus at risk because of cord compression as a result of oligohydramnios. The association noted between ruptured membranes, oligohydramnios, and increased morbidity in this study suggests that fetal morbidity may occur as a result of oligohydramnios after membrane rupture. To identify this population, ultrasound assessment of amniotic fluid volume should be performed on all patients who are admitted to the hospital in labor with ruptured membranes. It would seem logical that prophylactic amnioinfusion may decrease morbidity in this group of patients because the technique has been shown to relieve variable decelerations,[19] and decrease morbidity in preterm premature rupture of the membranes.[20] These approaches are being investigated.

The lack of correlation between abnormal Doppler S/D ratios and adverse fetal outcome is not surprising given the relatively small number of patients in the study. Although eight patients were found to have elevated S/D ratios, there were no cases of absent or reverse end-diastolic flow velocity, the abnormalities most predictive of poor fetal outcome. The mean S/D ratios in patients with and without fetal distress (2.26 versus 2.30) were not different, which suggests that elevated placental vascular resistance was not a common cause of fetal distress in the study population. In keeping with the findings of Brar et al.[18] it would appear that the role of Doppler velocimetry in the intrapartum period would be one as an adjunctive test in the presence of abnormal FHR patterns that are suggestive of uteroplacental insufficiency, rather than one as a screening test. Correlation of Doppler S/D ratios with a large number of patients who exhibit decreased variability and lack reactivity seems indicated given the association between late decelerations and abnormal S/D ratios. The lack of correlation between Doppler S/D ratios and variable decelerations is predictable because abnormal flow velocity in the umbilical artery is reflective of a primary lesion within the placental vascular bed,[21] whereas variable decelerations reflect acute cord compression,[22] two very distinct pathophysiologic mechanisms.

The value of a screening test is measured by its sen-

sitivity, specificity, and predictive value for abnormal outcome. With reference to a screening test for subsequent fetal distress, the clinician is most interested in the positive predictive value of the test (i.e., given abnormal test results, what is the risk for adverse outcome?). However, the positive predictive value of a test varies with the incidence of the disease. For example, when the incidence of the disease is 5% and sensitivity and specificity are kept constant at 95%, the maximum positive predictive value obtainable is 50% (i.e., 50% of patients with abnormal test results will have the abnormal outcome). In the current study 6 of 109 patients (5.9%) required cesarean delivery because of clinical fetal distress. This low incidence may account for the relatively low positive predictive values noted for all three testing modalities. Therefore, it would appear that the utility of abnormal screening test results would be to provide the clinician with the information that the risk of intrapartum fetal distress is increased. However, immediate intervention by cesarean delivery would not be indicated.

Conversely, the predictive value of negative (normal) test results can be clinically useful in the evaluation of a test that predicts fetal condition in subsequent labor. The high negative predictive values noted for all three testing modalities should reassure the clinician when the test results are normal. In this instance the finding of normal or "reassuring" test results may then allow triage of the patient to intermittent auscultation.

Sensitivity (the probability that the test results will be abnormal in all cases of adverse outcome) and specificity (the probability that the test results will be normal in all cases of normal outcome) are also important indicators of the accuracy of the screening test. Whereas the initial FHR tracing and the amniotic fluid index identified 83.3% and 50% of patients with abnormal outcome, respectively, Doppler S/D was not abnormal in any case of adverse outcome (mean S/D, 2.26; range, 1.36 to 2.66). However, all three testing modalities showed comparable specificity when compared to each other.

Overall, it would appear that both the initial FHR tracing and the amniotic fluid index may be of value as screening tests within the scheme outlined above; however, the lack of sensitivity and positive predictive value with Doppler S/D ratios mitigate against its use as a primary screening tool in this situation.

It would seem that the combination of initial FHR (or fetal acoustic stimulation) with amniotic fluid index assessment into a comprehensive admission test with Doppler velocimetry as an adjunctive test in the presence of an abnormal initial FHR or oligohydramnios may provide even better sensitivity, specificity, and predictive values than any single test. The finding of oligohydramnios in the presence of ruptured membranes increases the risk for fetal distress most likely as a result of acute cord compression; therefore, prophylactic amnioinfusion may be effective in decreasing fetal morbidity.

Table V. Sensitivity, specificity, and positive and negative predictive value of initial FHR, amniotic fluid index, and Doppler S/D for subsequent fetal distress requiring cesarean delivery (%)

	Sensitivity	*Specificity*	*Positive predictive value*	*Negative predictive value*
Initial FHR	83.3	84.5	23.8	98.9
Amniotic fluid index	50.0	86.4	17.6	96.7
Doppler S/D	0	92.2	0	94.1

In conclusion, our study suggests that the initial FHR strip or amniotic fluid index in early labor may be reasonable to use as a fetal admission test to guide subsequent labor management. Doppler velocimetry does not appear to be of use in this setting, but may be of value as an adjunctive test in cases in which abnormal heart rate patterns, decreased amniotic fluid volume, or reverse flow are seen or if flow is absent. Unfortunately, none of the latter were seen in this study; therefore, a larger study is being carried out.

Doppler assessment of the fetal and uteroplacental circulation during nifedipine therapy for preterm labor

Giancarlo Mari, MD, Brian Kirshon, MD, Kenneth J. Moise, Jr., MD, Wesley Lee, MD, and David B. Cotton, MD

Houston, Texas

To investigate the effects of nifedipine on the human fetal circulation, 11 fetuses whose mothers were treated with nifedipine for treatment of preterm labor were studied. Maximum velocity waveforms were obtained in the middle cerebral artery (n = 8), renal artery (n = 6), ductus arteriosus (n = 8), and umbilical artery (n = 10). Transvalvular maximal velocity waveforms were obtained across the aortic (n = 11) and pulmonary (n = 7) valves. Maternal uterine arteries also were studied (n = 7). Doppler data were collected before and 5 hours after nifedipine therapy. Patients received an oral loading dose of 30 mg of nifedipine followed by a second oral dose of 20 mg 4 hours later. No significant difference in the flow velocity waveforms was found in the vessels studied 5 hours after the initial dose. These results suggest that short-term nifedipine therapy does not influence either fetal or uteroplacental circulation as evaluated with the Doppler technique. (AM J OBSTET GYNECOL 1989;161:1514-8.)

Key words: Doppler, nifedipine, fetal blood flow

Nifedipine is a calcium channel blocker with hemodynamic effects, including negative inotropic action, inhibition of atrioventricular conduction, and coronary and peripheral vasodilation.[1] Nifedipine has been used in the treatment of pregnancy-induced hypertension[2,3] and preterm labor.[4,5] In view of potential adverse effects of calcium channel blockers in the rhesus monkey[6] and fetal lamb,[7] this drug has not been used extensively in human pregnancy. The purpose of this study was to evaluate Doppler blood flow velocity waveforms of various regional blood flows in fetuses whose mothers were given nifedipine for treatment of preterm labor. Additionally, the uteroplacental circulation was studied.

Material and methods

Image-directed pulsed Doppler techniques were used to obtain maximum blood velocity waveforms in 11 normal fetuses whose mothers received nifedipine for treatment of preterm labor. All of the patients ini-

tially received a 30 mg dose of oral nifedipine, followed by a 20 mg oral dose 4 hours later. The studies were performed before and 5 hours after the initial nifedipine dose (1 hour after the second dose) in the following vessels: middle cerebral artery (n = 8), renal artery (n = 6), umbilical artery (n = 10), ductus arteriosus (n = 8), pulmonary (n = 7) and aortic (n = 11) valves, and uterine arteries (n = 7). The decision to assess the fetal status by Doppler technique at 5 hours after the loading dose (30 mg) and 1 hour after the second dose was based on the fact that the half-life of nifedipine is 2 hours with peak blood levels occurring approximately 30 minutes after oral administration.[8] Because gastric absorption is delayed in pregnancy, we elected to study the fetus at 60 minutes instead of 30 minutes after the second dose of nifedipine. In so doing it was thought that an adequate maternal and fetal nifedipine level would be obtained.

The patients were studied between 10 AM and 10 PM and remained in a fasting state on entry into the study. All the patients had preterm painful uterine contractions when they were first seen, and the diagnosis was preterm labor in all. All patients gave written consent for the study, which was approved by the Baylor Human Investigational Review Board. After the initial dose of nifedipine, continuous fetal heart rate monitoring was performed. The maternal heart rate and pressure were recorded before nifedipine and thereafter at 15, 30, and 60 minutes and hourly thereafter. Nifedipine levels were determined (n = 8) by reverse-phase high-performance liquid chromatography analysis after Doppler evaluation (approximately 6 hours after the initial nifedipine dose).

Doppler ultrasonographic studies were carried out with a General Electric PASS II cardiac ultrasonography system. A 2.5 MHz transducer was used with a 2 mm sample volume. A 50 Hz pass filter was used. Doppler ultrasonographic energy was 114 mW/cm^2 spatial peak temporal average intensity. The fetuses were examined with the mothers in a semirecumbent position. Doppler examination of the renal artery was performed in the following manner: a sagittal section of the fetal body was visualized, and the ultrasonographic beam was directed laterally to the spine, to obtain a coronal section of the fetal body. By moving the transducer anteriorly, a coronal section of the descending aorta and kidneys was imaged. As the renal artery could not be visualized clearly, the sample volume was positioned in the renal hilum and then moved toward the aorta, enabling pulsed Doppler waveforms to be recorded at different points along the renal vessels. Doppler waveforms of the artery and vein were detected simultaneously and displayed on either side of the baseline (Fig. 1, *A*). Doppler examination of the middle cerebral artery (Fig. 1, *B*) was performed as reported previously.[9] The ductus arteriosus (Fig. 2, *A*) was studied as described by Huhta et al.[10] and Moise et al.[11] Umbilical artery waveforms were recorded by placing the sample volume in the cord; both artery and

vein could be recorded at the same time (Fig. 3, *A*). The uterine arteries (Fig. 3, *B*) were studied as described by Schulman et al.[12] Doppler velocity waveforms were recorded on videotape and a computer system was used to calculate the pulsatility index (peak velocity − end-diastolic velocity/mean velocity)[13] of the middle cerebral artery, renal artery obtained at level of the aorta, umbilical artery, and uterine artery. The peak velocity of the ductus arteriosus was also obtained. The time velocity integral, defined as the area under the Doppler velocity curve, was measured in the pulmonary artery at or slightly above the pulmonary valve (Fig. 2, *B*) and at the aortic valve (Fig. 2, *C*). The relationship between aortic and pulmonary time velocity integrals multiplied by heart rate (a parameter proportional to ventricular cardiac output)[14] was studied. Three consecutive waveforms were analyzed and the results averaged. Measurements were obtained only during fetal apnea. We defined apnea as the absence of visible changes in the waveform patterns for at least 15 waveforms.

Paired Student's *t* test was used to compare the baseline pulsatility index values with those obtained after the start of nifedipine therapy. Analysis of variance was used to compare the maternal blood pressure and heart rate at different time intervals. A probability value of <0.05 was considered to indicate statistical significance.

Results

The maternal age ranged between 17 and 39 (mean ± SD 22.3 ± 6). Parity ranged between 0 and 5. The gestational age of the fetuses ranged from 26 to 34 weeks (mean ± SD 31 ± 2.5 weeks).

The short-term effects of nifedipine on the fetal circulation as evaluated by the Doppler method were examined in the fetuses. The results are summarized in Table I.

The maternal nifedipine levels 6 hours after the initial dose (2 hours after the second dose) were between 23 and 145 ng/ml (51.2 ± 38 ng/ml) ($n = 8$). Preterm labor abated in all patients. Analysis of variance showed no significant difference in the maternal blood pressure

and heart rate ($p > 0.05$). No evidence of fetal distress was observed on the fetal heart rate monitor during the study period. The gestational age at delivery ranged between 33 and 41 weeks (mean ± SD 38.5 ± 2.54 weeks). The birth weight ranged between 1860 and 3950 gm (3026 ± 692 gm). Apgar scores at 1 and 5 minutes ranged between 6 and 9 (8.2 ± 0.9) and 8 and 10 (9.2 ± 0.6), respectively.

Comment

Oral nifedipine has been used to treat pregnancy-induced hypertension[2, 3] and preterm labor.[4, 5] Read and Wellby[4] found oral nifedipine to be more effective than ritodrine in suppressing premature uterine activity. Walters and Redman[2] observed a rapid and significant fall in maternal blood pressure by an average of 26/20 mm Hg 20 minutes after oral administration in 21 women with acute episodes of severe hypertension during pregnancy or in the puerperium. These authors observed no adverse fetal effects. Veille et al.[15] found no significant changes in maternal uterine blood flow, arterial blood pressure, and heart rate after intravenous administration of nifedipine in pregnant, unanesthetized pygmy goats. Ahokas et al.[16] investigated the short-term effects of nifedipine in 12 hypertensive term-pregnant rats. Nifedipine (200 μg/kg) lowered mean arterial pressure 25% by decreasing total peripheral resistance 38%. Cardiac output was increased 15%. Placental blood flow was not significantly altered, but resistance was decreased.

Ducsay et al.,[6] during periods of spontaneous uterine contractility, administered nicardipine (another calcium channel blocker) to chronically catheterized rhesus monkeys, at 128 and 132 days' gestation. Fetal heart rate and blood pressure were unaffected, however, fetuses became acidotic and hypoxemic after maternal nicardipine treatment. Harake et al.[7] administered nifedipine intravenously for 30 minutes to chronically instrumented pregnant ewes. Infusion of 5 μg/kg/min resulted in a 30% to 50% increase in total and regional fetal cerebral blood flow. Infusion of 10 μg/kg/min decreased uterine blood flow by 21% and fetal arterial oxygen content by 15%, with no further increase in fetal cerebral blood flow. Maternal arterial blood pressure decreased and heart rate increased with no change in maternal arterial blood gas values. The decrease of uterine blood flow reported by Harake et al.[7] could be a consequence of the redistribution of the blood flow to other maternal circulatory regions. The acidosis and hypoxemia observed by Ducsay et al.[6] after administration of calcium channel blockers could be a consequence of the reduced uterine blood flow as reported by Skillman et al.[17] in the fetal lamb.

Doppler studies have been shown to be a valuable tool to assess fetal well-being. Fetal Doppler studies have shown a correlation between abnormal flow velocity waveforms of the umbilical artery and an increased incidence of complications in the fetus and/or infant.[18] A significant relationship has been found between the pulsatility index of the umbilical artery (>1.5) in high-risk pregnant patients and pH, P_{CO_2}, and lactate concentrations obtained from umbilical blood sampled in utero.[19] The pulsatility index of cerebral waveforms has been found to be a powerful indicator for the development of neonatal neurologic abnormalities.[20] Pathologic uterine artery waveforms are associated with high-risk pregnancy.[21] Additionally, studies have demonstrated the ability of the Doppler technique to diagnose tricuspid regurgitation and fetal ductus arteriosus constriction, as a consequence of maternal indomethacin therapy used in the treatment of preterm labor.[10, 11]

Our results show no significant difference in the pulsatility index of the vessels studied. Additionally no significant changes were observed in the peak velocity of the ductus arteriosus and the product of the time velocity integral and heart rate in the pulmonary and aortic valves. The lack of change in the latter suggests that no significant change in cardiac output occurred during nifedipine. It is possible that higher doses of nifedipine and/or continuous intravenous administration could modify the pulsatility index values.

Plasma levels of nifedipine during the period of study were calculated with the effective half-life of the drug taken into account. Therapeutic effects of nifedipine (decrease of diastolic blood pressure) have been reported with plasma values in the range of 15 ng/ml.[22] Others, have reported a therapeutic action of nifedipine (decrease of mean arterial pressure) with plasma values as low as 3 ng/ml.[23] Finally, a large interindividual variation has been reported in the plasma level of nifedipine for different doses tested.[24] Our maternal plasma nifedipine levels ranged from 23 to 145 ng/ml. Thus absence of waveform changes occurred at a time when nifedipine was present in the circulation and presumably exerting other actions.

This study demonstrates that it is possible to study the effects of a calcium channel blocker on various human fetal areas with a noninvasive method. Our results suggest that nifedipine does not adversely affect uteroplacental and human fetal blood flow as evaluated by the Doppler method in the doses used for treatment of preterm labor in this study. Whether the same results will be obtained during long-term therapy or with a more aggressive dosage regimen remains to be established.

Maternal and fetal blood flow velocity waveforms in patients with preterm labor: Relationship to outcome

Harbinder S. Brar, MD, Arnold L. Medearis, MD, Greggory R. DeVore, MD, and Lawrence D. Platt, MD

Los Angeles, California

Elevated systolic/diastolic ratios obtained by umbilical and uterine velocimetry have been used to predict adverse pregnancy outcome. We performed pretherapy umbilical and uterine velocimetry by means of continuous-wave Doppler ultrasonography on 92 patients who came for treatment in preterm labor. Fourteen (15.2%) and 12 (13%) patients had elevated uterine (>2.6) and umbilical (>3.5) systolic/diastolic ratios, respectively, and 9 (9.8%) patients had both ratios elevated. Overall 17 (18.5%) patients had at least one abnormal systolic/diastolic ratio. Patients with abnormal Doppler waveforms had a significantly shorter gestation, infants with lower birth weights, and a higher incidence of adverse pregnancy outcome as determined by meconium, cesarean section for fetal distress, low 1- and 5-minute Apgar scores, and days in the neonatal intensive care unit, compared with patients with normal systolic/diastolic ratios. There was no significant difference in the ability of uterine, umbilical, or combined velocimetry to predict preterm birth or adverse pregnancy outcome. Doppler studies in preterm labor patients may help to identify patients at increased risk for preterm birth and poor pregnancy outcome. Further studies are warranted to assess its usefulness in the evaluation of these patients. (Am J Obstet Gynecol 1989;161:1519-22.)

Key words: Doppler ultrasonography, preterm labor

Perinatal morbidity and mortality have decreased over the last decade. However, further reduction in the incidence and complication of preterm birth continues to be a major goal in perinatal medicine.[1] Some recent reports have suggested retarded fetal growth in preterm deliveries.[2] The recent introduction of Doppler ultrasonography[3] has made it possible to study the fetoplacental[4] and uteroplacental[5] circulation in a noninvasive manner. Umbilical artery waveforms show increasing end-diastolic velocity with advancing gestation, probably as a result of increased compliance of the placenta.[4] Uterine artery compliance is achieved late in the second trimester, reflected by a peak systolic/end-diastolic (S/D) ratio of <2.6 and the absence of diastolic notching.[5] Umbilical and uterine artery waveforms obtained by Doppler ultrasonography have been useful for the surveillance of high-risk pregnancies including hypertension,[5] twins,[6] diabetes,[7] and placenta previa.[8] Abnormalities in waveforms also have been correlated with adverse pregnancy outcome in the preterm[9] and term[10] small-for-gestational-age fetus. Our previous studies have shown the effect of tocolytic agents on these waveforms[11] and an association between abnormal waveforms and failure of tocolysis.[12] The principal objective of this study was to determine the incidence of uterine and umbilical artery waveform abnormalities in patients with preterm labor and their ability to predict preterm birth and adverse pregnancy outcome in such pregnancies.

Material and methods

Ninety-two consecutive patients in preterm labor who were seen at the labor and delivery suite of Women's Hospital, Los Angeles County–University of Southern California Medical Center were studied. All patients signed informed consent forms before entry into the study. Inclusion criteria included premature uterine contractions with a frequency of ≥2 in 10 minutes, <36 completed weeks of gestation, documented cervical change, and cervical dilation <4 cm. Patients with ruptured membranes, known intrauterine growth retardation, medical complications of pregnancy, or a mature lung profile were excluded from the study. Pretherapy umbilical and uterine artery waveforms were obtained transabdominally with continuous-wave Doppler ultrasonography (Angioscan III, Ultrasonix Inc.) according to previously described techniques.[13] S/D ratios of three different umbilical waveforms were computed and the mean calculated. The mean of the right and left uterine artery S/D ratios was also calculated and used in the statistical analysis. Patients were then treated with ritodrine or magnesium sulfate according to the managing physician's choice. Magnesium

sulfate tocolysis was given as a 4 gm intravenous bolus over 15 minutes and maintenance therapy ranging from 1 to 4 gm/hr to suppress uterine contractions. Ritodrine was given as an intravenous infusion with a starting dose of 50 μg/min that was increased by 50 μg/min every 15 minutes until uterine contractions were suppressed, a maximum dose of 350 μg/min was reached, or significant side effects occurred. Data collected included age, parity, gestational age at entry and delivery, meconium at delivery, cesarean section for fetal distress, birth weight, and its classification for gestational age by California curves (small for gestational age was defined as <10th percentile), Apgar scores, Dubowitz score, neonatal death, and number of neonatal intensive care unit days. Patients were grouped for analysis according to whether or not they had normal or abnormal uterine and umbilical artery waveforms. A mean S/D ratio of >2.6 or the presence of diastolic notching of the uterine artery waveform was considered abnormal,[5] whereas the cutoff value for abnormal umbilical S/D ratio was 3.5.[12] This value was arbitrarily set higher than the traditional 3.0 value[14] because the patient population was preterm and the umbilical S/D ratio decreases with advancing gestation. The study group was also evaluated according to whether both uterine and umbilical waveforms were abnormal or normal. Comparison of outcome measures consisting of birth weight, preterm delivery at <37 completed weeks of gestation, small for gestational age, meconium, cesarean section for fetal distress, number of neonatal intensive care unit days, and neonatal deaths were performed in the different groups with χ^2 or Fisher's exact test as appropriate. A p value <0.05 was considered statistically significant. Descriptive statistics were calculated in the usual manner. The sensitivity, specificity, and predictive values of umbilical, uterine, and combined velocimetry for the prediction of adverse pregnancy outcome and preterm birth were also calculated.

Results

Fifty-eight patients received magnesium sulfate and 34 patients received ritodrine tocolysis. The mean maternal age was 24.5 ± 2.6 years (range, 18 to 32), and the mean parity was 1.8 ± 0.8 (range, 0 to 5). The mean gestational age at entry was 32.7 ± 1.8 (range, 27 to 36) weeks; women had a mean cervical dilation of 1.2 ± 0.5 cm (range, 0.5 to 4). The incidences of abnormality in umbilical and uterine S/D ratios were 12 patients (13%) and 14 patients (15.2%), respectively. Nine (9.8%) patients had an abnormal umbilical S/D ratio and an abnormal uterine S/D ratio. Seventeen (18.5%) patients had at least one abnormal S/D ratio. There was no significant difference in the mean gestational age and cervical dilation at entry in the normal and abnormal groups. The relationship of the umbilical S/D ratios to long-term pregnancy outcome is shown in Table I. A significantly higher number of patients with elevated umbilical S/D ratios were delivered preterm, and consequent their infant had lower birth weight when compared with patients with normal ratios. A significantly higher number of patients with abnormal umbilical S/D ratios had outcome parameters suggestive of adverse pregnancy outcome, including meconium in amniotic fluid, cesarean section for fetal distress, and low Apgar scores, compared with patients with normal ratios. Neonates of patients with abnormal umbilical S/D ratios spent a significantly longer time in the neonatal intensive care unit compared with patients with normal ratios. The single neonatal death in the group studied occurred in a patient with both abnormal ratios.

An association similar to umbilical S/D ratios was found between abnormal uterine S/D ratios and adverse pregnancy outcome (Table I). The mean gestational age and birth weight at delivery of patients with abnormal uterine S/D ratios was significantly lower ($p < 0.05$) than patients with normal ratios. There was a significant association between adverse pregnancy outcome as assessed by meconium, low Apgar scores, and cesarean section for fetal distress and abnormal uterine S/D ratios. In addition, neonates of patients with abnormal uterine ratios spent significantly ($p < 0.05$) more days in the neonatal intensive care unit compared with patients with normal ratios.

When both uterine and umbilical velocimetry are combined, nine patients had both ratios abnormal. There was a significant association between adverse pregnancy outcome and both ratios being abnormal (Table I).

The sensitivity, specificity, and positive and negative predictive values of umbilical, uterine, and combined velocimetry for the prediction of adverse pregnancy outcome and preterm birth are shown in Table II. There were no statistically significant differences in the predictive values, sensitivity, or specificity when different methods were compared.

Comment

Our previous study[12] showed the association between elevated umbilical and uterine S/D ratios and the failure of tocolysis with delivery within 48 hours. This study evaluates the role of screening Doppler waveform analysis to subsequent pregnancy outcome in preterm labor patients. Although we do not have a control population without preterm labor, the overall incidence (18.5%) of abnormal umbilical and uterine ratios in this group of patients is higher than that expected in a low-risk population, but similar to that reported in other high-risk pregnancy conditions.[14] The presence of el-

*Preterm birth was defined as <37 weeks. Adverse pregnancy outcomes included small-for-gestational-age fetus, cesarean section for fetal distress, meconium, and low 1- and 5-minute Apgar scores.

evated S/D ratios presumably represents elevated downstream vascular resistance.[15] There appears to be a progressive increase in the incidence of poor perinatal outcome and increase in S/D ratios with progressive changes within the placental vasculature.[16] Therefore the association between elevated S/D ratios and the presence of adverse pregnancy outcome in patients with preterm labor is consistent with other reports that suggest a similar association in other high-risk pregnancies, including pregnancy-induced hypertension,[5] twins,[6] diabetes,[7] and placenta previa.[8]

Abnormal uterine and umbilical S/D ratios have both been associated with retarded fetal growth.[16, 17] Abnormal (retarded) growth has also been observed in neonates delivered after preterm birth and premature rupture of membranes.[2] Although patients with prenatally diagnosed intrauterine growth retardation were excluded from the study, three neonates were classified as having intrauterine growth retardation after delivery; all three had abnormal umbilical and uterine S/D ratios. It is possible that other neonates who were not overtly growth retarded had abnormal slowing of the growth but had not fallen below the 10th percentile. Therefore the presence of abnormal S/D ratios in patients with preterm labor may be another indicator of decreased fetal growth, requiring careful assessment of fetal growth for the duration of pregnancy and the initiation of antepartum fetal assessment protocols.

There does not appear to be any significant difference in the predictive values or sensitivity and specificity of use of either the fetoplacental (umbilical) or the uteroplacental (uterine) S/D ratios or a combination of both in predicting adverse pregnancy outcome and preterm birth. Many of the fetuses we studied had both waveforms abnormal, and therefore would suggest that increased resistance on either side of the placenta has an equally adverse effect on the fetus.

Whereas abnormal ratios appear to predict preterm birth (<37 weeks) reasonably well, their sensitivity appears to be lower when compared with the prediction of failed tocolysis (delivery <48 hours after onset of preterm labor), as suggested in our previous study.[12] The patients with abnormal and normal S/D ratios had similar gestational ages and cervical dilation at time of

entry into the study. Therefore the higher incidence of preterm birth in patients with abnormal umbilical and uterine S/D ratios cannot be attributed to these variables. The role of uterine and umbilical velocimetry as a screening test in predicting preterm delivery in the general population is unknown and requires further investigation.

The association of abnormal waveforms with preterm birth is intriguing. It is possible that the stress of increased uterine or umbilical resistance and decreased flow may be linked to altered prostaglandin synthesis and production.[18] This may also explain the high incidence of preterm labor and birth in other high-risk pregnancies that also have a high incidence of abnormal uterine and umbilical ratios.[14] Another possible explanation for this relationship may be that preterm labor patients have a reduced expansion of intravascular volume that is also seen in patients with preeclampsia.[19] It is interesting to speculate that this more limited intravascular volume expansion could contribute to abnormal waveforms seen in preterm labor and preeclampsia of pregnancy.[5] Clearly further study is needed in this area to answer these questions.

The relationship of the success of tocolytic therapy to Doppler waveform has previously been shown.[12] Whether or not an abnormal Doppler waveform will prove to be a contraindication to tocolytic therapy has not been studied. However, from our previous work[11] it appears that there is no direct adverse effect on S/D ratios when tocolytic agents are used. In fact, the lowering of the S/D ratio caused by increasing heart rate[20] might somehow benefit the fetus. These hypotheses require well-designed prospective studies that include standard methods of fetal assessment, such as the nonstress testing, contraction stress test, or biophysical profile, and assessment of biochemical parameters of pregnancy outcome, such as umbilical cord gas measurements. In conclusion, it appears that incorporating umbilical and uterine artery velocimetry in the initial assessment of patients suspected to be in preterm labor may be a helpful adjunct in managing these pregnancies. Further study is warranted before its use can be considered standard for evaluation of preterm labor patients.

Clinical management of the fetus with markedly diminished umbilical artery end-diastolic flow

Michael Y. Divon, MD, Barbara A. Girz, DO, Richard Lieblich, MD, and Oded Langer, MD

Bronx, New York

This study was conducted to evaluate prospectively a management protocol for fetuses with a markedly abnormal umbilical artery velocity waveform. The study population consisted of fetuses whose systolic/diastolic ratio was >2 SD above the mean for gestational age. The matched control population consisted of fetuses with similar gestational ages, indications for testing, and estimated fetal weights with normal systolic/diastolic ratios. Abnormal Doppler results were used only to determine the frequency of fetal testing. Biophysical profile testing was performed semiweekly on all patients. Patients with absent or reversed end-diastolic flow were admitted for daily testing. The following criteria were used as indications for delivery: (1) worsening maternal condition, (2) oligohydramnios, (3) intrauterine growth retardation with lung maturity, and (4) biophysical profile score ≤4. Fifty-one patients (7%) had abnormal Doppler blood flow velocity studies. When the study population was compared with the control population at the time of delivery, there were no differences in umbilical artery pH, Apgar score, or incidence of intrauterine growth retardation. However, study patients were delivered at a significantly lower gestational age and lower birth weight and experienced a higher likelihood of neonatal intensive care unit admission. When study patients with documented end-diastolic flow were compared with study patients with no end-diastolic flow, there were no differences in umbilical artery pH, Apgar score, or incidence of intrauterine growth retardation. However, fetuses with no end-diastolic flow had a significantly shorter test-to-delivery interval, lower gestational age, lower birth weight, and more neonatal intensive care unit admissions. There were no perinatal deaths among the study patients. The range of systolic/diastolic ratios for the five patients who failed to follow our protocol for intensive maternal-fetal surveillance was 4.3 to infinity; all experienced fetal death within 18 days. These results suggest that immediate delivery of the fetus with diminished end-diastolic flow may not be mandatory. The combined use of fetal biophysical testing and commonly used criteria for delivery results in acceptable fetal outcome and prolongation of gestational age. (Am J Obstet Gynecol 1989;161:1523-7.)

Key words: Fetal Doppler, umbilical artery velocimetry management

Abnormal umbilical artery velocity waveforms have been associated with an increased risk for perinatal morbidity and mortality. Such waveforms probably reflect increased placental impedance to blood flow and are consistent with histologic evidence of a placental vascular lesion.[1] Recent reports have described the ominous fetal outcome associated with a markedly abnormal umbilical artery velocity waveform. Some authors have suggested that perinatal management of these pregnancies should be "aggressive" because perinatal mortalities range from 50% to 90%.[2, 3] Woo et al.[4] described eight perinatal deaths in nine fetuses with absent or reversed umbilical artery end-diastolic blood flow and concluded that this situation mandates immediate delivery. Schulman[5] suggested that absent end-diastolic flow is an emergency situation in which "frequent fetal surveillance" is mandatory. Despite the increased interest in the use of Doppler techniques in obstetrics, guidelines for clinical management of such pregnancies have not been established. The purpose of this study was to evaluate a management protocol for pregnancies complicated by a markedly abnormal umbilical artery velocity waveform.

Material and methods

A prospective, matched control study of two groups of fetuses was designed. The study population consisted of patients with markedly abnormal umbilical artery end-diastolic flow; the control population consisted of patients with similar indications for fetal testing, gestational ages, and estimated fetal weights with a normal umbilical artery blood flow pattern. No attempt was made to match for maternal age and parity.

The study population was drawn from a private,

middle-class patient population evaluated at the Maternal-Fetal Assessment Center of the Albert Einstein College of Medicine. Patients with congenital anomalies, postdate pregnancies, or gestational age <26 weeks were excluded from the study. The study period extended from July 1, 1985, through Jan. 31, 1989. Umbilical artery velocity waveforms were obtained with a continuous-wave Doppler device (Fetal-Flo, Medasonics, Calif., or Angioscan III, Multigon, N.Y.). The location of the umbilical cord was determined by a real-time ultrasonographic scanner, and the Doppler transducer was aimed in the direction of the umbilical cord. We accepted recordings for analysis only after obtaining a steady state of at least five consecutive pulsatile arterial waveforms. The umbilical artery flow velocity waveform was characterized by the ratio of peak systolic/end-diastolic frequencies (S/D ratio). Three S/D ratios were determined per patient, and the results were averaged. No waveforms were obtained during periods of fetal breathing movements, body movements, or cardiac arrhythmias.[6] An S/D ratio >2 SD above the mean for gestational age for this population was used to define a markedly abnormal test result.[7] The absence of end-diastolic flow was confirmed by turning off the thump filter during the examination. Alterations of end-diastolic flow were used only to determine the frequency of fetal testing. Biophysical profile testing was performed semiweekly on all patients. Patients with absent or reversed end-diastolic flow were admitted for bed rest and daily fetal testing. The following criteria were used as indications for delivery: (1) worsening maternal condition, (2) oligohydramnios (largest pocket of amniotic fluid <2 cm), (3) severe intrauterine growth retardation (IUGR) (when the sonographic estimated fetal weight was <3rd percentile for gestational age) with established lung maturity,[8] (4) biophysical profile score ≤4 (abnormal fetal heart rate was not used as a sole criterion for delivery). Patients with abnormal S/D ratios were not considered candidates for tocolysis; steroids were administered if delivery was planned or expected between 28 and 32 weeks' gestation. Outcome data were collected and included diagnosis-to-delivery interval, indication for delivery, mode of delivery, Apgar score, umbilical artery pH, gestational age at birth, birth weight, neonatal intensive care unit admission, and perinatal mortality. Gestational age was determined by the last menstrual period and an ultrasonographic examination before 22 weeks' gestation. IUGR was identified when the birth weight was below the 10th percentile for gestational age according to the Brenner curve.[9] Results were compared by Student's *t* test, Wilcoxon's test, or χ^2 as appropriate and considered significant at $p < 0.05$.

Results

During the study period 1186 singleton pregnancies were evaluated. Four hundred sixty-eight patients were excluded (17 with significant fetal anomalies and 451 with postdate pregnancies). Fifty-one patients (7%) had an S/D ratio >2 SD above the mean for gestational age. Fifteen of these patients had no end-diastolic flow; 3 of these 15 had reversed end-diastolic flow. The indications for fetal testing and delivery for the study patients and their matched controls are presented in Tables I and II, respectively. Most study patients (and therefore their matched controls) had either hypertension, diabetes, or IUGR. Study patients were significantly more likely to be delivered because of fetal indications and were therefore much less likely to experience spontaneous onset of labor.

Table III compares patient characteristics and fetal outcome for study and control patients. There were no significant differences in umbilical artery pH, Apgar score, or incidence of IUGR. However, study patients were delivered at a significantly lower gestational age, lower birth weight, and with a higher incidence of neonatal intensive care unit admissions. Table IV compares study patients with and without end-diastolic flow. There were no significant differences in umbilical artery pH, incidence of IUGR, or Apgar score <7 at 5 minutes. However, those fetuses with no end-diastolic flow had a significantly shorter test-to-delivery interval, lower mean gestational age, lower birth weight, and higher incidence of neonatal intensive care unit admissions.

There were no perinatal deaths among the study or control patients. However, there were five patients with abnormal S/D ratios who failed to follow our protocol for intensive maternal-fetal monitoring. Fetal death was confirmed within 18 days of the abnormal test. The range of S/D ratios for these patients was 4.3 to infinity.

All patients were hypertensive, and fetal testing at the time of the Doppler study was indicative of a nonasphyxiated fetus.

Comment

The fetal biophysical profile is commonly used for antepartum fetal assessment. Several studies have shown that a high biophysical profile score predicts fetal health with excellent accuracy.[10] Doppler velocimetry has been recently discussed as a potential means of fetal surveillance.[11-13] Several investigators have shown that abnormal umbilical artery velocity waveforms can be detected before the development of abnormalities noted on traditional fetal testing. Furthermore, recent reports have emphasized the ominous pregnancy outcome associated with markedly abnormal umbilical artery velocity waveforms.[2-5] The usefulness of fetal biophysical profile testing in patients with markedly abnormal umbilical artery velocity waveforms has not been previously assessed. The results of this study indicate that intensive monitoring of patients with very abnormal umbilical artery velocity waveforms, combined with the use of commonly accepted criteria for delivery, results in acceptable fetal outcome.

Our results demonstrate that fetuses with an abnormal umbilical artery velocity waveform are at a significantly increased risk for early delivery, decreased birth weight, and neonatal intensive care unit admission. Berkowitz et al.[14] evaluated fetal outcome among growth-retarded fetuses and have shown that those with an abnormal S/D ratio were at increased risk for early delivery, reduced birth weight, decreased amniotic fluid at birth, and neonatal intensive care unit admission. Similar results have been reported by other investigators.[15, 16]

The mean gestational age at delivery for the study patients was significantly lower than that for the control patients (35.4 ± 3.6 vs. 38.5 ± 2.5 weeks, respectively). In addition, patients with no end-diastolic flow were delivered at a significantly lower gestational age than study patients in whom some end-diastolic flow could be documented (33 ± 3.9 vs. 36 ± 3 weeks, respectively). These findings are probably related to the fact that as end-diastolic flow diminishes, the need to deliver the patient increases. The median test-to-delivery interval for study patients with documented end-diastolic flow was 24 days, compared with a median of 4 days for study patients with absent end-diastolic flow. Three

patients with reversed end-diastolic flow were all delivered on the day of the Doppler test. The same phenomenon is also reflected by the neonatal birth weights. The mean birth weights for control subjects, study patients with documented end-diastolic flow, patients with no end-diastolic flow, and patients with reversed end-diastolic flow were 2980, 2002, 1376, and 1150 gm, respectively. Thus, as the end-diastolic flow diminishes, the birth weight and the birth weight percentile are also smaller. On the basis of these data, it seems that umbilical artery diastolic flow should be considered as a continuum. This phenomenon is also time dependent. Although most study patients were delivered because of fetal or maternal indications, a few (16%) reached term and began labor spontaneously before the ill effects of the increased placental impedance could be documented by traditional end points, such as abnormal fetal testing, abnormal cord gas values, or presence of IUGR.

Should patients with no end-diastolic flow be delivered immediately? The range of diagnosis to delivery in the study group was 0 to 11 days, with a mean gestational age of 33 weeks. Although they were delivered within a median of 4 days of the abnormal test, these preterm fetuses would probably benefit from a no-intervention policy as long as other fetal testing modalities indicate fetal health. Brar and Platt[17] evaluated 31 fetuses with no end-diastolic flow whose diagnosis-to-delivery interval was 2 to 29 days and concluded that "it appears premature to intervene in a pregnancy solely on the basis of abnormal waveforms because antepartum improvement can occur." However, their perinatal mortality rate was 32.3%. The diagnosis-to-delivery interval in our study is much shorter than that reported by Brar and Platt and is the probable explanation for the fact that we report a lower perinatal death rate.

Brar and Platt[2] reported their experience with 12 fetuses who demonstrated umbilical artery reversed end-diastolic flow. Their test-to-delivery interval was 5 to 7 days and their perinatal mortality was 50%. Our experience with this group of patients is limited. Three of the study patients had reversed end-diastolic flow. These fetuses were delivered on the day of the Doppler test because of a biophysical profile score ≤4, were mildly acidotic at birth (with cord arterial pH values of 7.11, 7.14, and 7.21), were admitted to the neonatal intensive care unit, and had birth weights below the 5th percentile for gestational age. All mothers were hypertensive and one had superimposed preeclampsia. There were no perinatal deaths. Thus it seems unlikely that the duration of pregnancy can be significantly prolonged once the placental impedance is increased to the extent that it causes a rebound of blood flow during diastole.

Five study patients failed to follow our protocol for intensive fetal-maternal assessment. All five experienced intrauterine fetal death. The perinatal morbidity of the monitored study patients was zero, and their umbilical arterial pH was not statistically significant from that of the control patients (7.24 ± 0.045, range 7.11 to 7.32, vs. 7.29 ± 0.04, range 7.18 to 7.36, respectively). Furthermore, the fact that the lowest pH value obtained on the study patients was 7.11 seems to indicate that, despite the presence of very abnormal velocity waveforms, intensive monitoring combined with commonly accepted criteria for delivery was useful in preventing severe forms of fetal acidosis. The other management option would have been to deliver these fetuses immediately after documentation of a markedly abnormal umbilical arterial waveform. If this had been done, study patients would have been delivered at an undesirably low mean gestational age of 32.2 weeks instead of the actual gestational age at delivery, 35.4 weeks (Table II).

Because the purpose of our study was to evaluate commonly used fetal monitoring techniques in fetuses with abnormal umbilical artery velocity waveforms, patients with either significant congenital anomalies or gestational age <26 weeks were excluded from this study. Several investigators reported that abnormal waveforms can be detected in these patient populations.[3, 18, 19] Our reasons for exclusion of these patients seem obvious: (1) The management of significant congenital anomalies is complex and not always related to the ability to document fetal well-being; (2) we did not intend to study the efficacy of fetal surveillance before 26 weeks of gestation. Patients with postdate pregnancies were excluded from the study on the basis of our previous experience showing that "umbilical artery velocimetry is unlikely to be useful for the antenatal assessment of the postdate fetus."[20] Clearly, fetal outcome reported by investigators who include lethal congenital anomalies or gestational ages <26 weeks, or both, is expected to be less satisfactory than that reported in our study.

In conclusion, umbilical artery diastolic blood flow should be considered on a continuum. As the end-diastolic flow decreases, perinatal morbidity increases. The difficulty with delivery of every fetus with an abnormal umbilical artery velocity waveform is that these waveforms are often detected at early gestational ages when delivery may result in iatrogenic prematurity. The use of Doppler velocimetry, fetal biophysical testing, and commonly used criteria for delivery may result in a prolonged gestational age with acceptable fetal outcome.

Doppler assessment of the pulsatility index of the middle cerebral artery during constriction of the fetal ductus arteriosus after indomethacin therapy

Giancarlo Mari, MD, Kenneth J. Moise, Jr., MD, Russell L. Deter, MD, Brian Kirshon, MD, James C. Huhta, MD, Robert J. Carpenter, Jr., MD, and David B. Cotton, MD

Houston, Texas

To investigate the effects of constriction of the ductus arteriosus on the pulsatility index of the middle cerebral artery, maximum velocity waveforms were obtained in 13 fetuses (one set of twins) whose mothers were treated with indomethacin for preterm labor (n = 9) or polyhydramnios (n = 3). Eleven of the fetuses manifested ductal constriction within 48 hours of therapy, whereas two fetuses had constriction after 1 week of therapy. Six of the 13 fetuses also manifested tricuspid insufficiency in association with constriction of the ductus arteriosus. All abnormal cardiac changes resolved in utero after discontinuation of indomethacin. No difference in the pulsatility index values of the middle cerebral artery was observed in the fetuses with ductal constriction but without tricuspid regurgitation (n = 7) when the values were compared with those obtained in absence of ductal constriction (1.87 ± 0.37 vs. 1.88 ± 0.33). In the fetuses that manifested both ductal constriction and tricuspid insufficiency (n = 6), the pulsatility index values in the middle cerebral artery were significantly lower in the presence of ductal constriction when compared with the values obtained in the absence of ductal constriction (2.22 ± 0.26 vs. 1.57 ± 0.34). These results indicate that a response to indomethacin sufficient to cause both ductal constriction and tricuspid insufficiency decreases the pulsatility index of the middle cerebral artery. (AM J OBSTET GYNECOL 1989;161:1528-31.)

Key words: Fetal Doppler, fetal cerebral circulation, pulsatility index, middle cerebral artery, ductus arteriosus

Indomethacin has been used during pregnancy in the management of preterm labor[1,2] and polyhydramnios.[3,4] At our institution Doppler assessment of the fetal ductus arteriosus is performed in all women treated with indomethacin because of its ability to cause fetal ductal constriction.[5,6] The constriction of the fetal ductus arteriosus may redistribute the blood flow from the right to the left ventricle as has been reported in animal work.[7] In these circumstances an increase in blood flow to the brain could occur because of the greater amount of blood ejected by the left ventricle toward the brain.[8]

The purpose of this study was to investigate blood flow velocity waveforms in the fetal middle cerebral artery before and during indomethacin treatment to determine whether ductal constriction caused by this drug alters hemodynamic parameters in the cerebral circulation.

Material and methods

Image-directed pulsed and continuous-wave Doppler techniques were used to obtain maximum fetal blood velocity waveforms from the ductus arteriosus, tricuspid valve, and middle cerebral artery in 13 fetuses (one set of twins) whose mothers were treated with indomethacin for preterm labor (n = 9) or polyhydramnios (n = 3). The menstrual age varied between 25 and 33 weeks (mean ± SD: 30 ± 2.5 weeks). Seven fetuses manifested ductal constriction (group A); six fetuses also manifested tricuspid insufficiency in association with constriction of the ductus arteriosus (group B). Nine fetuses were noted to have normal baseline echocardiograms with subsequent constriction of the ductus arteriosus. Baseline echocardiograms were not obtained in four fetuses. In these four cases values obtained within 4 days from the resolution of ductal constriction were used as baseline values. The indomethacin dose in all the patients was 25 mg orally every 6 hours.

Doppler ultrasonographic studies were done with a

General Electric PASS II dynamic image scanner. A 2.5 MHz transducer was used with a 2 mm sample volume. A 50 Hz high-pass filter was used. The maximal Doppler ultrasonographic energy was 114 mW/cm², spatial peak temporal average. The fetuses were examined with the mothers in a semirecumbent position.

Doppler examination of the middle cerebral artery was performed as reported previously.[9] After imaging the ductus arteriosus in a sagittal plane as described by Huhta et al.[5] and Moise et al.,[6] pulsed and continuous-wave Doppler examinations of the ductus were performed and the maximal velocities were obtained. The tricuspid valve was examined in the four-chamber view of the heart.

The Doppler velocity waveforms were recorded on videotape and a computer system was used to calculate the following variables: peak systolic velocity, peak diastolic velocity, end-diastolic velocity, and mean velocity. Three consecutive waveforms were analyzed and the results averaged. The mean pulsatility index (peak systolic velocity − end diastolic velocity/mean velocity)[10] was then calculated for the middle cerebral artery. Ductal constriction was defined as the presence of a fetal ductal systolic velocity >1.4 m/sec in conjunction with a diastolic velocity of >0.35 m/sec.[5] Tricuspid regurgitation was considered to be present if a holosystolic regurgitation wave with a velocity >2 m/sec was detected with continuous-wave Doppler. Measurements were obtained only during fetal apnea. We considered apnea to be the absence of visible changes in the waveform patterns for at least 15 waveforms.

Paired Student's *t* tests were used to compare the pulsatility index values in the middle cerebral artery in the presence and absence of ductal constriction. A probability value <0.05 was considered to indicate statistical significance.

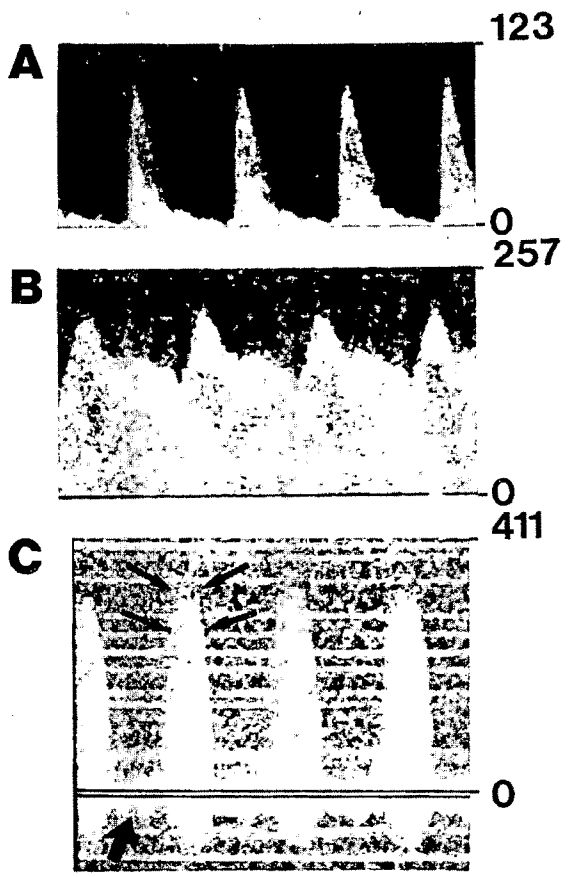

Fig. 1. Doppler waveforms of the ductus arteriosus before **(A)** and during **(B)** indomethacin treatment. (Diastolic velocity in **B** is 40 times the value recorded in **A**). Panel **C** shows the normal tricuspid valve waveform away from the transducer *(large arrow)*, with a regurgitant wave *(four arrows)* (4 m/sec) into the right atrium toward the transducer. All values are reported in centimeters per second.

Results

Eleven fetuses manifested ductal constriction within 48 hours after the initiation of therapy (Fig. 1). In two fetuses the increased blood velocity in the ductus was observed after 1 week of therapy. Ductal constriction and tricuspid insufficiency resolved in all fetuses within 48 hours of discontinuation of the therapy. No adverse fetal or neonatal effects were observed as a result of changes in ductal or tricuspid valve flow velocity waveforms.

No significant difference in the values of pulsatility index of the middle cerebral artery was seen in the seven fetuses with ductal constriction but without tricuspid insufficiency (1.87 ± 0.37 vs. 1.88 ± 0.33) (Tables I and III). A significant difference was observed in group B with both ductal constriction and tricuspid regurgitation (2.22 ± 0.26 vs. 1.57 ± 0.34; $p < 0.05$; Tables II and III). An evaluation of the power of this test indicated that differences ≥19% could have been detected with a probability of 90%.[11]

Comment

Indomethacin may cause constriction of the fetal ductus arteriosus during pregnancy in animals,[12] and the resulting pulmonary arterial hypertension may cause rapid death after delivery.[13] Recently a Doppler method has been validated for recording the blood velocity waveform in the human fetal ductus arteriosus that allows detection of ductal constriction in utero.[5, 6] From our experience in more than 500 studies of the human fetal ductus arteriosus, tricuspid insufficiency (Fig. 1, *C*) is often associated with ductal constriction when peak systolic and diastolic velocities in the Doppler waveforms of the ductus arteriosus are almost identical to those in Fig. 1, *B*. Tricuspid regurgitation probably results from elevated pressure in the right ventricular outflow tract produced by severe ductal

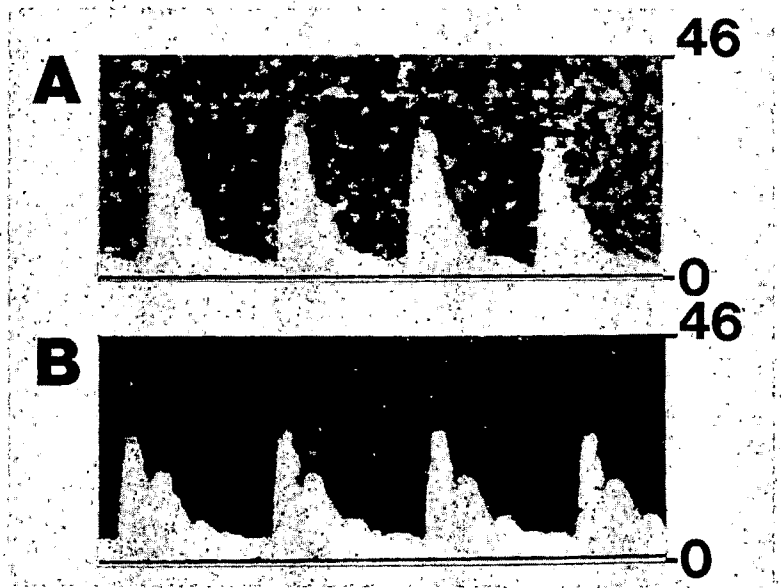

Fig. 2. Doppler waveforms of the middle cerebral artery before (**A**) and during (**B**) ductal constriction with tricuspid insufficiency.

constriction that leads to mild endocardial ischemia with papillary muscle dysfunction.[14]

Our results indicate that when both ductal constriction and tricuspid insufficiency occur simultaneously, the pulsatility index of the middle cerebral artery is significantly reduced (Tables II and III; Fig. 2), but this change is not seen if only ductal constriction is present

Table III. Pulsatility index values (mean ± SD) of middle cerebral artery in the two groups of fetuses

NS, Not significant.

(Tables I and III). The lower pulsatility index observed in these circumstances suggests hemodynamic changes consistent with an increase of cerebral blood flow. This change in flow would be a result of a redistribution of venous return from the right to the left ventricle, as has been demonstrated experimentally in fetal dogs after ligation of the ductus arteriosus.[7] Blood ejected by the fetal left ventricle is directed principally to the head and upper trunk.[8] If an increase of venous return to the left ventricle occurs as a result of severe constriction of the ductus arteriosus, an increase in cerebral blood flow would be expected.

Such changes in the pulsatility index of the middle cerebral artery are considered by several investigators to indicate fetal hypoxia. In a longitudinal study of 14 fetuses, Woo et al.[15] assessed the velocity waveforms of the middle cerebral artery by determining the peak systolic velocity/end diastolic velocity (A/B) ratio (often used as an alternative to the pulsatility index). Hypoxic fetuses were found to have a lower A/B value. Wladimiroff et al.[16] observed that in fetuses with intrauterine growth retardation there was an increase of the end-diastolic velocity in the internal carotid artery and

a decrease of the pulsatility index when compared with normal fetuses. These studies in the human fetus are consistent with experimental studies[17] showing that hypoxia induces increased cerebral blood flow by decreasing peripheral resistance.

Patients treated with indomethacin may also have disease processes that increase the risk of fetal hypoxia. If ductal constriction and tricuspid insufficiency are present, Doppler studies of cerebral arteries may be misleading because changes consistent with hypoxia could occur in the absence of hypoxia as a result of the blood redistribution caused by ductal constriction. In such situations other indicators of hypoxia must be evaluated.

Flow velocity waveforms of the middle cerebral artery are not useful in evaluation of the effects of the indomethacin therapy on the ductus arteriosus in all cases because ductal constriction without tricuspid insufficiency does not influence the pulsatility index of the middle cerebral artery.

In summary, when the middle cerebral artery of a fetus whose mother takes indomethacin is evaluated, it is fundamental to exclude ductal constriction and tricuspid insufficiency because these conditions may affect changes in the Doppler waveforms obtained from the cerebral circulation that could be incorrectly interpreted to represent fetal hypoxia. The decrease of the pulsatility index of the middle cerebral artery that we observed suggests, but does not prove, an increase in blood flow to the brain if indomethacin produces severe ductal constriction. Discontinuation of the therapy is not followed by adverse fetal or neonatal effects.

Human fetal tricuspid and mitral deceleration time: Changes with normal pregnancy and intrauterine growth retardation

Kathryn L. Reed, MD, Christopher P. Appleton, MD, David J. Sahn, MD, and Caroline F. Anderson, RDMS

Tucson, Arizona, and San Diego, California

Studies in instrumented adults have shown an association between Doppler echocardiography–derived atrioventricular valve deceleration times and ventricular function. To determine how gestational age affects deceleration time in the tricuspid and mitral valve, pulsed Doppler ultrasonographic examinations were performed in 54 normal human fetuses. In addition, 26 fetuses with growth retardation and the absence of end-diastolic Doppler velocities in the umbilical artery were examined. Measurements were obtained from strip chart recordings; between three and five beats were used to obtain an average heart rate, ratio of peak velocity at atrial contraction to peak velocity in early diastole, and deceleration time in early diastole. Deceleration times increased during gestation from 86 ± 27 to 116 ± 18 msec in the tricuspid valve and from 98 ± 25 to 132 ± 21 msec in the mitral valve. Fetuses with growth retardation and the absence of end-diastolic Doppler velocities in the umbilical artery had longer deceleration times than those of normal fetuses ($p < 0.01$). The increase in deceleration time across both atrioventricular valves in normal fetuses may be related to heart rate, an increased rate of ventricular relaxation, or an increase in ventricular compliance. The fetuses with intrauterine growth retardation and the absence of end-diastolic velocities in the umbilical artery have abnormally increased deceleration times; in the abnormal fetus this may be a result of impaired ventricular relaxation or decreased ventricular compliance. (AM J OBSTET GYNECOL 1989;161:1532-5.)

Key words: Doppler echocardiography, human fetuses, cardiac physiology

Studies in instrumented adults have shown an association between Doppler echocardiography–derived mitral and tricuspid flow velocity deceleration times and ventricular function. Mitral deceleration time correlates with the maximal negative rate of fall of pressure, the height of the left ventricular rapid filling wave ($-dP/dt$), pulmonary wedge pressure, left ventricular systolic pressure, and left ventricular end-diastolic pressure.[1] In addition, mitral valve deceleration time correlates with the rate of left ventricular relaxation.[2]

We studied Doppler echocardiography–derived deceleration times across the tricuspid and mitral valves in normal human fetuses and fetuses with intrauterine growth retardation (IUGR) and the absence of end-diastolic velocities in the umbilical artery (AEDV). The study was performed to establish the changes that occur during gestation and the changes that occur in the presence of fetal cardiac dysfunction associated with IUGR. AEDV is associated with IUGR and increased perinatal morbidity and mortality.[3-5] Fetuses with AEDV were found to have alterations in cardiac function as determined by Doppler ultrasonographic measurements of volume flow and mitral valve velocity waveforms.[4]

We hypothesized that inasmuch as fetal cardiac function differs from adult cardiac function, the Doppler echocardiography–derived mitral and tricuspid flow velocity deceleration times in the fetus should vary from normal adult values. Both animal[6] and human[7] studies have shown that cardiac function changes with age; therefore, deceleration time should lengthen with advancing gestation as heart rate decreases and the myocardium matures. In addition, because fetal heart rate is faster, deceleration time may be shorter than in the adult. Finally, changes in deceleration time would be predicted in association with the alterations in cardiac function in fetuses with abnormalities of umbilical artery velocity that accompany presumed increases in placental resistance.

Methods

Fetuses with suspected IUGR or suspected anomalies were subjects of this study. Approval for performance of Doppler ultrasonographic studies of the fetuses was obtained from the Human Subjects Committee, and

*p Values compare fetuses at 36 to 39 weeks with fetuses at 20 to 27 weeks.

individual mothers gave informed consent. Fetuses underwent two-dimensional examinations for establishment of fetal size and anatomy, location of the placenta, and amount of amniotic fluid. Normally grown fetuses with normal umbilical artery Doppler flow velocity waveforms and without congenital anomalies were subsequently defined as normal. Pulsed Doppler flow velocity tracings were obtained from the tricuspid valve and mitral valve in 54 normal fetuses and 26 fetuses with IUGR and the absence of end-diastolic Doppler velocities in the umbilical artery. Strip chart recordings obtained during the fetal examinations were measured with a digitizing board. Measurements performed included heart rate, peak velocity during early diastole (E), peak velocity during atrial contraction (A), ratio of peak velocity during atrial contraction to peak velocity during early diastole (A/E ratio), and deceleration time. Deceleration time was measured from the peak velocity during early diastole to the time the slope of the deceleration curve intersected the zero line. Values from three cardiac cycles were averaged for each fetus (Fig. 1). For two-dimensional studies, 3.5 and 5.0 MHz transducers were used; 3.5 MHz transducers were used for Doppler ultrasonographic studies.

Gestational age was established with menstrual dates and ultrasonographic measurements. For the purposes of analysis, normal fetuses were divided into four groups: those between 20 and 27 weeks' gestation, 28 to 31 weeks' gestation, 32 to 35 weeks' gestation, and 36 to 39 weeks' gestation. In addition, measurements from the group of fetuses with IUGR and the absence of end-diastolic velocities in the umbilical artery were compared with measurements from the entire group of normal fetuses. Growth retardation was defined as less than the tenth percentile birth weight by institutional standards.

Statistical analysis consisted of comparison of group means with the Student t test, and correlation of values with regression analysis; p values of 0.05 were considered significant.

Table II. Correlations between atrioventricular valve Doppler echocardiographic measurements, heart rate, and gestational age

	R values	*p Values*
Tricuspid valve A/E ratio versus tricuspid valve deceleration time	−0.31	<0.05
Mitral valve A/E ratio versus mitral valve deceleration time	−0.41	<0.01
Tricuspid valve A/E ratio versus heart rate	0.53	<0.001
Mitral valve A/E ratio versus heart rate	0.53	<0.001
Tricuspid valve A/E ratio versus gestational age	−0.56	<0.001
Mitral valve A/E ratio versus gestational age	−0.53	<0.001
Tricuspid valve heart rate versus gestational age	−0.44	<0.01
Mitral valve heart rate versus gestational age	−0.38	<0.01
Tricuspid valve deceleration time versus heart rate	−0.42	<0.01
Mitral valve deceleration time versus heart rate	−0.59	<0.001
Tricuspid valve deceleration time versus gestational age	0.46	<0.001
Mitral valve deceleration time versus gestational age	0.53	<0.001
Tricuspid valve A/E ratio versus mitral valve A/E ratio	0.65	<0.001
Tricuspid valve deceleration time versus mitral valve deceleration time	0.69	<0.001

Results

Changes in heart rate, tricuspid and mitral valve A/E ratios, and tricuspid and mitral valve deceleration times in the four groups of fetuses divided by gestational age are reported in Table I. Correlations between tricuspid and mitral valve A/E ratios, heart rates, gestational age, and deceleration times are shown in Table II. Table III compares measurements from the group of fetuses with IUGR and AEDV with the entire group of normal fetuses. The average gestational age of the group with IUGR and AEDV was 30.8 ± 4.6

Fig. 1. Mitral valve Doppler flow velocity tracing in 34-weeks' gestation fetus with absence of end-diastolic velocity in umbilical artery. Deceleration time is measured from time of peak velocity during early diastole to time of intersection of deceleration slope with zero line. Dots are 0.5 seconds apart in horizontal plane.

Table III. Comparison of normal fetuses and fetuses with IUGR and absence of end-diastolic velocities

	All normal fetuses n = 54	*Fetuses with IUGR and absence of end-diastolic velocities n = 26*	*p Value*
Triscuspid valve heart rate (beats/min)	138.9 ± 11.0	143.3 ± 8.9	NS
Mitral valve heart rate (beats/min)	138.7 ± 12.1	142.6 ± 8.9	NS
Tricuspid valve peak velocity during early diastole (cm/sec)	35.1 ± 6.8	31.0 ± 10.0	NS
Tricuspid valve peak velocity during atrial contraction (cm/sec)	44.9 ± 7.8	39.4 ± 11.3	<0.05
Mitral valve peak velocity during early diastole (cm/sec)	32.4 ± 7.5	27.5 ± 7.8	<0.01
Mitral valve peak velocity during atrial contraction (cm/sec)	39.9 ± 8.8	31.2 ± 10.7	<0.001
Tricuspid valve A/E ratio	1.31 ± 0.17	1.30 ± 0.21	NS
Mitral valve A/E ratio	1.26 ± 0.25 (p = NS)	1.10 ± 0.24 ($p < 0.01$)	<0.01
Tricuspid valve deceleration time (msec)	101 ± 28	119 ± 18	<0.001
Mitral valve deceleration time (msec)	113 ± 26 ($p < 0.05$)	127 ± 17 (p = NS)	<0.01

weeks, compared with the average gestational age of the normal group of 31.1 ± 4.7 weeks (p = NS).

In fetuses with IUGR and AEDV between 20 and 27 weeks' gestation, tricuspid valve deceleration time (138 ± 31 msec, $n = 5$) was longer than normal ($p < 0.01$), and mitral valve deceleration time (127 ± 18 msec, $n = 5$) was longer than normal ($p < 0.02$). Tricuspid valve peak velocity during early-diastolic filling (26.8 ± 3.3 cm/sec) was less than normal ($p < 0.05$), as was tricuspid valve peak velocity during atrial contraction (34.9 ± 9.5 cm/sec, $p < 0.05$). Mitral valve peak velocity during early-diastolic filling was also lower than normal (20.8 ± 4.2 cm/sec, $p < 0.01$), as was mitral valve peak velocity during atrial contraction (24.3 ± 9.9 cm/sec, $p < 0.01$).

Comment

Cardiovascular physiology in the fetus is usually examined with the use of noninvasive methods and this necessarily limits the amount of information obtained.

Information about blood pressure and resistance are only estimated; volume flow can be calculated but has a large component of error.[8] Studies that correlate information derived invasively from the instrumented adult to information derived noninvasively by Doppler echocardiography were extrapolated to the fetus. In a recent study by Appleton and colleagues,[1] left ventricular function was examined in the adult by comparing pressure and flow data with various Doppler echocardiography–derived indices from mitral flow velocity recordings obtained simultaneously. Mitral flow velocity deceleration times were correlated with ventricular diastolic properties including the rate of relaxation of the left ventricle. In general, mitral deceleration time was correlated with the maximal negative rate of fall of pressure ($-dP/dt$), the height of the left ventricular rapid filling wave, pulmonary wedge pressure, left ventricular systolic pressure, and left ventricular end-diastolic pressure. In addition, at relatively normal atrial filling pressures, deceleration time was also related to the time constant of isovolumic relaxation.[1]

In this study of normal fetuses, tricuspid and mitral flow velocity deceleration times were shortened as compared with adults. This may be partly because the adult heart rate averaged 65 beats/min in the study that reported a normal mitral valve deceleration time in adults of 193 ± 23 msec,[1] although the effects of heart rate on deceleration time have been only preliminarily studied. Atrioventricular valve deceleration time increased with gestational age and decreased with A/E ratio and heart rate. Tricuspid and mitral valve A/E ratios increased with heart rate and decreased with deceleration time and gestational age.

Human fetal life can be complicated by the development of growth retardation and later neonatal difficulties. Pulmonary hypertension is a known complication of the chronic intrauterine hypoxia associated with severe growth retardation. Fetuses with the absence of end-diastolic velocities in the umbilical artery were shown to have a high incidence of cardiac chamber dilatation, wall hypertrophy, and pulmonary hypertension in a preliminary study.[5] Perinatal morbidity and mortality were increased in the group of fetuses with the absence of end-diastolic velocity in the umbilical artery,[3-5] and cardiac function has been studied in this group.[4] These studies showed an increase in the relative amount of blood that flows through the right ventricle and pulmonary artery (2.15 : 1), compared with that in the left ventricle and aorta in normal fetuses (1.33 : 1).[4] In addition, a lower mitral valve A/E ratio was also shown, which suggests that changes had occurred in ventricular filling pressures or left ventricular diastolic function. Doppler echocardiographic measurements from fetuses with AEDV, an extreme of umbilical artery velocity abnormality, were therefore used in this report to compare with measurements from normal fetuses.

In fetuses with AEDV, tricuspid and mitral flow velocity deceleration times were longer than normal. This may occur as a result of a slower relaxation time in the ventricles of these fetuses. The mitral valve A/E ratio during early diastole ratio was lower than the tricuspid valve ratio. This is because peak velocities were decreased both during early diastole and during atrial contraction. Both peak velocities may be decreased in response to lower volume flow through the left side of the fetal heart with AEDV.[4]

We conclude that in the normal fetus, Doppler echocardiography–derived mitral and triscupid flow velocity deceleration times are shorter than those in normal adults and increase during gestation. In fetuses with IUGR and AEDV, deceleration time is abnormally prolonged. Whereas these changes may occur in part as a result of a decrease in heart rate, changes in ventricular chamber or myocardial compliance may also explain the lengthening of deceleration time in normal fetuses with advancing gestation. The changes in fetuses with IUGR and AEDV most likely result from a prolongation of ventricular relaxation, perhaps because afterload increases with placental resistance.

Effect of placental laterality on uterine artery resistance and development of preeclampsia and intrauterine growth retardation

Alexander D. Kofinas, MD, Mary Penry, RN, Melissa Swain, RN, and Christos G. Hatjis, MD

Winston-Salem, North Carolina

We studied 153 pregnant women with normal pregnancies and 147 women with complicated pregnancies (diabetes, hypertensive disorders, and intrauterine growth retardation) to evaluate the association of placental location and the development of preeclampsia, intrauterine growth retardation, and uterine artery resistance. The placental location was determined by real-time ultrasonography, and the uterine artery resistance was determined by continuous-wave Doppler flow velocity waveform analysis. In the presence of preeclampsia or intrauterine growth retardation, up to 75% of the patients had unilaterally located placentas and 25% central placentas, whereas in the absence of these two conditions only 51% of the patients had unilateral and 49% central placentas ($p < 0.02$). In patients with unilateral placentas, the incidence of preeclampsia and intrauterine growth retardation was 2.8-fold and 2.7-fold greater than in patients with central placentas ($p < 0.03$ and $p < 0.01$). Among all patients unilateral placental location was more likely to be associated with abnormal uterine artery flow velocity waveforms than central placental location ($p < 0.001$). We conclude that unilateral placental location may predispose to the development of preeclampsia and intrauterine growth retardation by its effect on uterine artery resistance. (AM J OBSTET GYNECOL 1989;161:1536-9.)

Key words: Placenta, preeclampsia, intrauterine growth retardation, flow velocity waveform analysis

The significance of placental location in the uterine cavity has been studied extensively. Placental location has been found to correlate with fetal position and presentation,[1,2] length of gestation,[3] course of labor,[4] presence of preeclampsia,[5,6] and pregnancy outcome.[7] Several methods have been used to document placental location, including manual exploration of the uterus, soft tissue x-ray films, and isotopic placentography.[1,8-11] In the past two decades ultrasonography has proved to be the safest, easiest, and most accurate method for assessing placental location.[2,12,13]

The relationship between placental location and the development of preeclampsia has been examined previously with controversial results.[5,6] In the two previous reports the placental location was examined with regard to its proximity to the uterine fundus. The two groups used different methods. There has been no study to examine the clinical significance of placental laterality and its association with the development of preeclampsia and intrauterine growth retardation (IUGR). There is a significant association between placental location and uterine artery resistance.[14] It is possible that placental location may influence uterine artery blood flow distribution and predispose the pregnancy to such adverse outcomes as preeclampsia, premature birth, and IUGR. This study was designed to examine the association of placental laterality and uterine artery resistance and the development of preeclampsia and IUGR.

Table I. Patient characteristics according to placental location

	Placenta location		
	Central	*Unilateral*	*p Value*
Maternal age (mean ± SD)	23.9 ± 6.0	23.9 ± 5.3	1.00
Gravidity (mean ± SD)	2.0 ± 1.1	1.9 ± 1.2	0.92
Parity (mean ± SD)	0.6 ± 0.8	0.6 ± 0.8	0.84

Material and methods

A total of 311 patients were enrolled in the study. Eleven were excluded because of insufficient pregnancy outcome information. Of the remaining 300 patients, 153 had normal uncomplicated pregnancies, and 147 patients had pregnancies complicated by diabetes

Table II. Relationship of placental laterality and presence or absence of preeclampsia, IUGR, or both

	Preeclampsia		*IUGR*		*Preeclampsia, IUGR, or both*	
Placental location	*Yes*	*No*	*Yes*	*No*	*Yes*	*No*
Central	9 (26%)	129 (49%)	11 (25%)	127 (49%)	16 (28%)	117 (48%)
Unilateral	25 (74%)	137 (51%)	30 (75%)	132 (51%)	41 (72%)	126 (52%)
χ^2 test	$p < 0.03$		$p < 0.02$		$p < 0.007$	

mellitus ($n = 39$), hypertensive disorders ($n = 69$), and pregnancies suspected of IUGR ($n = 39$). Of the 39 women with diabetes 18 had gestational diabetes and 21 had insulin-dependent diabetes. The normal patients were recruited from a population referred to the ultrasonography unit for pregnancy dating and from the low-risk prenatal clinic. The high-risk patients were recruited from a population referred to the antenatal testing unit for fetal surveillance. All high-risk patients were examined during the third trimester of pregnancy. The majority of the normal patients were also examined during the third trimester, and the remainder were examined between 24 and 28 weeks of gestation. The study was approved by the institution's Clinical Research Practices Committee; all patients gave written informed consent.

Diagnosis and classification of the hypertensive disorders were according to criteria of the American College of Obstetricians and Gynecologists.[15] Growth charts appropriate for our population were used to classify the infants as small for gestational age or appropriate for gestational age.[16]

The placental location was determined by real-time ultrasonography. The method has been previously described.[14] In brief, the placenta was classified as right, left, or central regardless of its anteroposterior and fundal position. For the purpose of analysis the patients with right or left placentas were classified as having unilaterally located placentas. Placental location was evaluated without prior knowledge of the flow velocity waveforms. The interobserver variation in assignment of placental location was 13%.

The flow velocity waveforms were obtained with the mother lying comfortably in a slight left lateral tilt according to method that has been described previously.[14] A 4 MHz continuous-wave Doppler device equipped with a real-time spectrum analyzer was used to obtain the uterine artery flow velocity waveforms. Briefly, two measurements were obtained from each side. The average of the two measurements on each side is classified as right uterine artery flow velocity waveform and left uterine artery flow velocity waveform, respectively. When necessary for comparisons, the mean of the right and left uterine arteries is classified as the uterine artery flow velocity waveforms. The uterine artery flow velocity waveforms were classified as abnormal if they exceeded the 95th percentile of our normal values (systolic/diastolic ratio >2.8 after 24 weeks' gestation). The intraobserver coefficient of variation for the flow velocity waveforms was 8%. Statistical significance of the results was evaluated by the χ^2 test. A value of $p < 0.05$ was considered statistically significant.

Table III. Incidence of preeclampsia and IUGR in study group according to placental location

	Placental location	
	Central	*Unilateral*
Presence of preeclampsia		
Yes	9 (6.5%)	25 (15.4%)
No	129 (93.5%)	137 (84.6%)
	χ^2, $p < 0.03$	
Presence of IUGR		
Yes	11 (8%)	30 (18.5%)
No	127 (92%)	132 (81.5%)
	χ^2, $p < 0.01$	

Results

Data from a total of 300 patients were used for analysis. There was no difference in the incidence of laterality between pregnancies <28 weeks' gestation and those of >28 weeks or between white and nonwhite patients. Maternal characteristics are listed in Table I. The incidence of the different placental locations with regard to laterality in the entire group was as follows: central, 46%; right-sided, 33%; left-sided, 21%. Thus the incidence of unilateral placentation was 54%. The incidence of unilateral placentation in the normal group was not statistically different from the group of high-risk patients (52% vs. 56%). However, when the patients with preeclampsia and/or IUGR were grouped together and compared with the rest of the patients, significant associations and differences were found (Table II).

Patients with unilateral placental location had a 2.8-fold higher increase in the incidence of preeclampsia than patients with centrally located placentas ($p < 0.03$). Similarly, patients with unilateral placental location had a 2.7-fold increase in the incidence of IUGR than patients with centrally located placenta ($p < 0.01$, Table III).

Table IV. Placental laterality according to uterine artery flow velocity wave forms

	Right or left uterine artery		*Mean of both sides*	
Placental location	*Abnormal*	*Normal*	*Abnormal*	*Normal*
Central	20 (27%)	118 (52%)	16 (30%)	122 (49%)
Unilateral	55 (73%)	107 (48%)	37 (70%)	125 (51%)
χ^2 test	$p < 0.001$		$p < 0.02$	

Regardless of which vessel was examined (right or left uterine artery or the mean of the two sides), 70% to 73% of patients with abnormal flow velocity waveforms had unilaterally located placentas (Table IV). In the presence of preeclampsia and abnormal uterine artery flow velocity waveforms ($n = 20$), 16 (80%) of the patients had unilateral placentas and only four (20%) had centrally located placentas. In the presence of IUGR with abnormal uterine artery flow velocity waveforms ($n = 18$), 15 (83%) of the patients had unilateral placentas and only three (17%) had central placentas. In the group of diabetic patients five (13%) developed preeclampsia; four of those five patients (80%) had unilateral placentas and only one (20%) had a central placenta.

Comment

This study provides evidence of the existence of a significant association between placental laterality and the presence of preeclampsia, IUGR, or both. It also appears that the placenta is located laterally in the majority of patients with abnormal uterine artery flow velocity waveforms.

The association of placental location and the development of preeclampsia has been examined twice with contradictory results.[5,6] Both reports examined the placental location with regard to the proximity of the placenta to the fundus. Booth et al.[5] found a significant association between fundal placentas and the presence of preeclampsia; they explained it by Bieniarz's theory. Bieniarz[17] theorized that when the placenta is located high in the uterine cavity, the draining of the uteroplacental circulation might cause a pathologic redistribution of blood in the renal and visceral circulation, resulting in preeclamptic toxemia. In contrast, Little and Friedman[6] failed to find any association between highly implanted placentas and preeclampsia.

Preeclampsia and IUGR are both conditions strongly related to poor placental development and function. Khong et al.[18] showed that poor trophoblastic conversion of the spiral arterioles leads to development of preeclampsia, IUGR, or both conditions. It has been shown in humans that both uterine arteries have a significant number of branches and that each supplies the corresponding uterine side. In some patients arcuate branches of the uterine artery cross over to the other side and create major anastomoses.[19] Although anatomic anastomoses between the two uterine arteries exist, there is no proof that these anastomoses are functional.

When the placenta is laterally located, the uterine artery close to the placenta has lower resistance than the one opposite from it. In patients with centrally located placentas both uterine arteries demonstrate similar resistance.[14,20] It is possible that when the placenta is centrally located, the uteroplacental blood flow needs are met by equal contribution from both uterine arteries. However, when the placenta is laterally located, in the majority of patients the uteroplacental blood flow needs are to be met primarily by one of the uterine arteries, with some contribution by the other uterine artery via collateral circulation. The degree of collateral contribution, however, may not be the same in all patients and deficient contribution may facilitate the development of preeclampsia, IUGR, or both. The existence of major vascular anastomoses in some patients may explain the normal uterine artery flow velocity waveforms and the absence of preeclampsia and IUGR despite the presence of a unilateral placenta.

The pathophysiologic characteristics of preeclampsia are complex and the cause remains unknown. One of the fundamental disturbances in patients with this condition is decreased uteroplacental blood flow. However, whether this is the cause or the result of preeclampsia is yet to be discovered. Our data indicate that the presence of a unilateral placenta and abnormal uterine artery flow velocity waveforms (suggestive of high uterine artery resistance) is strongly associated with preeclampsia. Studies are currently being conducted both in the United States and abroad to evaluate the impact of aspirin in the prevention of preeclampsia. Further studies are necessary to evaluate the sensitivity of placental laterality and abnormal uterine artery flow velocity waveforms as a predictor of the development of preeclampsia. If this proves to be the case, the use of aspirin in those patients who are at increased risk will help prevent or at least ameliorate some of the severe consequences of preeclampsia.

In summary, this study is the first to demonstrate a significant relationship between placental laterality and the presence of preeclampsia, IUGR, or both. There is strong evidence to indicate that patients with unilateral

placentation are more likely to have abnormal uterine artery flow velocity waveforms indicative of high uterine artery resistance. It is speculated that insufficient collateral blood supply in patients with unilateral placentation may facilitate the development of preeclampsia, IUGR, or both. Further study of this relationship is needed to evaluate its sensitivity as a screening tool for patients at risk to develop preeclampsia or IUGR.

Ultrasonographic criteria for the prenatal diagnosis of placental chorionicity in twin gestations

Hung N. Winn, MD,[a] Sandro Gabrielli, MD,[a] E. Albert Reece, MD,[a] J. Andres Roberts, MD,[a] Carolyn Salafia, MD,[b] and John C. Hobbins, MD[a]

New Haven, Connecticut

Thirty-two patients with uncomplicated twin pregnancies had ultrasonographic examinations for genetic amniocentesis, confirmation of twinning, or assessment of fetal growth. The dividing membranes between the fetuses were visualized, and the thickness of the membranes was measured. With a thickness of 2 mm used as a cutoff point, the accuracy in predicting monochorionic or dichorionic twinning was 82% and 95%, respectively. Prenatal assessment of these dividing membranes may be helpful in the management of twin gestations. (AM J OBSTET GYNECOL 1989;161:1540-2.)

Key words: Twins, chorion, amnion, ultrasonography, prenatal diagnosis

In the United States, the overall incidence of twinning is about one in 90 pregnancies.[1] Complications from twin pregnancies still contribute significantly to the overall perinatal mortality and morbidity. The incidence of morbidity is affected by the status of the placental chorion and amnion. Since monochorionic placentas almost always have some vascular anastomoses between the two fetal circulations, identification of placental chorion is useful in the management of a twin pregnancy, especially when it is complicated by growth discrepancy, fetal hydrops, or fetal death. Whereas the identification of different fetal genders or two separate placentas indicates dichorionic twinning,[2] differentiation between monochorionic and dichorionic placentas must rely on other parameters when only one placenta or similar genders exist. Qualitative evaluation of the dividing membranes by ultrasonography has been attempted to determine the type of placental chorion.[3] The current study was undertaken, however, to quantitatively establish the sonographic criteria for the prenatal diagnosis of chorion status in twin gestations.

Patients and methods

This study was conducted at the Perinatal Unit of Yale–New Haven Hospital during the period January 1987 to January 1988. Indications for ultrasonographic examination included confirmation of twin gestation, assessment of fetal growth, and genetic amniocentesis. The dividing membranes between the twins were evaluated as part of the ultrasonographic examination. After the membranes were well visualized and delineated, their thickness was measured between the outer borders, perpendicular to the long axis of the membrane segment (Fig. 1), without prior knowledge of fetal gender or number of placentas. The segment of the dividing membranes used was as perpendicular to the ultrasonographic beams as possible to utilize the better axial resolution. The ultrasonographic scans were obtained with the Acuson-128 ultrasonography machine (Acuson, Mountinview, Calif.) with 3.5 and 5 MHz transducers and an axial resolution of about 0.5 mm. Placental chorionic type was confirmed by histologic examination after delivery. The cutoff point of the membrane thickness measured by ultrasonography to differentiate between monochorionic and dichorionic placentas was retrospectively determined on the basis of results of the histologic examinations. Thirty-two twin pregnancies with dividing membranes evaluated both ultrasonographically and histologically formed the basis of this report. In four patients who had longitudinal ultrasonographic examinations of the dividing membranes, only one measurement for each patient was used to determine the cutoff point of membrane thickness (Tables I and II). The difference between the mean membrane thickness was analyzed by the *t* test.

Results

Of 6029 deliveries during the study period, 103 twin pregnancies occurred. Therefore the incidence of twinning was 1.7% among viable pregnancies. Thirty-one percent of the twin gestations were monochorionic and 62.1% were dichorionic. The remaining 6.9% (seven

Table II. Placental chorionic status in twin gestations ($n = 32$)

Membrane thickness	Placental histology		Total
	Monochorionic	Dichorionic	
<2 mm	9	2	11
≥2 mm	1	20	21
TOTAL	10	22	32

For dichorionic twinning: sensitivity = 90.9%; specificity = 90.0%; positive predictive value = 95.2%; negative predictive value = 81.8%.

pregnancies) consisted of twin pregnancies that did not have histologic placental examinations. These seven twin gestations consisted of five sets of the same gender and two sets of different genders. Among 103 twin pregnancies, only 32 twin pregnancies had both ultrasonographic examinations of the membranes (eight during the second trimester and 24 during the third trimester) and pathologic confirmation. The membrane thickness was essentially unchanged from the second to third trimester in four patients who had serial measurements of the dividing membranes. There was a significant difference in the mean membrane thickness between the monochorionic and dichorionic membranes ($p < 0.001$) (Table I). With a thickness of 2 mm used as a cutoff point, the accuracy in predicting monochorionic and dichorionic membranes was 82% and 95%, respectively (Table II). The interobserver and intraobserver variability of measurements was 15% and 10%, respectively.

Comment

The overall incidence and distribution of monochorionic and dichorionic twin gestations in our patient populations were comparable to those previously reported. The incidence of twinning in the United States ranges from 1% to 2% with dichorionic placentations being present in two of three twin gestations.[1, 4] Determination of the type of placental chorion is helpful in the management of twin gestations. Vascular communications between the two fetal circulations occur almost exclusively in monochorionic twinning, and almost all monochorionic placentas have some degree of vascular anastomoses.[5, 6] Clinically significant twin-twin transfusion occurs in about 20% to 30% of monochorionic twinning.[7] Therefore monochorionic twinning requires more intense surveillance of fetal growth and well-being. Although growth discrepancy may occur in both monochorionic and dichorionic twinning, the diagnosis of twin-to-twin transfusion, which has a more omnious prognosis, should be strongly considered in monochorionic gestations. Furthermore, when fetal death occurs, the surviving twin with the monochorionic placenta may suffer thromboembolic complications resulting in multicystic encephalomalacia,[8] disseminated intravascular coagulation, and infarction of other visceral organs.[9] As a result, selective feticide of one twin would be ill-advised in the case of monochorionic twinning if one twin should have a congenital anomaly. In general, there is a high discordancy rate for congenital anomalies between twin pairs.[10] Identification of monochorionic placentas, however, indicates monozygotic twinning, which usually has identical chromosomal anomalies.

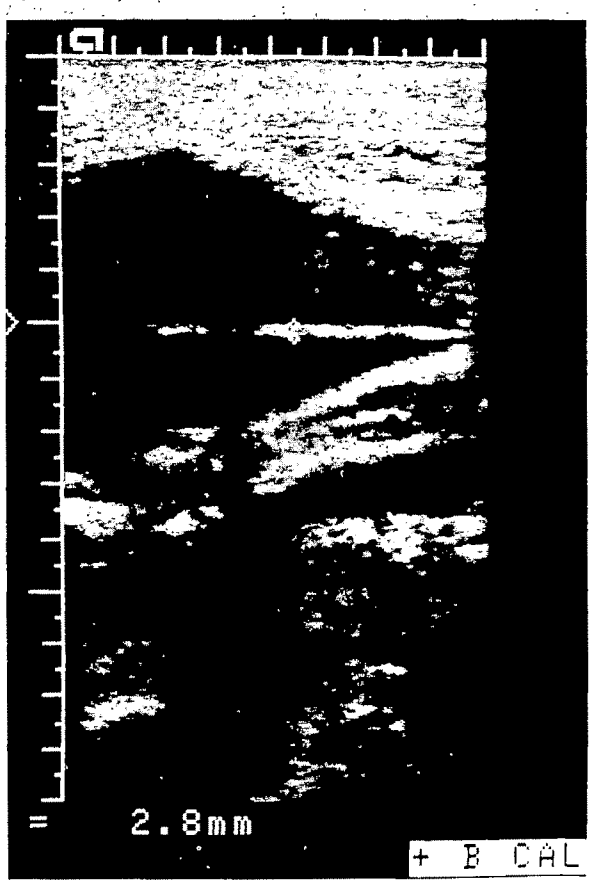

Fig. 1. The thickness of the dividing membranes was measured between the outer borders (+). The segment chosen was perpendicular to the ultrasonography beams.

Histologically, the dichorionic dividing membranes are thicker than the monochorionic membranes, because the former contain two layers of chorion and two layers of amnion whereas the latter contain only two layers of amnion. Ultrasonography has been used recently for the prenatal diagnosis of placental chorion status, which is based on the difference in thickness between the two types of membranes. Qualitative evaluation of the membranes by inspection has been reported with a high degree of accuracy.[3] This method, however, is applicable when the membrane thickness is at the extremes of measurement and depends, to a great extent, on the ultrasonographer's experience. We have found that there was a significant difference in mean membrane thickness between monochorionic and dichorionic placentas, and often the difference in membrane thickness is <1 mm and may not be accurately assessed by simple inspection. Our results also demonstrated that the membranes of monochorionic gestations are measurable.

In conclusion, the determination of the types of placental chorionic type is helpful in the management of twin gestations. Ultrasonography has permitted prenatal diagnosis of monochorionic and dichorionic twinning with a high degree of accuracy by identifying the number of placentas and fetal gender and measuring the membrane thickness. It should be emphasized that these measurements should be done only with high-resolution ultrasonography machines and that, even with quantitation of the membrane thickness, the two types of chorionicity cannot always be distinguished. A prospective study is being conducted to confirm these findings.

Esterase activity in second- and third-trimester amniotic fluid: An indicator of chorioamnionitis

Iffath Abbasi Hoskins, MD, Joseph Katz, PhD, Steven A. Ordorica, MD, and Bruce K. Young, MD

New York, New York

Accurate and rapid diagnosis of chorioamnionitis poses a major diagnostic dilemma. We previously reported that leukocyte esterase activity in amniotic fluid, as measured by dipstick assay, could be used as an aid in the diagnosis of chorioamnionitis. This study examines the effectiveness of an in vitro spectrophotometric assay of esterase activity in amniotic fluid. We define baseline levels of esterase activity in uninfected amniotic fluid and demonstrate a quantative increase when infection is present. Fifty-seven amniotic fluid samples obtained at second- and third-trimester amniocenteses were divided into three parts, one for culture and two for a comparison of esterase activitites by the dipstick and spectrophotometric methods. In this study, the spectrophotometric assay, because of its higher specificity and sensitivity in the determination of elevated esterase activity, was shown to be more reliable for predicting chorioamnionitis than either the dipstick or culture method. (Am J Obstet Gynecol 1989;161:1543-5.)

Key words: Leukocyte esterase, chorioamnionitis screening, in vitro assay

Chorioamnionitis plays a major role in perinatal morbidity and mortality. One of the basic problems in its diagnosis is the lack of uniformity and accuracy of the criteria on which this diagnosis is made. The clinical diagnosis is usually based on a syndrome of fever, maternal or fetal tachycardia, uterine tenderness, foul odor of the amniotic fluid, and peripheral blood leukocytosis, but there is uncertainty regarding early diagnosis and laboratory confirmation.[1] Since leukocytes are known to be released in response to infections, examination of the amniotic fluid for their presence may prove to be useful in the evaluation of chorioamnionitis. Neutrophilic leukocytes contain several esterases that are not present in serum, urine, or vaginal secretions.[2,3] * We have previously described the reliability of leukocyte esterase activity in the rapid detection of urinary tract infections in obstetric patients[4] and for the detection of chorioamnionitis in term pregnancies uncomplicated by other diseases.[5] In the present study, we assessed the use of an in vitro assay to establish baseline levels of esterase activity in second- and third-trimester amniotic fluid samples and to demonstrate any alterations of these levels in chorioamnionitis.

Material and methods

Sterile specimens of amniotic fluid were obtained from 57 antepartum patients who had undergone amniocenteses during the second and third trimesters for genetic studies, for rhesus isoimmunization, for fetal lung maturity studies, or to rule out chorioamnionitis. Thirty-nine samples were obtained from uninfected patients along with 18 samples from women who had chorioamnionitis as determined by the presence of at least two of the clinical criteria used for its diagnosis, including maternal pyrexia (temperature >37.8° C), leukocytosis (white blood cell count >12,000/mm^3), uterine tenderness, and fetal tachycardia (heart rate >160 beats per minute). Each sample was divided into three parts: one for the in vitro leukocyte esterase assay, one for detection of leukocyte esterase activity by dipstick, and one for Gram's stain and aerobic and anaerobic cultures.

Table II. Reliability of parameters used to detect chorioamnionitis

	Sensitivity (%)	*Specificity (%)*	*Predictive values*	
			Positive	*Negative*

Culture	78	95	90	80
Gram's stain	83	95	93	88
Leukocyte esterase activity				
Dipstick assay	94	95	97	90
In vitro assay	100	100	100	100

For in vitro leukocyte esterase assay, known amounts (10 λ) of amniotic fluid were added to the solutions containing 20 λ of a 5 μmol/L solution of *p*-nitrophenyl hexanoate in dimethyl sulfoxide and 1 ml of buffer (0.1 mol/L phosphate, pH 7.4). Activity was calculated from the initial slopes of the change in absorbance at 405 nm as a function of time. One unit of activity was defined as a change of 1 absorbance unit at 405 nm/min. Each sample was then centrifuged at 2000 rpm for 10 minutes and the assay was repeated.

Aliquots of the same amniotic fluid samples were tested for leukocyte esterase activity by immersion of the dipstick (Chemstrip 9, Boehringer-Mannheim Diagnostics, Bio-Dynamics Division) in the fluid and comparison of the color reaction with the color chart after 1 minute.

Gram's stain test was performed with commercial reagents (crystal violet, safranine, Gram's iodine; Difco Laboratories, Detroit) under standard conditions.[6] The presence of white blood cells and microorganisms was noted, and a semiquantitative assessment was made after examination of 20 high-power fields. A positive Gram's stain was defined as one in which there were any microorganisms per high-power field. The amniotic fluid aliquots destined for cultures were collected in plastic-capped syringes and transported to the laboratory immediately after collection for inoculation into the culture media.

Positive cultures were defined as those containing one or more types of organisms in excess of 10^4 cfu/ml. The leukocyte esterase activity test results were then compared with the results obtained from Gram's stains and aerobic and anaerobic cultures.

Results

Table I represents the relationship between leukocyte esterase activity, as measured by dipstick and in vitro assay, and results of Gram's stain culture in both the uninfected and infected samples of amniotic fluid. There were 39 uninfected samples for analysis. Twenty-one of these were obtained during the second trimester after amniocenteses for genetic indications. Eighteen were obtained during the third trimester—4 for Rh sensitization and 14 for studies of lung maturity. No differences were found between the Rh-sensitized and normal samples. Two samples from the third trimester showed positive cultures with *Escherichia coli* organisms $>10^4$ cfu/ml. Both of these samples were also positive on Gram's stain analysis and showed leukocyte esterase activity, as measured by dipstick. However, when the in vitro enzyme assay was performed, the leukocyte esterase activity was within the ranges we had defined as baseline normal (5.8 and 6.3 enzyme activity units) for uninfected samples (Fig. 1).

There were 18 infected samples of amniotic fluid obtained from women with chorioamnionitis. All of these samples were obtained during the third trimesters from patients who had undergone amniocenteses to rule out chorioamnionitis (spontaneous rupture of membranes, 8; preterm labor, 10). Fourteen of these women had positive amniotic fluid cultures, with organism counts $>10^4$ cfu/ml (*E. coli*, 10; group B streptococci 2; *Enterobacteriaceae* 2). However, if a positive culture was defined as one containing organisms $>10^2$ cfu/ml, then all 18 samples were found to be positive (*E. coli*, 13; group B streptococci, 2; *Enterobacteriaceae*, 3). Only 15 of these samples were positive by the Gram's stain test, and the organisms revealed by this test were similar to those revealed by cultures. Seventeen of the 18 infected specimens were positive by leukocyte esterase dipstick assay, but only 15 of these showed evidence of bacteria on Gram's stain analysis. The two samples with positive leukocyte esterase activity revealed by dipstick but negative Gram stains showed varying numbers of white blood cells on the slides. The one sample that tested negative by dipstick assay grew organisms $>10^4$ cfu/ml *(Enterobacteriaceae)*. When the in vitro enzyme assay was performed, the observed esterase activity was severalfold higher (range, 17.8 to 18.2 enzyme activity units) than that of the uninfected normal samples (Fig. 1). When the uninfected samples were centrifuged and assayed by the in vitro leukocyte esterase method, there was a severalfold increase in observed esterase activity (range, 14.6 to 17.2 enzyme activity units) to levels similar to those seen in the infected samples. This increase was found to be due to cell disruption and lysis that allowed the release of azurophilic, esterase-containing granules in the leukocytes.

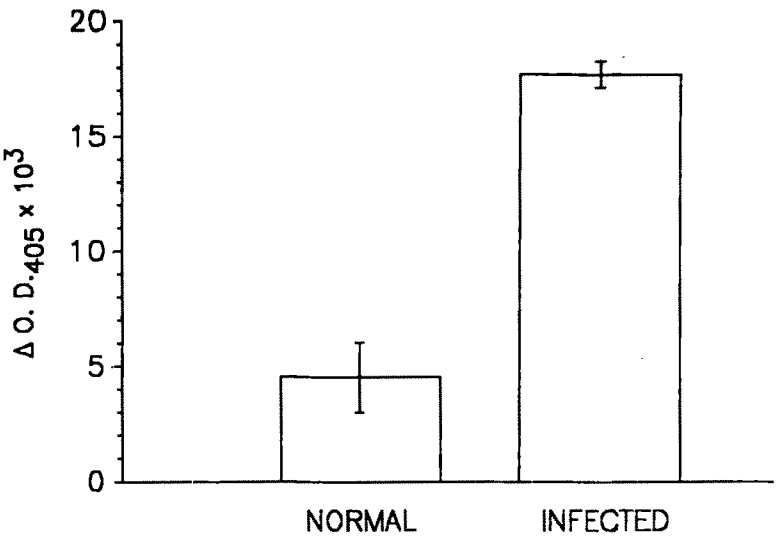

Fig. 1. Esterase activity in normal and infected samples of centrifuged amniotic fluid.

Table II shows the sensitivity, specificity, and predictive values of the various parameters used in the comparison of leukocyte esterase activity by the dipstick and the in vitro methods. In our study, the in vitro assay had a 100% sensitivity and a 100% specificity for chorioamnionitis, whereas the leukocyte esterase dipstick had a sensitivity of 94% and a specificity of 95%. The cultures of these samples had shown a sensitivity of only 78% and a specificity of 95%.

Comment

Acute chorioamnionitis remains a serious infection for the mother and her baby. Despite the seriousness of this condition, there are major problems associated with its diagnosis. At present it is impossible to determine what constitutes an optimal diagnostic finding, and attempts to improve our ability to diagnose intrapartum infections have met with little success. To identify an optimal screening test for chorioamnionitis, we reported previously[5] on the dipstick method of measuring leukocyte esterase activity as an inexpensive and reliable (sensitivity 91%, specificity 95%) test for diagnosing chorioamnionitis in term patients in the absence of significant numbers ($<10^4$ cfu/ml) of organisms on culture. However, the results of the dipstick assay, like those of the aerobic and anerobic cultures, can sometimes be misleading or equivocal. When that is the case, in vitro spectrophotometric assay of esterase activity may be more useful in identifying infected amniotic fluid samples and eliminating any confusion, since this test has both a sensitivity and a specificity much higher (100% each) than those of the other tests.

Thus a simple, rapid, and inexpensive regimen for the evaluation and diagnosis of chorioamnionitis could involve the use of the dipstick assay of esterase activity as an initial screening test (before culture results have been obtained), with in vitro spectrophotometric assay as a backup for samples that yield equivocal or negative results by the dipstick method. The use of this test may serve to eliminate the need for any additional testing or aid management decisions in situations in which waiting for culture results is not feasible.

Rapid chromosome analysis with the use of spontaneously dividing cells derived from umbilical cord blood (fetal and neonatal)

Robert E. Tipton, MD, Avirachan T. Tharapel, PhD, Hua-Hua T. Chang, BS, Joe Leigh Simpson, MD, and Sherman Elias, MD

Memphis, Tennessee

An accurate and reproducible method to obtain high-quality metaphases within 24 hours has been developed. Preparations can be derived from cord blood samples obtained either at delivery or by percutaneous umbilical blood sampling. Mitogens are not required. Rapid cytogenetic analysis can facilitate management of pregnancies charcterized by malformations or intrauterine growth retardation. (AM J OBSTET GYNECOL 1989;161:1546-8.)

Key words: Rapid karyotyping, prenatal cytogenetic diagnosis, fetal anomalies, percutaneous umbilical blood sampling

Rapid chromosome analysis (within 24 hours) would provide timely diagnostic information that could alter pregnancy management in instances in which the fetus is found to have ultrasonographic evidence of malformations or intrauterine growth retardation. A rapid diagnostic method also would facilitate management of anomalous or growth retarded neonates. Until recently the only available method to obtain rapid chromosome analysis used immature cells from bone marrow aspirated from iliac crest or tibia.[1,2] In 1987 Garnham and Sutherland[3] reported that spontaneously dividing cells present in newborn umbilical cord blood could be used for rapid chromosome analysis. Although later confirmed by Day et al.,[4] the quality of these chromosomal preparations was not adequate to allow identification of subtle structural chromosomal abnormalities. Moreover, these initial studies had not ascertained whether spontaneously dividing cells were present in fetal blood. Thus it was not known whether blood samples obtained by percutaneous umbilical blood sampling could provide rapid chromosomal analysis. In this study we sought to develop methods to reliably obtain high-quality metaphases from spontaneously dividing cells present in cord blood.

*Bloody pleural fluid obtained by intrauterine thoracocentesis.

Material and methods

Umbilical cord blood samples were obtained at delivery from 59 phenotypically normal newborns (gestational ages 29 to 42 weeks). Percutaneous umbilical blood sampling was performed on three fetuses, all with malformations and growth retardation (22, 27, and 32 weeks' gestation). In addition, we processed a sample of bloody pleural effusion obtained by intrauterine thoracocentesis from a fetus with chylothorax at 31

weeks' gestation. Each of the 59 newborn cord blood specimens (2 to 10 ml) were collected in Vacutainers that contained sodium heparin and were transported to the cytogenetics laboratory within 1 to 2 hours. Percutaneous umbilical blood samples and pleural effusion fluid were collected in heparinized syringes.

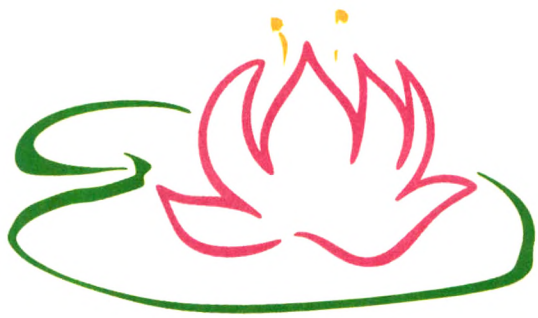
Cultures that contained 1 ml heparinized blood were incubated 18 hours in 9 ml modified Eagle's minimum essential medium (Irvine Scientific, Santa Ana, Calif.) supplemented with 15% Chang medium (Hana Biologics, Alameda, Calif.), 15% fetal bovine serum, and final concentrations of 0.8% L-glutamine, 100 μg/ml streptomycin, and 10 IU/ml penicillin. No mitogens were added. Cultures were incubated at 37° C for 17 hours and then were treated with 0.5 μg/ml actinomycin D and 0.2 μg/ml demecolcine (Colcemid). After incubation for 1 additional hour, cultures were centrifuged for 8 minutes at 1000 rpm. The supernatant was discarded and the cells were washed twice in 10 ml Hank's balanced salt solution. This supernatant was discarded and the cell pellet was resuspended at room temperature for 2 hours in 10 ml Ohnuki's hypotonic solution, consisting of 0.055 mol/L potassium chloride, sodium nitrate, and sodium acetate (ratio 10:5:2).[5, 6] After 2 hours of hypotonic treatment, 2 ml of 3:1 methanol-glacial acetic acid mixture was added. The cell suspension was mixed and centrifuged for 8 minutes at 1000 rpm. The supernatant was again discarded, the cells were fixed twice more for 10 minutes each, and then they were centrifuged again. With a Pasteur pipette, four to six drops of diluted cell suspension was dropped from a distance of 30 to 60 cm onto precleaned, wet, chilled slides. Slides were dried on a hot plate for 1 to 2 minutes at 60° C. Chromosomal preparations were stained (trypsin-Giemsa). The bloody pleural effusion was processed in a similar fashion to that of the blood specimens, except that 5 ml of the effusion was incubated with 5 ml of culture medium. For each case at least five metaphases were counted and two karyotypes prepared. To confirm the accuracy of our results, conventional 72-hour cultures were initiated for the first 20 cases with the mitogens phytohemagglutinin and pokeweed. At least five metaphases were analyzed from each of these 20 cultures. No attempt was made to determine the exact mitotic index.

Results

Metaphases readily allowing diagnoses were obtained in all 63 cases: 59 neonatal cord blood specimens, three

percutaneous umbilical blood samples, and one bloody fetal pleural effusion (Table I). Numbers of well-banded metaphases in the unstimulated preparations averaged 5 to 10 per slide, lower than our usual number for routine blood cytogenetics but easily sufficient to allow diagnosis. Moreover, the quality of the chromosome preparations was adequate to diagnose structural abnormalities. Banding resolution approximated 400 to 450 bands (Fig. 1). Hypomodal cells, a reflection of metaphase spreads broken in preparation, were minimal. There were no diagnostic discrepancies in the 20 cases in which both conventional cytogenetic analysis and the newly described method were used. Thus it seems there is no reason to doubt the accuracy of the method we used. No relationship between the gestational age and the numbers of dividing cells was apparent.

Comment



The method we describe allows cytogenetic diagnosis within 24 hours of specimen collection. Spontaneously dividing cells were detected not only in newborn umbilical cord blood samples (gestational ages 29 to 42 weeks) but also in fetal blood samples (gestational ages 22, 27, and 32 weeks). Overnight incubation consistently provided well-banded metaphases suitable for analysis, thus offering a marked improvement over earlier methods.[3, 4] The quality of the preparations is consistent (400 to 450 band resolution) to allow detection of chromosomal rearrangements such as deletions, duplications, or translocations. If percutaneous umbilical blood sample is available, the chromosomal complement of the fetus can be established more rapidly than with conventional laboratory methods, which facilitates pregnancy-management decisions. If fetal anomalies or intrauterine growth retardation are detected at birth, processing a blood specimen from the umbilical cord by our method provides a noninvasive method to determine chromosomal status. This would be especially useful in preterm infants, whose blood volume is correspondingly small.

The origin of these spontaneously dividing cells is uncertain. Our finding of spontaneously dividing cells in percutaneous umbilical blood samples as early as 22 weeks' gestation casts doubt over previous claims that such cells were present in cord blood as result of spillover of cells from bone marrow because of anoxic stresses.[3, 4] One of the percutaneous umbilical blood samples in our series was obtained on a a fetus possibly undergoing anoxic stress, as manifested by acidotic cord blood pH and poor biophysical profile score. However, there was no reason to suspect anoxia in the other two fetuses from which percutaneous umbilical cord blood sampling was obtained, nor to believe that anoxia was frequent in the 59 neonates who had undergone normal deliveries.

Finally, a discovery to end vaginal dryness

New

REPLENS™

Replenishes vaginal moisture

Vaginal moisture that lasts and lasts

Mucoadhesive delivery provides ongoing moisturization

Until now, the millions of women with vaginal dryness could ease their discomfort only temporarily. But today, new REPLENS ends dryness by replenishing vaginal moisture. REPLENS is delivered through mucoadhesion, a system that holds moisture in place. The primary ingredient, polycarbophil, is not absorbed. By design it is able to hydrate underlying vaginal tissue to provide lasting vaginal moisture and continuous lubrication.

Lasting moisture—clinically proven to end discomfort and painful intercourse

In double-blind clinical studies, REPLENS has been proven to be more effective than the most widely used lubricant for promoting lasting moisturization.[1] REPLENS increases mucosal thickness, elasticity, and turgor, thereby ending painful intercourse and vaginal discomfort. And when compared with K-Y® jelly, both patients and their spouses preferred REPLENS.

Three-day-a-week regimen ensures full-time comfort

When used three times a week, REPLENS provides vaginal moisture every minute of every day. Unlike other lubricants, women don't need to reapply before intercourse—encouraging spontaneity and avoiding embarrassment.

For your patients over 40 and some younger, restore a natural feeling

Menopausal women, nursing mothers, and any of more than 25 million women who suffer from vaginal dryness will appreciate your recommendation of REPLENS. When you replenish vaginal moisture, you bring back a sense of youth and confidence that many women thought they had lost forever.

K-Y is a registered trademark of Johnson & Johnson Products.

New

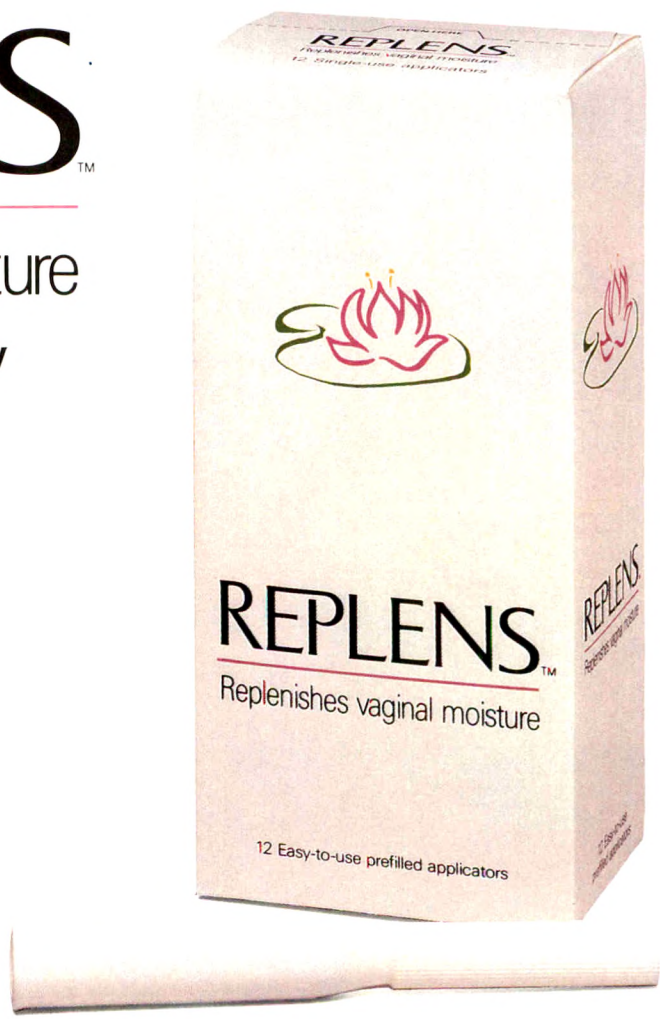
REPLENS™

Replenishes vaginal moisture

new comfort for more than 25 million women

Introducing

REPLENS™



Replenishes vaginal moisture

Vaginal moisture that's back to stay

- Mucoadhesive delivery provides lasting moisturization, continuous lubrication
- Clinically proven relief of dryness, discomfort, and painful intercourse[1]
- For menopausal women, new mothers, and all women with vaginal dryness
- Three-time-a-week regimen ensures full-time comfort
- Available in boxes of 12 single-use prefilled applicators

Use REPLENS Vaginal Gel three times a week at bedtime.

Effects of fetal sex and dexamethasone on preterm maternal serum concentrations of human chorionic gonadotropin, progesterone, estrone, estradiol, and estriol

Ray V. Haning, Jr., MD,[a, b] Luis B. Curet, MD,[b] W. Kenneth Poole, PhD,[c] Lynn M. Boehnlein, BS,[b] Donna L. Kuzma, BS,[b] and Sandra M. Meier, BS[b]

Providence, Rhode Island, Madison, Wisconsin, and Research Triangle Park, North Carolina

The serum human chorionic gonadotropin concentration for the 43 female-bearing gestations was significantly higher (geometric mean 15,603 mIU/ml; 95% confidence interval 12,337 to 19,733) than that for 26 male-bearing pregnancies (geometric mean 8902 mIU/ml; 95% confidence interval 6288 to 12,596), $p = 0.0087$. The mean gestational age was 32 ± 2.4 weeks (mean ± SD). There was no significant difference between male- and female-bearing pregnancies for progesterone, cortisol, estrone, estradiol, estriol, or gestational age. In 19 placebo-treated pregnancies and 14 dexamethasone-treated pregnancies with a mean gestational age of 31.5 ± 2.7 weeks, there was no significant change from the baseline value observed for either maternal serum human chorionic gonadotropin level or maternal serum progesterone level at 42 hours after institution of treatment. In the dexamethasone-treated subjects the geometric mean was reduced to 20% of baseline for cortisol; 42% of baseline for estrone; 30% of baseline for estradiol; and 41% of baseline for estriol (all $p < 0.001$). (AM J OBSTET GYNECOL 1989;161:1549-53.)

Key words: Pregnancy, sex difference, hCG, progesterone, estrogens, dexamethasone

There are two lines of evidence to indicate the secretion of human chorionic gonadotropin (hCG) by the placenta is partially under fetal endocrine control. First, unlike human placental lactogen and pregnancy-specific β_1-glycoprotein, which are also secreted by the syncytiotrophoblast and which rise progressively in relationship to the rise in trophoblastic mass, hCG rises exponentially to a peak at 8 to 10 weeks, then falls to a plateau for the remainder of pregnancy.[1] Second, unlike the other hormones secreted by the syncytiotrophoblast, which have similar concentrations in both male- and female-bearing pregnancies, the concentration of hCG in maternal peripheral blood[2-4] and placental tissue[5, 6] is higher at term in female-bearing pregnancies than in male-bearing pregnancies even though no difference has been demonstrated earlier in pregnancy until this investigation. Studies from our laboratory have demonstrated statistical evidence for an inhibitory effect of the fetal adrenal gland on in vivo secretion of hCG[7] and in vitro evidence that addition of dehydroepiandrosterone sulfate to cultures of term human placental explants could inhibit the stimulation of hCG secretion produced by gonadotropin-releasing hormone.[8] These two observations led us to investigate whether administration of dexamethasone to pregnant women would produce stimulation of hCG secretion by suppressing the fetal adrenal. The residual samples from the completed double-blind prospective trial of dexamethasone versus placebo in premature labor[9] offered a unique chance to investigate both the effect of the sex of the fetus and the effect of administration of dexamethasone on secretion of hCG, progesterone, estrone, estradiol, and estriol in vivo before term in a double-blind randomized study.

Material and methods

Human subjects. The process of informed consent and patient selection for the dexamethasone study has been described.[9] Briefly, a total of 7893 patients from the five participating centers were screened; 347 of them received placebo and 349 received dexamethasone. Subjects received 5 mg of dexamethasone phosphate every 12 hours intramuscularly or a placebo in a similar vehicle for up to 4 doses (a total of 20 mg of active drug). Since the first dose was administered at time "zero," the last of the four doses was administered at time "36 hours." The sample at "42 hours" used for our posttreatment level was thus drawn 6 hours after the last dose of dexamethasone, a time when the concentration of maternal serum dexamethasone had be-

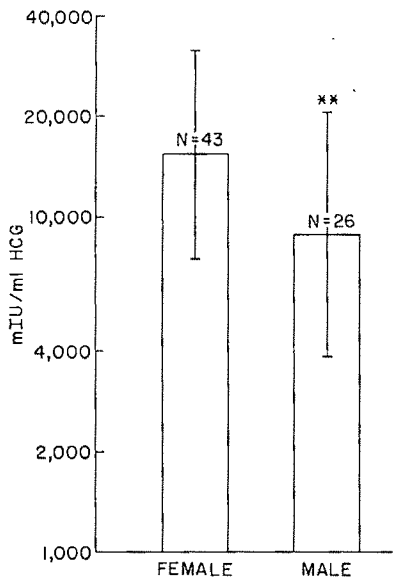

Fig. 1. Effect of fetal sex on maternal serum concentration of hCG determined in baseline samples. Data shown are mean and SD calculated on log-transformed data (note log scale). *Double asterisk,* $p < 0.01$.

gun to fall but the concentrations of maternal serum cortisol and estradiol were still suppressed.[9] We obtained access to the residual samples from the study after completion of all planned analyses and based our sample selection on the volumes of the residual baseline and paired residual 42-hour sample without knowledge of the mode of treatment, the outcome of the pregnancy, the sex of the infant, or any other laboratory or clinical information. After completion of the analyses for hCG and progesterone, the data on the mode of treatment, sex of the infant, and other clinical variables were requested along with the values previously determined in the selected samples for cortisol, estrone, estradiol, and estriol.[9]

Chemical analyses. hCG was determined by direct double-antibody radioimmunoassay with an antibody produced in this laboratory as previously described.[7] An hCG standard (Calbiochem, La Jolla, Calif.) calibrated against the World Health Organization second international standard was used. The cross-reaction of this antibody (H1-9/2/76) with human luteinizing hormone was 0.16%. Between- and within-assay variations were 3.8% and 3.7%, respectively. The assay sensitivity was 0.5 mIU/ml.[7] Progesterone was determined by radioimmunoassay without extraction with the Pantex Immuno-direct progesterone iodine 125 kit (Pantex, Santa Monica, Calif.) provided without charge by the manufacturers. The cross-reactivity was 6.5% with 20α-hydroxy-pregn-4-ene-3-one, 1.5% with deoxycorticosterone, and 0.18% with 17α-hydroxyprogesterone. Aldosterone, androstenedione, androsterone, dehydroepiandrosterone, dihydrotestosterone, 17α- and 17β-estradiol, estriol, estrone, etiocholanolone, and testosterone all had values <0.1%. Cholesterol, corticosterone, cortisol, 11-deoxycortisol, 17-hydroxypregnenolone, pregnenolone, and pregnenolone sulfate had values <0.01%. Between- and within-assay variation were 5.7% and 5.3%, respectively, with a 50 ng/ml serum pool run in each assay with the actual samples. The assay sensitivity was 0.07 ng/ml, and the lowest standard used was 0.5 ng/ml.

Statistical analysis. The data were analyzed by one-way analysis of variance, Student's *t* test, and the paired *t* test with the Minitab statistical program[10] used after log transformation to correct for the log-normal distribution of the data.

Results

Effect of sex of fetus on hormone concentrations in baseline samples. Samples from 69 single pregnancies with sufficient volume for determination of hCG and progesterone were analyzed. Missing data resulted in decreases in the number of data points available for certain variables. There were 43 female-bearing and 26 male-bearing pregnancies determined by the sex of the infant at delivery. The mean gestational ages for these pregnancies were 32.1 ± 2.4 and 31.8 ± 2.3 weeks, respectively (mean ± SD). This difference was not statistically significant ($p > 0.5$). The mean gestational age for all 69 pregnancies was 32.0 ± 2.4 weeks. The range of gestational ages was 27 to 37 weeks, and the median gestational age was 32 weeks. The sex of the infant and data for cortisol, estrone, estradiol, and estriol previously determined on these samples were collated with the data for hCG and progesterone obtained in our laboratory. The baseline samples were analyzed for effect of the sex of the fetus by Student's *t* test. The serum hCG concentration for the female-bearing gestations was significantly higher (geometric mean 15,603 mIU/ml; 95% confidence interval 12,337 to 19,733) than that for male-bearing pregnancies (geometric mean 8902 mIU/ml; 95% confidence interval 6288 to 12,596), $p = 0.0087$ (Fig. 1). However, there was no significant difference between male- and female-bearing pregnancies for progesterone, cortisol, estrone, estradiol, or estriol (data not shown).

Effect of treatment on maternal serum hCG and progesterone. To eliminate all subjects who gave birth before the time that the 42-hour sample was obtained, all subjects who gave birth <3 days after the study was begun were eliminated from all statistical analyses involving the 42-hour samples. There remained 19 placebo-treated pregnancies (13 female-bearing and 6 male-bearing) and 14 dexamethasone-treated pregnancies (9 female-bearing and 5 male-bearing) available for analysis of treatment effects. The mean gestational age of these 33 pregnancies was 31.5 ± 2.7 weeks (mean ± SD) with a median age of 32 weeks and a range of 28 to 37 weeks. The combined data for both sexes for maternal serum hCG and progesterone levels in the baseline placebo-, baseline dexamethasone-, 42-hour

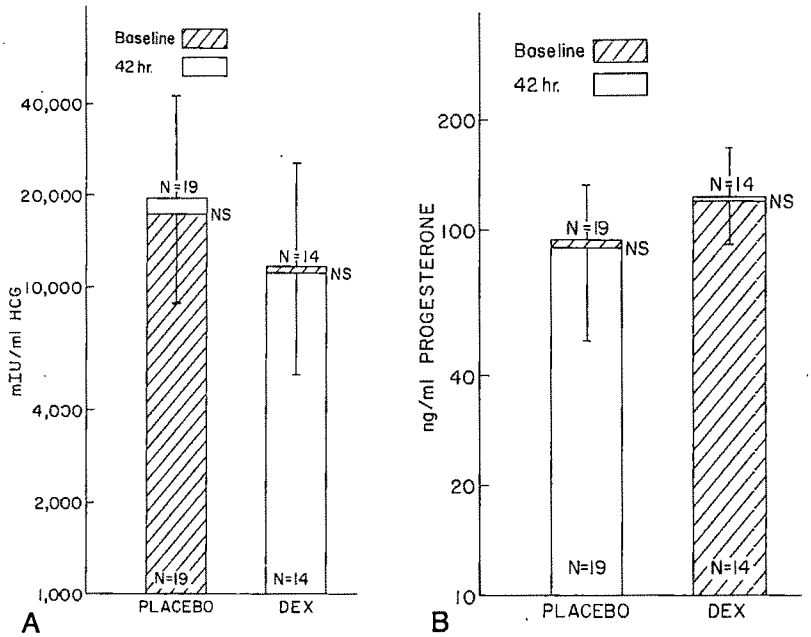

Fig. 2. Maternal hCG **(A)** and progesterone **(B)** concentrations determined in baseline placebo-, baseline dexamethasone-, 42-hour placebo-, and 42-hour dexamethasone-treated subjects. Data shown are mean and SD calculated on log-transformed data (note log scale). Test for significance of difference between baseline and 42-hour samples in placebo- and dexamethasone *(DEX)*–treated subjects was calculated from paired *t* test, with each subject serving as her own control (*NS*, not significant).

placebo-, and 42-hour dexamethasone-treated subjects are presented in Fig. 2, *A* and *B*, respectively. To test for an effect of placebo or dexamethasone treatment we used the pairing between baseline and the 42-hour posttreatment samples to evaluate the paired differences (42-hour sample minus baseline) in the log transformed data, with each subject serving as her own control. There was no significant change from the baseline value observed in either the placebo-treated subjects or the dexamethasone-treated subjects for either maternal serum hCG or maternal serum progesterone level. There was no effect of fetal sex or of administration of antibiotics, ethanol, or isoxsuprine on the paired differences for maternal serum hCG or progesterone concentrations (data not shown).

Effect of treatment on maternal serum cortisol, estrone, estradiol, and estriol. Data analysis was restricted to the same groups of patients used above for analysis of hCG and progesterone concentrations. Analysis of the log transformed data for maternal serum cortisol, estrone, estradiol, and estriol by paired *t* test with each patient serving as her own control showed that there was no significant decrease from the baseline value for cortisol, estrone, estradiol, or estriol in the placebo-treated subjects. When each 42-hour value was expressed as a percent of baseline in the dexamethasone-treated subjects, the geometric mean was 20% for cortisol (95% confidence interval 14% to 28%; $p < 0.0001$), 42% for estrone (95% confidence interval 33% to 53%; $p < 0.0001$), 30% for estradiol (95% confidence interval 22% to 40%; $p < 0.0001$), and 41% for estriol (95% confidence interval 31% to 53%, $p < 0.0001$). There was no effect of fetal sex or of administration of antibiotics, ethanol, or isoxsuprine on the paired differences for maternal serum cortisol, estrone, estradiol, or estriol concentrations (data not shown).

Comment

The hormones investigated here can be divided into those known to be dependent on adrenocorticotropic hormone and those not known to be dependent on adrenocorticotropic hormone. Both cortisol and dehydroepiandrosterone sulfate are secreted almost entirely by the maternal or fetal adrenal, and both are dependent on adrenocorticotropic hormone. Since dehydroepiandrosterone sulfate and 16α-hydroxydehydroepiandrosterone sulfate (derived from dehydroepiandrosterone sulfate by 16α-hydroxylation in the liver or adrenal) are the principal precursors for estrone and for estradiol and estriol, respectively, in pregnancy, the administration of dexamethasone was expected to suppress the 42-hour values for cortisol, estrone, estradiol, and estriol by inhibiting both maternal and fetal adrenocorticotropic hormone secretion.[9, 11] On the other hand, since neither progesterone nor hCG is dependent on adrenal substrates, no effect of either placebo or dexamethasone administration would be anticipated on their secretion. One of the reasons that the current study was undertaken was the observation by Haning et al.[8] that administration of dehydroepiandrosterone sulfate to placental ex-

plants in vitro had inhibited the stimulatory effect of gonadotropin-releasing hormone on hCG secretion. Also, statistical analysis of the concentrations of hCG, estrogens, and progesterone in the maternal peripheral blood and the estimated masses of the fetal adrenal and the placental trophoblast had provided evidence of an inhibitory effect of the fetal adrenal gland on secretion of hCG.[7] We reasoned that if there were no direct action of dexamethasone itself on hCG secretion, administration of dexamethasone to pregnant women would be expected to stimulate hCG production by reducing the concentration of dehydroepiandrosterone sulfate in both maternal and fetal compartments.

The duration of our period of testing for an effect of dexamethasone administration on secretion of hCG was limited by the design of the original study, a multicenter, double-blind trial of dexamethasone versus placebo completed many years before we obtained access to the samples. The 42-hour time interval was selected for analysis because it was the last sample before the adrenal gland could be expected to recover from the suppressive effect of dexamethasone, on the basis of data for maternal serum cortisol and estradiol.[9] We found no evidence for an effect of dexamethasone on hCG secretion under the conditions of this study. Both direct inhibitory[12] and direct stimulatory[13] in vitro effects of glucocorticoids on hCG have been reported. Likewise, in experiments performed in this laboratory, even direct addition of 2 mmol/L dibutyryl cyclic adenosine monophosphate to placental explants in vitro has a delayed effect with the maximal result not achieved until day 6 in placentas from term pregnancies.[14] There was a relatively smaller effect of dibutyryl cyclic adenosine monophosphate in placental tissue obtained from 12- to 17-week pregnancies, and a statistically significant effect of 2 mmol/L dibutyryl cyclic adenosine monophosphate administration on hCG secretion could not be demonstrated until days 5 and 6, even though a trend was evident as early as day 2.[14] Thus it is possible that a longer period of treatment with dexamethasone would have produced an effect on the concentration of maternal serum hCG. It is also possible that a direct effect of dexamethasone on the placenta could have obscured an effect produced by reduction in the concentration of circulating dehydroepiandrosterone sulfate. However, it is obvious that we have not provided any evidence for the anticipated stimulatory effect on hCG secretion of reducing the concentration of dehydroepiandrosterone sulfate in the present study.

Likewise, Grimshaw et al.[15] have demonstrated that dehydroepiandrosterone, estrone, androstenedione, and testosterone could all inhibit the conversion of pregnenolone to progesterone in vitro. However, the present study demonstrated no significant effect of dexamethasone on the concentration of progesterone in the maternal peripheral blood even though the dexamethasone produced decreases in estrone, estradiol, and estriol to be 42%, 30%, and 41% of baseline, respectively.

The sex of the fetus was demonstrated to modulate the maternal serum concentration of hCG in the present study. There was no demonstrable effect of fetal sex on maternal serum progesterone, cortisol, estrone, estradiol, or estriol concentration. Previous studies also have failed to demonstrate an effect of fetal sex on the maternal peripheral blood concentration of progesterone.[2] Higher concentrations of maternal serum hCG in female-bearing pregnancies than in male-bearing pregnancies have been reported at term by others,[2-4] and the placentas from female infants are known to have a higher content of hCG per unit weight of tissue at term[5,6] and to secrete more hCG in vitro per unit weight of tissue,[14] when compared with those from male infants. However, the reason for this phenomenon still awaits elucidation. The mean gestational age of the pregnancies in this study was 32 weeks. To our knowledge, this is the first study to demonstrate a statistically significant effect of sex on the concentration of maternal serum hCG this early in pregnancy. It is possible that the observed difference in the maternal peripheral blood hCG concentration between female-bearing and male-bearing pregnancies in the last trimester will provide a clue to understanding the mechanism modulating hCG in early pregnancy as well.

High glucose levels decrease proliferation of cultured human fetal cells from placenta

D. Michael Nelson, MD, PhD, and Edward M. Curran, MS
St. Louis, Missouri

We used the placenta as a source of undifferentiated cells to study the effect high glucose levels can have on human fetal cell proliferation in vitro. Cells were subcultured in a modified minimum essential medium with 10% fetal bovine serum containing either 5.5 mmol/L (100 mg/dl) D-glucose (control), 11 mmol/L (200 mg/dl) D-glucose, or 22 mmol/L (400 mg/dl) D-glucose. Cells grown in mannitol-containing media were used as controls for osmolality. After 3 and 7 days' growth in different media, the labeling index was determined by autoradiographic analysis, and cell numbers were determined with a Coulter counter. The labeling indices for cells grown 3 days in 11 or 22 mmol/L D-glucose were 89% ($p < 0.002$) and 84% ($p < 0.001$), respectively, of control cells grown in 5.5 mmol/L D-glucose. After 7 days' growth, the labeling indices of cells grown in 11 or 22 mmol/L D-glucose were 84% ($p < 0.002$) and 70% ($p < 0.001$), respectively, of cells grown in 5.5 mmol/L D-glucose media. There was a significant decrease in the number of cells present at both 3 and 7 days in cultures grown in 22 mmol/L D-glucose compared with control. We conclude that a few day's exposure to high glucose levels can have an effect on proliferation of human placental cells in vitro. We suggest that a glucose effect on proliferation of other cells derived from the products of conception might be one mechanism contributing to abnormal development in some pregnancies of diabetic women. (AM J OBSTET GYNECOL 1989;161:1553-8.)

Key words: High glucose, cell proliferation, placenta

Studies of pregnant diabetic women who are hyperglycemic during organogenesis[1] and those who have increased glycosylated hemoglobin levels in the first trimester of pregnancy[2] suggest that elevated glucose levels adversely affect the developing conceptus. Hyperglycemia in pregnant diabetic women increases the risk for spontaneous abortion,[3, 4] anomaly development,[2, 5] and growth delay in the first trimester.[6] The mechanisms by which elevated glucose levels adversely affect the products of conception during morphogenesis are unknown. We have used the placenta as a source of rapidly proliferating, undifferentiated cells to study the effect of high glucose concentrations on proliferation of cultured human cells derived from the products of conception.

Material and methods

Cell cultures. Placentas were obtained from normal term pregnancies in women who had negative results of screening for gestational diabetes. All deliveries were by repeat cesarean section with patients under epidural anesthesia after hydration with 15 ml/kg of lactated Ringer's fluid.

Primary cell cultures were obtained according to a previously published method.[7] Briefly, villous tissue was

rinsed with a modified Eagle's minimum essential medium and treated 10 minutes at 37° C with the enzyme dispase (Collaborative Research, Inc., Lexington, Mass.); cells in the supernatant were harvested. Most cells stained cytochemically for cytokeratin intermediate filaments indicating they were trophoblastic cells, but 8% of the cells were vimentin positive and Factor VIII negative.[7] The latter population was an undifferentiated stromal cell that rapidly proliferated during long-term culture without density limitation after reaching confluence. These cells were grown in a humidified 5% carbon dioxide in air atmosphere at 37° C in modified Eagle's minimum essential medium with 100 U/ml penicillin G, 100 μg/ml streptomycin sulfate, 0.25 μg/ml Fungizone, and 10% (vol/vol) chemically defined fetal bovine serum (Hyclone, Logan, Utah) containing an average of 7.3 μU/ml insulin and 102 μg/ml of lactic acid.

Labeling index. Cells from the fourth passage of four primary cultures were collected after detachment with 0.01% (wt/vol) trypsin (type XII from bovine pancreas, Sigma Chemical Co., St. Louis), and viability was >95% after exposure to trypan blue. Cells were subcultured on slide flasks (Nunc, Schaumburg, Ill.) or Petri dishes (Corning Glass Works, Corning, N.Y.) at 2.0×10^4 cells per 21 cm^2 in 4 ml modified Eagle's minimum essential medium with 10% fetal bovine serum (vol/vol) containing 5.5 mmol/L (100 mg/dl) D-glucose and antibiotic-antimycotic solution. After 24 hours, the cells were rinsed with fresh medium to eliminate unattached cells, and quadruplicate slide flasks or Petri dishes were established for each of the differential treatments: modified Eagle's minimum essential medium plus 10% fetal bovine serum containing either 5.5 mmol/L (100 mg/dl) D-glucose (control media), 11 mmol/L (200 mg/dl) D-glucose, 22 mmol/L (400 mg/dl) D-glucose, 5.5 mmol/L D-glucose plus 5.5 mmol/L mannitol, or 5.5 mmol/L D-glucose plus 16.5 mmol/L mannitol. Media osmolality and glucose levels were determined before and after incubation with cells. Triplicate slide flasks from each of the five media treatments were rinsed with modified Eagle's minimum essential medium after 3 or 7 days of growth, incubated in 2 ml modified Eagle's minimum essential medium containing 0.5 μCi/ml [^{3}H]thymidine (15.7 Ci/mmol/L; New England Nuclear, Boston) for 3 hours at 37° C, rinsed twice with ice-cold modified Eagle's minimum essential medium, and either fixed in situ with methanol or detached and embedded in plastic as a cell pellet for autoradiographic analysis as previously described.[8] The rinse procedure was established to remove unincorporated [^{3}H]thymidine. In the first of the four labeling index experiments, autoradiographic analysis of cells grown 3 or 7 days in the different media was done after fixation in situ on their slide flasks.

The cells grown 3 days were easily evaluated, but the higher density of cells present after 7 days' growth made some areas of the slide flask difficult to analyze in this experiment. Thus cells from day 7 in the subsequent three experiments were detached from their slide flasks and embedded in plastic as a cell pellet for autoradiographic analysis. The number of fields of nuclei available for analysis (and thus the total number of nuclei present) was less for the experiments done with plastic sections than for the three done with in situ fixed specimens.

An observer, who was blinded to the experimental conditions, examined a series of equidistant fields of each autoradiogram, recording the total number of nuclei and nuclei with ≥5 overlying grains. The labeling index is the number of labeled nuclei divided by the total number of nuclei counted.

Cell numbers during growth in high-glucose media. Cells from four different primary cultures were subcultured onto 32 Petri dishes at 2.0×10^4 cells per 60 mm dish (21 cm^2) containing 4 ml modified Eagle's minimum essential medium with 10% fetal bovine serum, 5.5 mmol/L D-glucose, and antibiotic-antimycotic solution. After 24 hours to allow cell attachment, medium in each of eight dishes was changed in a blinded manner to medium containing either 5.5, 11, or 22 mmol/L D-glucose. Cells cultured in 5.5 mmol/L D-glucose plus 16.5 mmol/L mannitol provided the control for osmolality. Media were replaced again at 2, 4, and 6 days. On the third or seventh day after the differential treatment conditions were established, medium from each dish was collected and assessed for the presence of detached, nonviable cells. Attached cells in the same dishes were detached with trypsin, assessed for viability by trypan blue exclusion, and counted in a ZBF model Coulter counter equipped with a 100 μm aperture.

Statistical analysis. The number of labeled and unlabeled nuclei in the control and experimental treatments was compared by χ^2 analysis. The differences in number of cells in control cultures and cultures exposed to differential treatments were evaluated by analysis of variance for individual experiments and by the Wilcoxon signed-rank test for the series, since the cell numbers for different placentas were not normally distributed populations. Values are reported as mean ± SD. A computer software package was used for analysis (Abstat, Anderson Bell, Parker, Colo.) with $p < 0.01$ for significance because multiple comparisons were made.

Results

Characteristics of media and cells. Osmolality was 294 ± 2 (mean ± SD) mmol/kg in media containing 5.5 mmol/L D-glucose, 300 ± 3 (mean ± SD) mmol/kg in media containing 11.0 mmol/L D-glucose,

Cells were subcultured at 2.0×10^4 cells per 21 cm^2, grown 7 days in normal or high-glucose media, exposed to [^{3}H]-thymidine, and processed for autoradiographic analysis by an observer blinded to treatment conditions as described in Material and methods. The labeling index is the ratio of labeled nuclei divided by total nuclei counted. Results are mean (±SD) from $n = 12$ in four experiments.

*$p < 0.002$, compared with control.

†$p < 0.0001$, compared with control.

‡$p < 0.005$, compared with 11 mmol/L glucose, 5.5 mmol/L mannitol, and 16.5 mmol/L mannitol.

§$p < 0.025$, compared with control.

‖$p < 0.004$, compared with control.

300 ± 2 (mean ± SD) mmol/kg in media containing 5.5 mmol/L D-glucose and 5.5 mmol/L mannitol, 312 ± 2 (mean ± SD) mmol/kg in media containing 22.0 mmol/L D-glucose, and 311 ± 3 (mean ± SD) mmol/kg in media containing 5.5 mmol/L D-glucose and 16.5 mmol/L mannitol. No morphologic differences could be detected by phase-contrast microscopy in the placental cell cultures grown in different media. Glucose concentrations remained within 4% of the initial glucose level of the media. Cell viability by trypan blue exclusion remained at >95% for all cultures.

Labeling index. Background grain counts on control slides were ≤1/500 μm. Preliminary experiments established that the use of ≥5 grains overlying a nucleus clearly differentiated labeled from unlabeled nuclei. In addition, unlabeled cells had background grain counts, thereby excluding dexoyribonucleic acid repair as a significant contributor to [^{3}H]thymidine incorporation.

An alteration in cell proliferation in cultures with high glucose levels was identified by studying the labeling index of cells grown in control medium with 5.5 mmol/L D-glucose compared with cells grown in media containing either 11 or 22 mmol/L D-glucose. Parallel cultures of cells grown in the presence of mannitol were used to control for the change in osmolality that accompanied the high-glucose media. The labeling indices of cells grown with the high glucose levels were significantly lower after 3 days (Table I) and 7 days (Table II) in culture than those of control cells grown in 5.5 mmol/L D-glucose medium without mannitol. The effect was greater after 7 days' growth in high levels of glucose than after 3 days' exposure, and the effect of 22 mmol/L D-glucose was greater than the effect of 11 mmol/L D-glucose. The lower labeling index for cells grown 3 days in the high-glucose conditions could not be solely attributed to the higher osmolality of the media since no significant difference in labeling index was present in cells grown 3 days in

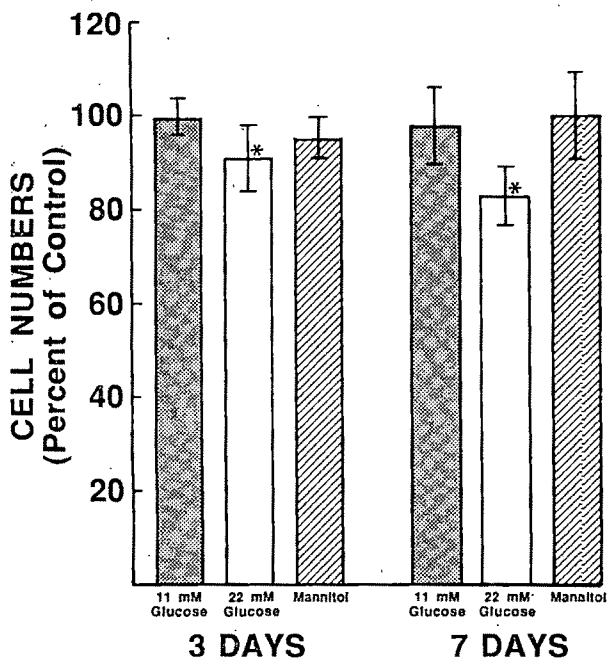

Fig. 1. Differences in cell numbers in cultures grown 3 or 7 days in hyperglycemic or mannitol-containing (16.5 mmol/L) media compared with control media with 5.5 mmol/L glucose. Each percentage is the mean ± SD calculated from $n = 16$ from four experiments. *Asterisk*, $p < 0.01$ compared with control.

mannitol-containing media when compared with cells grown in 5.5 mmol/L D-glucose. However, a part of the decrease in the labeling index observed in cells grown 7 days in the high-glucose conditions was attributable to a change in osmolality since the labeling index of cells grown in mannitol-containing media for 7 days also had a labeling index that was significantly lower than that of control cells.

Cell numbers during growth in high-glucose media. Cells to be exposed to the different treatments were initially grown 24 hours after subculture in modified Eagle's minimum essential medium with 10% fetal bovine serum containing 5.5 mmol/L D-glucose. Medium was then replaced with one of the study media. This approach avoided any effect of high glucose level or high osmolality on plating efficiency. The number of cells in cultures grown 3 or 7 days in 11 mmol/L D-glucose was not significantly different from the number of cells in the control medium with 5.5 mmol/L D-glucose (Fig. 1). However, there was a significant ($p < 0.01$) decrease in the number of cells present in cultures grown 3 or 7 days in medium with 22 mmol/L D-glucose when compared with those in control medium (Fig. 1). The average number of cells present in control media after 3 or 7 days' growth was 6.21 ± 1.3 (mean ± SD) × 10^5 and 4.20 ± 1.10 (mean ± SD) × 10^6, respectively ($n = 16$ from four experiments). The numbers of cells in the 22 mmol/L D-glucose cultures ranged between 1.0% and 25.0% lower than control after 3 days' growth, with an average decrease of 9.7%. The decrease in numbers of cells after 7 days ranged between 4.7% and 26.8% for the 22 mmol/L D-glucose cultures compared with control, with an average decrease of 17.8%. There was no difference in the number of cells in cultures grown in the presence of 16.5 mmol/L mannitol compared with control cultures grown in 5.5 mmol/L D-glucose (Fig. 1).

The number of detached, nonviable cells present in the media at the time of media changes was <500 cells in all cultures. Viability of attached cells by trypan blue exclusion remained at >95% in all cultures with no differences attributable to the growth medium.

Comment

These data indicate that proliferation of cultured human fetal cells from term placentas is altered by short-term exposure to high glucose concentrations. The effect on the labeling index was dependent on both the glucose concentration and the time of exposure to the high glucose levels. The glucose caused a decrease in number of cells present in the cultures exposed to the 22 mmol/L (400 mg/dl) D-glucose concentration when compared with those in control cultures with 5.5 mmol/L (100 mg/dl) D-glucose. Whether the antiproliferative effect of glucose resulted from an alteration of the cell cycle, the growth fraction, or both remains to be determined. We conclude that a few days' exposure to high glucose levels can have an effect on proliferation of human placental cells in vitro. We suggest that a glucose effect on proliferation of other cells derived from the products of conception might be one mechanism contributing to abnormal development in some pregnancies of diabetic women.

Average blood glucose levels for nondiabetic pregnant patients are in the range of 5.5 mmol/L (100 mg/dl) D-glucose.[9, 10] We selected 11 mmol/L (200 mg/dl) as an average high glucose level and 22 mmol/L (400 mg/dl) as an extreme glucose level that realistically can be observed in some diabetic women during pregnancy.

Malformations characteristic of offspring from diabetic women are established by the seventh week of gestation.[11] The specific insult that causes malformations is not organ specific since a variety of organ systems are affected by anomalies.[5] To expect that a complex problem such as anomaly development will be explained by a single mechanism is unrealistic.[12, 13] However, cell proliferation is a prerequisite for normal development throughout pregnancy, and small changes in cell replication activity caused by a teratogenic agent during critical stages of fetal development could affect morphogenesis. We selected the labor

intensive approach of autoradiographic analysis of [^{3}H]thymidine incorporation as the best method to identify small but significant differences in cell proliferation activity.[14] Using autoradiographic analysis, we also avoided two criticisms raised when [^{3}H]thymidine is used for biochemical studies of cell proliferation[14]: Our results cannot be due to glucose-induced alterations in [^{3}H]thymidine transport by the cells because a change in thymidine pools would change only the density of labeling of a cell, not the number of cells labeled; and our results are not due to a glucose-induced increase in deoxyribonucleic acid repair[15] since this would appear as a generalized increase in radioactive background in all cells.

Experimental studies of anomaly development in pregnancies complicated by diabetes mellitus have generally used animal models.[16-24] Animal models offer the advantage of in vivo study of environmental influences that might affect growth and differentiation of embryos, but caution is required when extrapolating results in animals to answer questions about human development. Our cell system is not proposed to be a model of human embryogenesis. The novelty of our cell model resides in the use of undifferentiated, rapidly proliferating human cells that are derived from the products of conception to study the effect high glucose levels can have on cell proliferation in a controlled environment. The disadvantages of our model include the use of term cells instead of first-trimester cells and the use of placental cells instead of cells from the embryo. We therefore recognize that our conclusion that high glucose levels affect the proliferation of cultured human fetal cells from term placentas may not apply to human fetal cells obtained from the embryo in the first trimester where factors regulating growth and development may be very different. However, our study is the first to show that a high glucose level itself has a direct effect on cell proliferation in a human fetal cell system that is not solely due to a change in osmolality. The only other report to use human fetal cells to study glucose effects on cell proliferation used umbilical vein cells.[25] Cells cultured in 20 mmol/L D-glucose or 20 mmol/L mannitol were delayed in reaching confluence when compared with cells grown in 5 mmol/L D-glucose. This was due in part to a decrease in the mitotic index and in part to excess cellular death. These results were not specific to the high glucose levels but were related to the change in osmolality occurring in both the high-glucose and mannitol-containing media.

Cell death did not influence our results since viability as measured by trypan blue exclusion was the same in all cultures and the number of detached, nonviable cells was negligible. We also found a labeling index lower than that in control cultures in cells grown 3 or 7 days in 11 mmol/L D-glucose or 7 days in mannitol. However, the number of cells in these cultures were not significantly different from control. The growth of our cells was not density limited, and growth beyond 7 days in culture resulted in marked cell piling. This phenomenon created irreversible cell clumping and damage when we attempted to detach cells to determine their numbers at later time points beyond 7 days in culture. We were thus not able to determine if the number of cells in the 11 mmol/L D-glucose or mannitol-containing media would become significantly lower than those in control after growth beyond 7 days.

A derangement in maternal metabolism is a causative factor for developmental abnormalities in the offspring of diabetic women.[12, 13] Hyperglycemia is the marker of decompensated diabetes most easily assessed clinically and most commonly associated with anomaly development.[1, 2] Associated derangements of maternal metabolism implicated in anomaly development include hyperketonemia,[19] somatomedin inhibitors,[20] alterations of glycolysis,[21] hypoglycemia,[22] alterations of trace metals,[23] and enhanced synthesis of hyaluronic acid.[24] Recent studies suggest a role for arachidonic acid,[16, 17] myoinositol,[26] and glycolytic substrates[21] for anomaly development in experimental animal diabetes. Ely[27] proposed that hyperglycemia may inhibit mitosis by lowering intracellular ascorbic acid levels while raising plasma dehydroascorbic acid levels. The molecular mediators involved in the antiproliferative effect we associated with high glucose levels are unknown, but further studies using our cell system should help to identify such mediators.

We are grateful to Dr. Ronald C. Strickler and Dr. Donna R. Farmer for their helpful reviews.

Stimuli for fetal swallowing: Systemic factors

Michael G. Ross, MD, Dan J. Sherman, MD, M. Gore Ervin, PhD, Linda Day, and James Humme

Torrance and Los Angeles, California, and Tel Aviv, Israel

Although the fetal gastrointestinal tract is believed to be a major site of amniotic fluid absorption, there is little information with regard to the acute regulation of fetal swallowing. A model for the study of ovine fetal swallowing was developed to incorporate electromyogams, an esophageal flow probe, and a computer data acquisition and analysis program. The fetal swallowing responses to two primary thirst stimuli, plasma hyperosmolality and angiotensin II, were studied. On alternate days, chronically prepared fetal lambs (131 ± 2 days) received an intravenous infusion of angiotensin II (100 ng/kg per minute) or bolus injections (3 ml) of 0.15 and 3.97 mol/L saline solution. In response to the angiotensin II infusion, fetal systolic (49.3 to 64.7 mm Hg; $p < 0.05$) and diastolic (31.1 to 40.5 mm Hg; $p < 0.05$) blood pressures significantly increased. However, fetal swallowing did not change from basal rates of 0.85 swallows per minute and a net esophageal flow of 0.98 ml/min. In response to the injection of 3.97 mol/L saline solution, fetal plasma osmolality increased (292 to 306 mOsm; $p < 0.05$) and subsequently decreased to 300 mOsm at 15 minutes after the injection. Within 1 minute after injection of the hypertonic saline solution, fetal swallowing activity (6.0 swallows per minute; $p < 0.05$) and net esophageal flow (2.4 ml/min; $p < 0.05$) significantly increased. Swallowing returned to basal values within 5 minutes after the injection. The data indicate that ovine fetal responses to osmolar thirst challenges are intact at 130 days' gestation. Fetal swallowing and thus amniotic fluid volume may be affected by fetal responses to in utero stimuli. (AM J OBSTET GYNECOL 1989;161:1559-65.)

Key words: Ovine, thirst, gastrointestinal tract

Swallowing may be of great importance to the developing fetus. Both the ovine and human fetuses have been estimated to swallow 500 to 1000 ml per day of amniotic fluid and likely additional volumes of pulmonary and salivary secretions.[1-7] Accordingly, alterations in amniotic fluid volume have been attributed to abnormal swallowing in human fetuses[8, 9] and a direct relationship between fetal swallowing and amniotic fluid volume has been shown in animal models.[10-12] Furthermore, fetal swallowing of amniotic fluid may be essential for normal gastrointestinal development and maturation.[13] Yet, the regulation of fetal thirst and swallowing is largely unexplored.

In the adult mammal there appear to be two stimuli for primary (thirst-mediated) drinking, one arising from cellular dehydration and the other from extracellular volume depletion.[14] Cellular dehydration, or perhaps cell shrinkage, is sensed centrally in areas near the preoptic nucleus of the hypothalamus and the tissue surrounding the anteroventral portion of the third ventricle.[15] These parapreoptic neural regions may respond to either plasma or cerebrospinal fluid osmolality changes, mediated in part by the cellular permeability to the osmotic agent. Notably, these regions are in close proximity to hypothalamic nuclei synthesizing arginine vasopressin. Extracellular thirst stimulation appears to be mediated principally by neuroendocrine factors. In particular angiotensin II, secreted in response to perceived intravascular volume depletion, may act either systemically or centrally to stimulate thirst.[15]

The ontogeny of the physiologic and endocrine mechanisms that regulate swallowing has received only limited study, primarily in the newborn rat.[17] The fetus develops in an aquatic environment and thus requires only reflex or "secondary" drinking for the ingestion of fluid. It is possible that "primary" drinking mechanisms do not develop in utero. However, previous studies indicate a significant in utero maturation process of endocrine systems that mediate renal antidiuresis, the unconscious counterpart to thirst.[18] Thus it is likely that thirst mechanisms also mature. To initiate studies of the regulation of fetal "thirst," we developed a model for the quantification of swallowing activity and volume in the ovine fetus. Fetal responses to two primary systemic thirst stimuli, plasma hyperosmolality and angiotensin II, were studied. The results suggest an intact "thirst" mechanism in the late gestation ovine fetus.

Animals and methods

Six chronically instrumented Western crossbred ewes with singleton fetuses were studied. Guidelines for the care and use of animals approved by Harbor–University of California at Los Angeles Medical Center were followed in all studies. Five experiments were performed to quantify the swallowing response to angiotensin II, and four experiments studied the fetal swallowing activity in response to plasma hyperosmolality. Three animals had both studies performed, with the sequence of the angiotensin II or hypertonic saline solution study chosen at random. The mean gestational age for both studies was 131 ± 2 days. Animals were housed indoors in individual steel study cages and acclimated to a lighting regimen of 12-hour light and dark periods. Both food (alfalfa pellets) and water were available as desired, except for the withholding of food during the 24-hour period immediately preceding surgery.

Anesthesia for surgery was induced by an intramuscular injection of ketamine hydrochloride (800 mg) plus atropine sulfate (300 mg) and was subsequently maintained by a continuous intravenous infusion of ketamine (600 mg/hour) plus locally applied lidocaine (Xylocaine) (1%) for all maternal and fetal incisions. The uterus was exposed by a midline abdominal incision and a small hysterotomy was performed to provide access to a single fetal hind limb. Polyethylene catheters (inner diameter, 1.0 mm; outer diameter, 1.8 mm) were placed in a fetal dorsal hind limb vein and artery and threaded to the inferior vena cava and aorta, respectively. Before hysterotomy closure, an amniotic fluid catheter (Corometrics Medical Systems, Wallingford, Conn.) was sutured to the distal tip of the fetal hind limb.

A second hysterotomy was made over the fetal neck and a 3 cm vertical incision was made in the fetal nuchal midline, extending cephalad from the thyroid cartilage. The skin was gently clamped to the uterus and the pharyngeal muscles were identified. Two wires (AS632, Cooner Wire, Chatsworth, Calif.) were inserted into one thyrohyoid muscle and a third ground wire was placed in the adjacent subcutaneous tissues. The nuchal esophagus was exposed and similarly prepared with bipolar electromyogram and ground electrodes. The skin incision and uterus were closed. The fetal thorax was positioned, the uterus was incised, and the fetal left hemithorax was entered via the eighth intercostal space. The peritoneum overlying the esophagus was incised for a distance of 2 cm cephalad to the diaphragm. Electromyogram electrode wires were placed on the thoracic esophagus and a 4 mm ultrasonographic flow probe (Transonic System Inc., Ithaca, N.Y.) was placed loosely around the esophagus, distal to the electromyogram wires. The fetal chest was closed in layers, the uterus and maternal incisions were repaired, and the catheters and electrodes were externally accessed via a maternal flank incision. Catheters also were placed in the maternal inferior vena cava and abdominal aorta via the femoral vein and artery in one leg. Fetal vascular catheters were maintained patent by filling the catheter dead space (1 ml) with 1000 U/ml sodium heparin; catheters were sealed with sterile plastic caps. Maternal vascular catheters were filled with heparinized saline solution (10 U/ml) and both fetal and maternal catheters were flushed daily. All animals were allowed a minimum of 5 days for postoperative recovery during which time the fetuses received intravenous infusions of methicillin sodium (100 mg) twice daily. Methicillin sodium (400 mg) and chloramphenicol (500 mg) also were administered into the maternal vein and amniotic cavity. After the studies, the animals were killed and the flow probe was removed from the fetal esophagus. There was no evidence of obstruction or constriction of the esophagus in any fetus.

Experimental protocol

Angiotensin infusion. All experiments were performed on unanesthetized ewes standing in the same individual cages in which they were maintained. During an initial 60-minute control period (time −60 to 0) fetal swallowing activity was continuously monitored. At 0 minutes, a fetal intravenous infusion of angiotensin II (100 ng/kg per minute) in 0.9% saline solution was administered at a rate of 0.05 ml/kg per minute and maintained for 60 minutes. The infusion was preceeded by a 1 ml bolus injection of angiotensin II (20 ng/kg). Infusion concentrations were determined on the basis of estimated fetal body weight (FBW) from the formula FBW (kg) = [0.096 × gestational age (days)] − 9.2228, as described by Robillard and Weitzman.[18]

At 60 minutes the angiotensin II was discontinued and the animals were monitored for an additional 60-minute recovery period (time 60 to 120 minutes). Fetal arterial blood samples (2.5 ml), obtained at −30 and 0 minutes of the control period, 15, 30, and 60 minutes of the angiotensin II infusion, and 75, 90, and 120 minutes of the recovery period were collected into iced tubes that contained 10 μl lithium heparin per milliliter of blood and were immediately centrifuged. Osmolality was measured in aliquots of the prepared plasma. An additional 0.5 ml of blood was collected into heparinized 1 ml syringes for immediate measurement of pH, P_{O_2}, and P_{CO_2}. The total volume of fetal blood withdrawn at each sampling was immediately replaced with an equal volume of heparinized maternal blood withdrawn before the study. Maternal arterial blood samples were drawn at −30, 0, 60, and 120 minutes for

measurement of hematocrit, pH, P_{O_2}, P_{CO_2}, and plasma osmolality. Fetal arterial blood pressure and heart rate were monitored continuously by means of a Beckman R-612 physiologic recorder (Beckman, Palo Alto, Calif.) with a Statham P23 transducer (Gould Inc., Oxnard, Calif.). Amniotic fluid pressure was subtracted from fetal arterial pressure.

Hypertonic saline solution infusion

On a different day, four of the animals were studied to determine the effect of acute plasma hyperosmolality. During an initial 60-minute control period (time −60 to 0 minutes) fetal swallowing activity was continuously monitored. Basal maternal and fetal blood samples (3.0 ml) were drawn at −30 and 0 minutes for hematocrit, pH, P_{O_2}, P_{CO_2}, plasma osmolality, and plasma arginine vasopressin as described above. At time 0, an intravenous bolus (3 ml) of isotonic (0.15 mol/L) saline solution was injected into the fetus. Repeat fetal blood samples were drawn at 1, 5, 10, and 15 minutes after the injection. At 15 minutes, an intravenous bolus of 3.97 mol/L saline solution was injected into the fetus and identical blood sampling was performed at 16, 20, 25, and 30 minutes. Preliminary studies had indicated that fetal plasma osmolality remained elevated for >30 minutes after injection of hypertonic saline solution. To avoid the potential effect of persistent plasma hyperosmolality on the response to isotonic saline solution, the injection of 0.15 mol/L saline solution was performed before the injection of 3.97 mol/L saline solution in all studies. Injections were not administered during spontaneous bouts of swallowing. In such cases, the injection was delayed until there was a return to basal activity. Repeat maternal blood samples were drawn at 15 and 30 minutes.

Analytical methods

Plasma arginine vasopressin levels were measured by radioimmunoassay of 1 ml plasma samples extracted on Sep-Pak (Waters Associates, Milford Mass.) columns. The extraction procedure of LaRochelle et al.[19] was modified to include 0.1% trifluoroacetic acid (in place of 4% acetic acid) and sample elution was accomplished with 2 ml of 50% methanol in 0.1% trifluoroacetic acid. Synthetic arginine vasopressin (obtained from Bachem, Torrance, Calif.) was used as the standard. The arginine vasopressin radioimmunoassay used in our laboratory is sensitive to 0.8 pg of arginine vasopressin per milliliter of plasma (0.16 pg/tube). The intra-assay and interassay coefficients of variation are 6% and 9%, respectively.

Blood pH, P_{O_2}, and P_{CO_2} values were measured at 39° C with a BM 33 MK 2-PHM 72 MK2 acid base analyzer system (Radiometer, Copenhagen, Denmark). Plasma osmolality was measured by freezing point depression on a digimatic osmometer (model 3MO, Advanced Instruments, Needham Heights, Mass.).

All electromyogram signals were directed into a Beckman R612 physiologic recorder with a Beckman voltage-pressure/pulse coupler (type 9853A). A common ground was formed from each of the electromyogram ground wires. The electrode impedence in muscle tissue was 1 to 15 kOhms at 1 kHz. The raw signal ranged from 0.1 to 1 mV. Amplifier impedence was 2×10^6 ohms, sensitivity range was 0.5 to 5 V/mm, and the common mode rejection ratio was 100 dB at 60 Hz. A low cut-off 5.3 Hz filter was present on the preamplifier with a narrow band (60 Hz) filter on the amplifier. A "leaky" integrator (moving average) with a variable time constant was inserted in series after preamplication of the raw electromyogram signal, which served to rectify and integrate the electromyogram signal. The integrated signal was further amplified (×100) and the output was plotted on the chart recorder and directed in parallel to both an FM tape recorder (Tandberg Instrument Recorder Series 100, Tandbergs Radiofabrikk, Oslo, Norway) and a microcomputer. With the use of an analog to digital–converter and Asyst (MacMillan Software Company, N.Y.) software, the integrated electromyograph signals were digitized at 50 samples per second per channel. Flowmeter signals (milliliters per minute) were processed without electronic integration and were similarly stored on the hard disc.

Flowmeter signals were displayed after the study. An analysis program calculated mean and SD of periods of zero flow (absent swallowing). With the use of mean and 3 SDs to represent the range of baseline noise, the program determined psoitive and negative thresholds for flow analysis and subsequently identified all positive (cranial to caudal) and negative (caudal to cranial) flows. Each flow was mathematically integrated by the computer, yielding actual volume per swallow. Net esophageal flow was calculated as positive flow minus negative flow. Similarly, electromyograph patterns were displayed and threshold voltages were selected for discrimination of noise versus signal. The analysis program scanned each channel denoting the time of onset, maximum amplitude, and the duration of each "spike" (single channel). "Swallows" were defined as a sequence of spikes from the thyrohyoid through the thoracic esophagus within time limitations determined for each fetus by analysis of wave form progression (Fig. 1).

The transit-time ultrasonographic flowmeter (T101, Transonic Systems Inc., Ithaca, N.Y.) produces linear bidirectional flow signals over a range of ±500 ml. The transit-time flowmeter is unaffected by vessel dimensions or misalignment and does not require a constric-

tive fit to the vessel. Flowmeter calibration was confirmed in vitro and in vivo. All flow probes are factory precalibrated. On receipt, an additional bench calibration with a variable infusion pump setup and collection of outflow confirmed the factory calibration. During chronic implantation, the flowmeter confirms zero and full-scale flow calibration. Furthermore, a zero-baseline adjustment allows for correction for minimal baseline noise.

After computer analysis the reduced data are presented as swallows or volume swallowed per unit of time. All values are expressed as the mean ± SEM. Differences over time were assessed by one-way analysis of variance with repeated measures. Differences within groups were determined with Dunnetts test. Maternal samples were analyzed by the Student paired t test to compare the mean of basal values with the mean of the values at the conclusion of the studies.

Results

Angiotensin infusion. During the infusion of angiotensin II to the fetus there was a significant increase in fetal systolic (49.3 ± 3.6 to 64.7 ± 5.2 mm Hg) and diastolic (31.1 ± 3.1 to 40.5 ± 4.5 mm Hg) blood pressures, which returned to basal values during the recovery period (49.3 ± 3 mm Hg, 32.5 ± 2.0 mm Hg, respectively) (Table I). Fetal heart rate did not change during the infusion of angiotensin II but did increase significantly 15 minutes after the conclusion of the infusion. Fetal hematocrit increased significantly during the angiotensin II infusion (30.5% ± 1.6% to 32.4% ± 1.3%) and returned to basal levels during the recovery period. Fetal arterial pH, P_{O_2}, P_{CO_2}, and plasma osmolality did not change during the study (Table I).

Fetal swallowing activity averaged 0.85 ± 0.21 swallows per minute and esophageal flow was 0.98 ± 0.64 ml/min during the 60-minute control period.

Table II. Mean (±SEM) fetal arterial values in response to isotonic and hypertonic saline solution infusions* ($n = 4$)

*0.15 mol/L Saline solution administered after 0-minute sample; 3.97 mol/L saline solution administered after 15-minute sample.

In response to the angiotensin II infusion, swallowing activity (0.62 ± 0.15 swallows per minute) and flow (0.40 ± 0.06 ml/min) did not change significantly. Swallowing remained stable during the recovery period (0.99 ± 0.25 swallows per minute, 0.50 ± 0.26 ml/min). In response to the fetal angiotensin II infusion, maternal mean blood pressure (86 ± 1 mm Hg), heart rate (135 ± 8 beats/min), hematocrit (28.5 ± 1.9%), pH (7.48 ± 0.01), P_{O_2} (99.4 ± 6.7 mm Hg), P_{CO_2} (30.6 ± 0.5 mm Hg), and plasma osmolality (297 ± 3 mOsm) did not change.

Hypertonic saline solution administration. Throughout the hypertonic saline solution study, fetal hematocrit, pH, P_{O_2}, P_{CO_2}, heart rate, and systolic and diastolic blood pressure values did not change (Table II). Fetal plasma osmolality (292 ± 3 mOsm) did not change significantly after the 0.15 mol/L sodium chloride injection (Fig. 2). However, 1 minute after the 3.97 mol/L sodium chloride bolus, fetal plasma osmolality significantly increased to 306 ± 5 mOsm, and subsequently decreased to 300 ± 3 mOsm by 15 minutes after the injection. Fetal plasma levels of arginine vasopressin did not change in response to the 0.15 mol/L saline solution bolus. There was a small but nonsignificant increase in plasma arginine vasopressin ($p = 0.058$) in response to the 3.97 mol/L saline solution bolus (Fig. 2).

In response to the 0.15 mol/L saline solution bolus, fetal swallowing activity (0.81 ± 0.18 swallows per minute) or volume (0.46 ± 0.20 ml/min) did not change. However, fetal swallowing activity significantly increased (6.0 ± 1.7 swallows per minute; $p < 0.05$) and swallowed volume increased fivefold (2.4 ± 1.0 ml/min; $p < 0.05$) at 1 minute after the 3.97 mol/L saline solution injection. Both swallowing activity and volume returned to basal values 5 minutes after the injection (Fig. 2).

Maternal hematocrit (29.0% ± 3.3%), pH (7.46 ± 0.01), P_{O_2} (98.4 ± 4.3 mm Hg), P_{CO_2} (34.3 ± 2.3 mm Hg), and plasma osmolality (294 ± 3 mOsm) did not change in response to the fetal 0.15 mol/L and 3.97 mol/L injections of saline solution.

Comment

Human fetuses have been estimated to swallow up to 500 ml/day of amniotic fluid, in addition to significant volumes of lung fluid and salivary secretions.[6,7] Similarly, ovine fetuses swallow up to 1 L per day near term.[2-4] As fetal swallowing appears to be a primary route of amniotic fluid reabsorption, an interruption of normal swallowing in human fetuses or animal models may result in polyhydramnios.[8-12] Fetal swallowing also has been shown to have significant effects on gastrointestinal development. In the absence of swallowing, the maturation of gastric and intestinal tissue is retarded in fetal sheep[20] and rabbits.[13] Intragastric infusions of amniotic fluid, though not saline solution, normalized the maturation. In addition, decreased somatic growth may be a result of inhibited swallowing in either human[9] or rabbit fetuses.[13]

To permit quantification and analysis of fetal swallowing, we developed a model that combines electromyograms, an esophageal flow probe, and a computer data acquisition and analysis program. In pilot studies we showed that fetal esophageal electromyogram activity parallels intraesophageal pressure waveforms during swallowing. Furthermore, in the newborn lamb we have confirmed that isolated thyrohyoid electromyogram activity is associated with licking or sucking, whereas true drinking demonstrates electromyograph progression to the thoracic esophagus. Extrapolation from the basal fetal swallowing rates before the infusion of angiotensin II or saline solution shows that fetuses swallowed between 660 and 1400 ml per day, volumes consistent with previous determinations.[2-4] Prolonged recordings of swallowing activity in our laboratory have

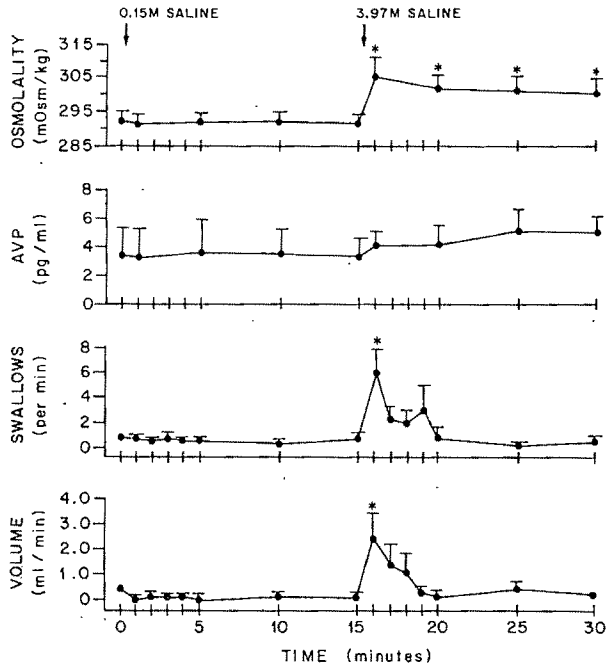

Fig. 2. Fetal plasma osmolality, plasma arginine vasopressin, electromyographic swallows, and net esophageal volume flow in response to intravenous injection of 0.15 or 3.97 mol/L saline solution. *$p < 0.05$ Versus time zero (mean control period value).

confirmed this range of daily volumes (unpublished observations).

Adult mammals display thirst behavior in response to two primary systemic stimuli: plasma hyperosmolality and extracellular volume depletion.[14] Although controversial, it is believed that central or systemic angiotensin II contributes to swallowing stimulation during the latter.[16] However, it is unknown whether the fetus exhibits thirst behavior in response to these or other stimuli.

This study indicates that fetal swallowing is stimulated in response to acute increases in plasma osmolality. At 1 minute after the hypertonic saline solution bolus, fetal plasma osmolality increased by 14 mOsm. Within 5 minutes, plasma osmolality had decreased to within 10 mOsm of basal values. Stimulation of swallowing was observed for 5 minutes, with the maximum effect occurring at 1 minute. Despite the continued plasma hyperosmolality, swallowing returned to basal levels within 5 minutes. Thresholds for thirst sensation in the adult generally occur in response to 2% to 3% (6 to 9 mOsm) increases in plasma osmolality.[21] However, the fetal arginine vasopressin secretory response to increased plasma osmolality is suppressed relative to the newborn or adult.[22] If the assumption is made that the fetal plasma osmolality threshold for stimulation of thirst also is less sensitive than that in the adult, one explanation for the results might be that the osmotic stimulus was above the fetal thirst threshold only during the first 5 minutes after administration of the hypertonic saline solution. This may explain the lack of a significant increase in fetal plasma arginine vasopressin. Alternatively, termination of swallowing may have occurred in response to liquid entering the pharynx or upper gastrointestinal tract.[23] Notably, maternal and thus fetal plasma osmolality may increase to this extent in response to diet, moderate exercise, or dehydration.[21]

During the fetal angiotensin II infusions, fetal arterial blood pressure significantly increased. In response to an identical angiotensin II infusion dose (100 ng/kg per minute), Robillard et al.[25] measured fetal plasma angiotensin II levels of approximately 400 pg/ml. This angiotensin II level is well above the proposed plasma angiotensin II dipsogenic threshold of 200 pg/ml.[26] However, in the present study fetal swallowing activity did not change in response to intravenous angiotensin II infusion. Controversy persists as to the physiologic role of angiotensin II in the regulation of thirst. Exogenous intravenous angiotensin II infusions have been shown to both stimulate[27,28] or have no effect[29] on thirst in adult rats and dogs. Intracarotid angiotensin II, although not intravenous angiotensin II, induces water drinking in adult sheep.[30] Although some studies administered pharmacologic dosages of angiotensin II, others have shown thirst stimulation with physiologic plasma angiotensin II concentrations. However, the lack of an effect of angiotensin II in other studies has raised questions of its importance in thirst regulation. Robinson and Evered[29] have noted that the physiologic conditions in which thirst may be stimulated by renin-angiotensin (dehydration, extracellular volume depletion) generally occur during periods of near or below normal mean arterial pressure. These investigators have proposed and experimentally supported the hypothesis that the failure of intravenous angiotensin II infusions to stimulate thirst in some studies may be a result of the increased blood pressure induced by angiotensin II in the normovolemic state. Thus the hypertension induced in the current study may have inhibited the stimulatory effect of increased plasma angiotensin II on swallowing. Alternatively, central angiotensin II rather than plasma angiotensin II has been proposed to be the actual dipsogen.[16] In adult sheep, angiotensin II injection into the third ventricle consistently stimulated drinking.[30] Thus the ovine fetus may be more likely to respond to central, rather than peripheral, angiotensin II.

Studies of the ontogeny of thirst behavior generally have been limited to neonatal rat and dog pups. However these investigations have inherent difficulties including the stimulation of water intake before weaning and the differentiation of stimuli for food versus water.

More recent studies[17] have circumvented these obstacles and shown the maturation of responses to thirst challenges in the newborn suckling rat: cellular dehydration at the age of 2 days, hypovolemia at 4 days, and β-adrenergic activation at 6 days. Although no responses to thirst challenges were noted in 1-day-old rats, it is possible that stresses associated with birth and neonatal transition inhibited the responses. Alternatively, the neonatal development of swallowing in the rat may be consistent with the altricial development of this species.

The current data represent the first report of the stimulation of fetal swallowing confirmed by direct measurement; the ovine fetal response to osmolar thirst challenge is intact at 130 days' gestation. Thus increased fetal plasma osmolality in response to maternal plasma hypertonicity or dehydration may increase fetal swallowing. The increased resorption of amniotic fluid by swallowing coupled with a decrease in urine production[21] potentially may alter the volume and composition of amniotic fluid. The precise role of fetal thirst and the effects of stimulated or suppressed swallowing remain to be determined.

Effect of whole-body pH changes on thoracic duct lymph flow in anesthetized sheep

Guillermo J. Valenzuela, MD, Hugh W. Forbes, and Justo G. Alonso, MD
Loma Linda, California

Physiologic alterations of pH in vitro produce alterations of the oncotic pressure of both plasma and interstitial proteins, the effect being more marked in the latter. Therefore we postulated that by changing an animal's pH we could produce alterations in fluid distribution and affect the whole-body lymph flow rate. To test this hypothesis, we infused seven acutely nephrectomized anesthetized sheep with 2% body weight/volume isosmotic lactated Ringer's solution and bicarbonate (200 mEq) after a 30-minute control period. The fluid was infused over a 10-minute period with 20-minute recovery intervals. To another group of seven ewes, we infused the same volume of lactated Ringer's solution and hydrochloric acid (40 mEq). Throughout the experiment, we continuously measured arterial and venous pressures and lymph flow rate. Every 10 minutes we obtained samples for arterial pH, for hematocrit, and for plasma and lymph protein anc osmolality. The infusion of bicarbonate was associated with a comparatively lower peak lymph flow rate (383% over baseline compared with 757% for acid infusion). Also the lymph flow rate after acid infusion started to increase ~5 minutes after the beginning of the infusion, as compared with ~10 minutes after the base infusion. Acid infusion did not increase arterial pressure, in contrast to the other infusions. The changes in pH obtained with the infusions were insignificant for the Ringer's infusion, +0.17 for the base, and −0.16 for the acid. The plasma/lymph protein concentration ratios at the end of the infusion were no different for acid or base: 112.4% ± 4.4% and 101.9% ± 5% (difference from control, mean ± SEM) respectively ($p > 0.1$). In conclusion, minimal alterations of pH produced alterations in the cardiovascular and lymph flow rate responses to fluid challenge in anesthetized animals. (Am J Obstet Gynecol 1989;161:1566-70.)

Key words: Changes of pH, fluid distribution, lymph flow

The distribution of fluid between the intravascular and interstitial systems follows Starling's equation. Hydrostatic intravascular and interstitial oncotic pressures drive fluid into the interstitial space, while interstitial hydrostatic pressure and plasma oncotic pressure try to maintain the fluid intravascularly. In the interstitium, hyaluronic acid is organized in a mesh impregnated with water, which gives the interstitium a gel structure with a negatively charged surface.[1] Therefore it is possible to postulate that even small changes in an animal's pH could affect the Donnan equilibrium in the interstitial gel, thus affecting the oncotic pressure differences across the capillaries and between the interstitial gel and the free fluid. Will and Brace[2] demonstrated in vitro that increases in pH can increase the plasma oncotic pressure in a linear fashion. This phenomenon could be relevant to a better understanding of maternal fluid retention during pregnancy and in the fetus, since pH is different from that in the nonpregnant state in both instances. To test the hypothesis that pH changes would affect the whole-body lymph flow rate, we performed a series of infusions in anesthetized animals, using fluid with normal pH, alkaline pH, and acidic pH, and measured the response of the systemic vasculature and lymph flow.

Material and methods

A total of 14 ewes was obtained from local breeders and femoral artery and vein, left thoracic duct, and jugular vein catheters were placed with the animals under general anesthesia, as described in detail elsewhere.[3] The renal circulation was tied off bilaterally through a flank incision, and splenectomy was performed at the same time. The arterial and venous pressures were recorded continuously and stored every 1 minute for later analysis with an on-line data-acquisition system as described by Dale et al.[4] The lymph flow was drained to a weighed vial 30 cm below heart level; the lymph flow rate was obtained from the weight differential and stored every 1 minute. In chronic preparations we have demonstrated that changes in the negative pressure of the lymph catheter

(between 0 to −30 cm) do not affect lymph flow rate.[5] The animals were allowed to breathe spontaneously during the experiments to avoid any effect of mechanical ventilation on lymph flow rate. We attempted only moderate changes in pH, because of concern about the direct cardiovascular effects of the base or acid infusions. We also wanted to minimize any possible effect of respiratory rate while still affecting in a measurable manner the circulating pH. The animals underwent splenectomy because of the large red blood cell reservoir represented by the spleen in the sheep.

Experimental protocol. The experiments were initiated 1 hour after the end of surgery, with the animals receiving oxygen (3 L/min), maintained in a state of light anesthesia (0.5% to 1% halothane), and breathing spontaneously. In seven animals the experiment consisted of a 30-minute control period during which baseline measurements of arterial and venous pressures and thoracic duct lymph flow rates were obtained. Lymph was returned continuously to the animal through a neck vein at the lymph flow rate. At the end of the control period, lactated Ringer's solution was infused (2% body weight/volume) over a 10-minute period. Then, after an interval of 20 minutes, we administered sodium bicarbonate (200 mEq) as isosmotic solution (prepared for each animal), over the same time interval (10 minutes) and in the same total volume as the lactated Ringer's solution (2% of body weight). In another seven ewes we infused lactated Ringer's solution and then acid (in the same volume as described above). Arterial samples for pH, plasma osmolality, and hematocrit were obtained every 10 minutes throughout the experiment. Lymph samples for osmolality and protein concentration were also obtained every 10 minutes. Protein concentration was determined with a hand-held refractometer (American Optical). Samples of blood were transported in a capped syringe, and blood gas values were determined immediately.

Vascular and interstitial fluid compliance calculations. Vascular compliance was obtained by estimating the changes in intravascular volume from the changes in hematocrit and venous pressure. An index of the changes in the interstitial fluid compliance was obtained from the changes in interstitial fluid volume, assuming that the changes in interstitial hydrostatic pressure were similar on both sides of the capillaries. Since a known amount of fluid was infused and the ewes were nephrectomized and splenectomized, the changes in intravascular volume could be estimated and the fluid transferred to the interstitial space thus calculated.

Data analysis. Arterial and venous pressures were averaged for the control period (initial 30 minutes), and for the 10 minutes thereafter during the infusions. The changes with time for each group were analyzed by analysis of variance.

The arterial and venous pressures, lymph flow rate, and heart rate for the base and acid groups were compared for the period of the last 5 minutes of the infusion together with the first 5 minutes of the recovery period after the end of the infusion. The acid and base infusion comparisons of lymph to plasma protein concentration ratio, hematocrit, arterial and venous pressures, and heart rate were calculated by assessing the change (in percent over baseline) at the end of the infusion; these results were compared by unpaired t test. The excess lymph over baseline after the base or acid infusion was calculated by measuring the area over baseline and expressed as a ratio of the control period area and compared by t test.

Results

The control values for the 14 ewes (average ± SEM) are presented in Table I. The lymph flow responses to blood volume expansion (expressed as percent of baseline) for the two different groups are presented in Fig. 1. We present the data as the percent change over baseline to correct for interanimal variation. During the infusion of lactated Ringer's solution both group of animals responded similarly ($p > 0.1$); however, the response to the second infusion was higher for the acid ($p < 0.05$). For the sequence lactated Ringer's solution to base, the peak lymph flow after the base infusion occurred at 23 minutes after the beginning of the infusion (383% of control); for the lactated Ringer's solution to acid sequence, the peak after acid occurred at 21 minutes (782% of control). For the latter infusion, the lymph flow rate started to increase at 5 minutes after the beginning of the infusion, compared with after 10 minutes for either lactated Ringer's solution or base.

Fig. 2 shows the arterial pressure response to the fluid infusion. The acid infusion was characterized by absence of an increase in arterial pressure when compared with the response to either lactated Ringer's solution or base ($p < 0.05$).

In Table I, the changes in arterial and venous pressures, heart rate, hematocrit, and pH are presented. The values for the pressures and the lymph flow rate represent the interval 5 minutes before and 5 minutes after the end of the infusion. Osmolality did not change throughout the experiment.

We could not detect a significant change in the estimated blood volume, vascular compliance, or interstitial compliance by t test or Sign test.

The lymph/protein ratio was 101% ± 5% (percent over baseline) at the end of the base infusion and 109.4% ± 4.4% for the acid infusion, a nonsignificant difference ($p > 0.1$). The ratio for excess lymph flow area was 277% for the acid infusion as compared with 120% for the base infusion. Plasma and lymph osmo-

pH	7.16 ± 0.05	7.18 ± 0.04	7.04 ± 0.02*†	7.33 ± 0.06*†	—	—

Control is the average ± SEM for the initial 30 minutes. Infusion is the average ± SEM during the infusion of base or acid. Percent of baseline is the average ± SEM (expressed as percent) for the period 5 minutes before and 5 minutes after the end of infusion.

*Significantly different from control ($p < 0.05$).

†Significantly different from alternative treatment ($p < 0.05$).

lality changes also were not significantly different throughout the experiments when compared within one group or between groups ($p > 0.1$).

There was minimal correlation ($r = 0.28$) between pH and baseline lymph flow.

Comment

Fluid balance is maintained within narrow margins in healthy animals, and the distribution of fluid between the intravascular and interstitial spaces plays an important role in avoiding major swings in intravascular volume during fluid ingestion. The fluid distribution across the capillaries depends on Starling's equation of fluid distribution.[6] Proteins are electrically charged molecules, and an important fraction of the oncotic pressure that they generate derives from the covalently bound ions (Donnan equilibrium). Theoretically, a change in whole-body pH can alter protein electric charge, thus affecting the oncotic pressure. This was confirmed experimentally in vitro by Will and Brace,[2] who demonstrated that pH changes within the physiologic range can alter both plasma and interstitial oncotic pressure.

To our knowledge this is the first attempt to study the effect of pH changes on the whole-body lymph flow rate. The study of this phenomenon is relevant to the understanding of fluid distribution in some pathologic states associated with acidosis or alkalosis and to a better understanding of the fluid distribution in cardiovascular or septic shock, the treatment of which requires the infusion of large amounts of fluids. It also is relevant in some physiologic states such as pregnancy, when there is a normal increase in the arterial pH.[7]

An important finding was the rate at which lymph flow started to increase after the fluid infusion. In several previous works of our own,[8,9] the lymph flow rate started to increase an average of 12 minutes after the beginning of fluid infusion, a value not different from the values obtained here for the lactated Ringer's solution or base infusion. However, the acid infusion produced an increase in the lymph flow rate much sooner. There are several possibilities to explain this finding. One is an alteration of capillary permeability as a secondary effect of the infusion of acid; however, there were no differences in the lymph-protein ratio with either acid or base. Another alternative is that the acid produced a generalized vasodilatation, as evidenced by the decrease in arterial pressure,[10] and the area of interchange increased with the resulting increase in lymph flow; however, the response is too rapid to be attributed only to alterations in interchange area. A third possibility is that the acid infusion produced a release of hormones that could affect capillary permeability or lymphatic contractility directly; we did not address this question in the present experimental protocol.

Another interesting aspect of the lymph flow response to solutions with varying pH levels is the different quantitative response obtained. For instance, that the infusion of base was associated with a lower peak lymph flow rate and a lower total lymph flow response when compared with acid infusion is of interest. There are several possible explanations for the differences in the lymph flow response. One is that the lower lymph flow rate is partially due to a longer intravascular retention of the fluid administered; however, there were no differences in the degree of blood volume expansion with the different infusions. The other possibility is a water inhibition of the gel matrix, which is a secondary effect of an increase in the oncotic

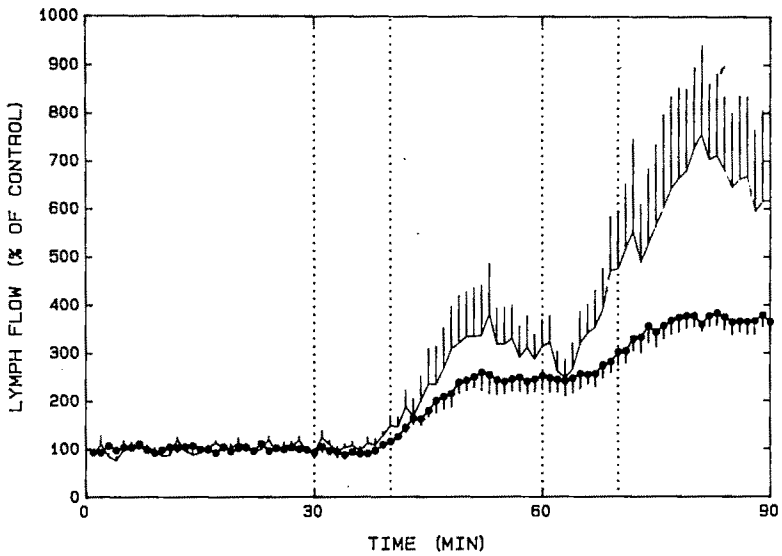

Fig. 1. Lymph flow rate (expressed as percent over baseline) is presented as —— for the sequence lactated Ringer's solution to acid. The sequence lactated Ringer's solution to base is represented as ●—●. *Vertical dotted lines* represent the times of infusion. The sequence with acid first was associated with a significantly higher lymph flow ($p < 0.05$).

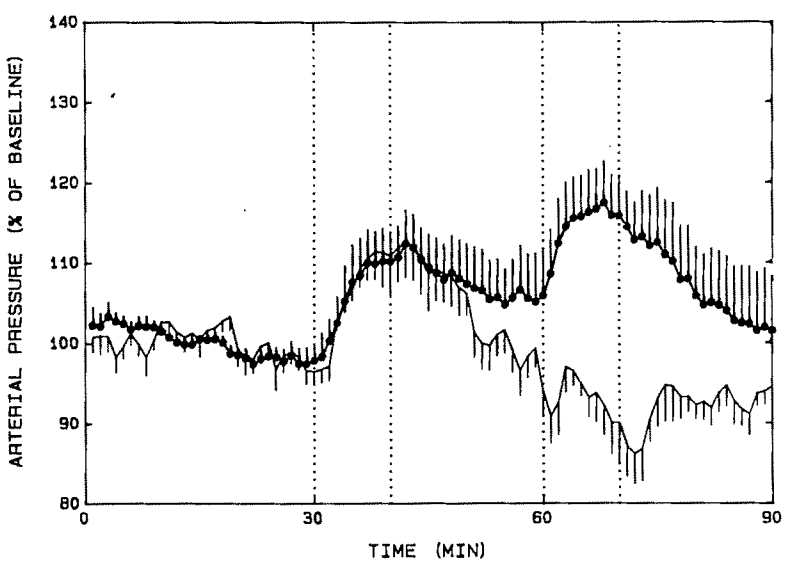

Fig. 2. Arterial pressure (expressed as percent over baseline) is presented as —— for the sequence lactated Ringer's solution to acid and as ●—● for lactated Ringer's solution to base. The arterial response was significantly lower for acid infusion ($p < 0.05$).

pressure inside the gel matrix during the bicarbonate infusion. This later interpretation is compatible with the finding of Will and Brace[2] of a greater increase in the oncotic pressure with increasing pH. We postulate that during the acid infusion the fluid is not incorporated into the gel; therefore smaller changes in pressure produce larger increases in lymph flow. Another factor that may play a role in the responses obtained is the renal ligature; Harake and Power[11] demonstrated a decrease in baseline lymph flow after the ligation of the renal circulation in a group of nonpregnant ewes in a preparation similar to this.

The components of Starling's equation seem not to be changed during the base infusion. There were no changes in the lymph/plasma protein concentration ratio; also there was no difference between the average venous pressures at the end of either base or acid infusion, suggesting that the interstitial fluid pressure changes were not different. It is therefore necessary to consider the possibility that here are factors beyond the

interchange at the capillary level that may affect the distribution of fluid in the whole animal.

Some of the cardiovascular and lymphatic responses in this group of animals may be altered because of an acidotic condition of the animal at the beginning of the experiment; however, our goal in the present study was to observe cardiovascular and lymph flow changes after pH changes. We think that since the pH of most of the proteins is far from physiologic, the effects of base and acid infusions will differ because these infusions are affecting the proteins at different portions of the dissociation curve.

The present results also showed a significant lack of arterial pressure increase during the acid volume infusion, accompanied by a modest increase in venous pressure, higher than during lactated Ringer's solution but lower than during base infusion. These results are in agreement with those changes described for acid infusion by Bygdeman[12] in cats and by Sharpey-Schafer et al.[13] in humans.

In conclusion, a mild change in baseline pH produced a significant change in the lymph and arterial pressure responses to fluid infusion. This study suggests that physiologic changes of pH during a state of cardiovascular shock may play an important role in third-space fluid retention and thus may have important therapeutic implications. Also it can have a significant role in explaining the fluid retention of pregnancy. The next step is to assess the role of pH changes in cardiovascular adaptations and fluid distribution of chronically catheterized animals with normal kidney function.

We thank L. Buyak, C. W. Hewitt, and J. I. Valenzuela for expert technical assistance.

Does furosemide alter the hemodynamic response to rapid intravascular transfusion of the anemic fetal lamb?

David H. Chestnut, MD, Kenneth L. Pollack, MD, Carl P. Weiner, MD, Jean E. Robillard, MD, Christine S. Thompson, and Craig S. DeBruyn

Iowa City, Iowa

The purpose of this study was to define the hemodynamic response to rapid intravascular transfusion of the anemic fetal lamb and to determine whether furosemide alters that response. Sixteen experiments were performed in nine chronically instrumented gravid ewes between 0.8 and 0.9 of timed gestation. On day 1 of each experiment, each fetus was subjected to hemorrhage (40 ml/kg of estimated fetal weight) over 1 hour. On day 2, plasma was withdrawn from the stored fetal blood until the hematocrit was approximately 70%, and the packed red blood cells were returned to the fetus intravenously over 10 minutes. Each fetus received either furosemide (2 mg/kg)or control saline solution intravenously at time zero and again at 5 minutes. The order of experiments was randomly determined for each animal. Hemorrhage resulted in a similar decrease in fetal hematocrit in the two groups. The mean ± SEM fetal hematocrit before hemorrhage was 38 ± 3% in the furosemide group (n = 8) and 36 ± 2% in the control group (n = 8). On day 2, the mean ± SEM fetal hematocrit before transfusion was 28 ± 2% in the furosemide group and 25 ± 1% in the control group. There was no significant difference between groups in the fetal hemodynamic response to transfusion. At the end of the transfusion, the fetal central venous pressure had increased from 4.9 ± 0.5 to 6.2 ± 0.5 mm Hg in the furosemide group (p = 0.01) and from 3.9 ± 0.2 to 5.8 ± 0.3 mm Hg in the control group (p = 0.0001). Fetal mean arterial pressure increased from 42 ± 1 to 50 ± 1 mm Hg in the furosemide group (p = 0.0001) and from 40 ± 1 to 46 ± 1 mm Hg in the control group (p = 0.0007). Fetal heart rate decreased from 187 ± 2 to 169 ± 5 beats/min in the furosemide group (p = 0.004) and from 188 ± 4 to 170 ± 5 beats/min in the control group (p = 0.0008). Transfusion did not significantly change fetal pH in either group. At 120 minutes, the fetal Po_2 had increased from 17 ± 1 to 19 ± 1 mm Hg in the furosemide group (p = 0.03) and from 19 ± 1 to 21 ± 2 mm Hg in the control group (p = 0.05). We conclude that rapid transfusion of the anemic fetal lamb resulted in modest increases in fetal central venous pressure and mean arterial pressure. Second, furosemide did not significantly alter the hemodynamic response to rapid transfusion. (AM J OBSTET GYNECOL 1989;161:1571-5.)

Key words: Anemia, fetal lamb, furosemide, transfusion

Direct intravascular transfusion of packed red blood cells has supplanted intraperitoneal transfusion for treatment of fetal hemolytic disease in many centers.[1-6] The method is empiric. Some practitioners perform exchange transfusion to avoid an abrupt increase in fetal intravascular volume.[4,5] In contrast, others have performed rapid intravascular transfusion without exchange.[3,6] There are few data on the fetal hemodynamic response to intravascular transfusion. We hypothesized that furosemide might facilitate fetal adaptation to the abrupt increase in fetal intravascular volume by dilating the capacitance vessels.[6,7] The purpose of this study was to define the hemodynamic response to rapid intravascular transfusion of the anemic fetal lamb and to determine whether furosemide alters that response.

Table I. Fetal hematocrit measurements before hemorrhage and before transfusion

	Furosemide (n = 8)	*Control (n = 8)*
Day 1, before hemorrhage	38% ± 3%	36% ± 2%
Day 2, before transfusion	28% ± 2%	25% ± 1%

All values are expressed as mean ± SEM.

Material and methods

The protocol was approved by the University of Iowa Animal Care Committee. Mixed-breed ewes were obtained from a commercial breeder at approximately 118 days of timed gestation (term = 145 days). Each animal fasted for 36 hours before surgery. At 120 days' gestation, thiopental sodium 600 to 750 mg was given intravenously to induce general anesthesia.

Table II. Baseline maternal and fetal hemodynamic, blood gas, and acid-base measurements before transfusion on day 2

	Furosemide (n = 8)	*Control (n = 8)*
Maternal		
Heart rate (beats/min)	104 ± 5	108 ± 3
Mean arterial pressure (mm Hg)	89 ± 7	91 ± 6
Arterial pH	7.48 ± .01	7.47 ± .01
Arterial P_{O_2} (mm Hg)	109 ± 5	109 ± 4
Arterial P_{CO_2} (mm Hg)	35 ± 1	36 ± 1
Hematocrit (%)	30 ± 2	30 ± 2
Fetal		
Heart rate (beats/min)	187 ± 2	188 ± 4
Mean arterial pressure (mm Hg)	42 ± 1	40 ± 1
Central venous pressure (mm Hg)	4.9 ± 0.5	3.9 ± 0.2
Arterial pH	7.32 ± .01	7.29 ± .03
Arterial P_{O_2} (mm Hg)	17 ± 1	19 ± 1
Arterial P_{CO_2} (mm Hg)	51 ± 1	50 ± 1

Maternal and fetal arterial blood samples were obtained from the maternal and fetal descending aorta, respectively. Blood gas and acid-base values were corrected for temperature.

All values are expressed as mean ± SEM.

Anesthesia was maintained with halothane 1%, nitrous oxide 50%, and oxygen 50%. Laparotomy and hysterotomy were performed with sterile technique, and catheters (polyethylene-90) were placed in the fetal descending aorta and inferior vena cava, via each femoral artery and vein, and in the amniotic cavity. Catheters (polyethylene-240) were then placed in the maternal descending aorta and inferior vena cava via the left mammary artery and vein, respectively. All catheters were tunneled subcutaneously and exteriorized through a small incision in the left flank.

After surgery each animal was kept in an approved cage in a restricted area, fed a balanced diet, and allowed a recovery period ≥5 days before experimentation. Procaine penicillin G (500,000 U) and dihydrostreptomycin (625 mg, Combiotic, Pfizer, New York) were given to the mother before surgery and daily for 3 days after surgery. Gentamicin (80 mg) was given to the mother on the day of each experiment, and gentamicin (40 mg) was given by means of the amniotic catheter during surgery and on the day of each experiment.

Each experiment was done with the animal standing unrestrained within an approved transport cart. One hour was allowed for the animal to acclimate to the laboratory environment. On day 1 of each experiment, each fetus was subjected to hemorrhage (40 ml/kg estimated fetal weight) over 1 hour. The blood was withdrawn in four 10-minute intervals with a constant-rate withdrawal pump. Fetal blood was replaced with an equal volume of normal saline solution. The estimated fetal weight was calculated according to this formula:[8] Estimated fetal weight in kg = (0.096 × gestational age in days) − 9.223. After hemorrhage, the ewe was returned to the Animal Care Unit. Fetal blood was refrigerated overnight in citrate phosphate dextrose adenine (CPDA-1) anticoagulant.

On day 2, the animal returned to the laboratory and again was allowed 1 hour to acclimate to the laboratory environment. The stored fetal blood was warmed to room temperature, and plasma was withdrawn until the hematocrit was approximately 70%. At time zero the packed red blood cells (approximately 20 ml/kg) were returned to the fetus intravenously over 10 minutes. Each fetus received either 2 mg/kg of furosemide (Elkins-Sinn, Cherry Hill, N.J.) or control saline solution intravenously, at time zero and again at 5 minutes. (This furosemide regimen is identical to the regimen used for transfusion of human fetuses in our hospital.) The volume of furosemide or control saline solution was approximately 0.5 ml for each fetus. Maternal and fetal hemodynamic measurements were continued through 120 minutes after the start of transfusion.

Each animal was allowed to rest ≥24 hours before the experimental sequence was repeated. The order of experiments was determined randomly for each animal. We intended to perform both experiments in each animal. However, catheter occlusion precluded the performance of a second experiment in two of the animals. Therefore, 16 experiments were performed in nine animals. (Both experiments were performed in seven animals, and one experiment was performed in each of the other two animals.)

Maternal and fetal arterial hematocrit, blood gas, and acid-base values were determined at baseline and at 15, 60, and 120 minutes after the start of transfusion. Blood gas and acid-base values were determined with a Instrumentation Laboratory 1302 blood gas analyzer (Leighton, Mass.). All values were corrected for temperature. Fetal blood was replaced by an equal volume of normal saline solution.

Maternal and fetal systemic arterial pressures and amniotic fluid pressure were recorded at 10 second intervals by means of a customized physiologic data acquisition system (Coulbourn Instruments, Lehigh Valley, Pa.) interfaced to an AST 286 premium computer (Irvine, Calif.). Fetal arterial and central venous pressures were corrected by subtracting the simultaneous intraamniotic pressure. Maternal and fetal mean arterial pressures were calculated arithmetically. Maternal and fetal heart rates were calculated from maternal and fetal arterial waveforms.

Statistical analysis was by three-factor analysis of variance, followed by t tests for individual measurements. A p value <0.05 was considered significant.

Results

On day 1, estimated fetal weight was 2.78 ± 0.09 kg in the furosemide group and 2.77 ± 0.05 kg in the

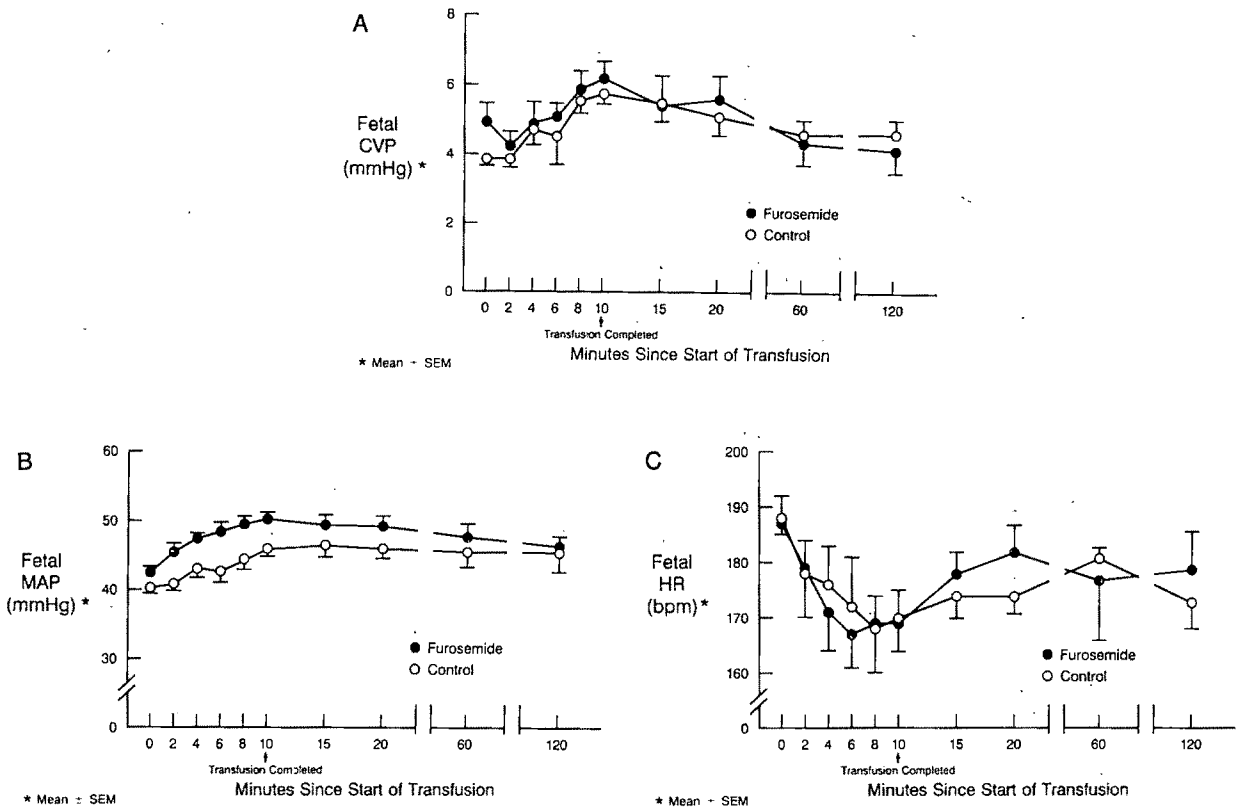

Fig. 1. A, Fetal central venous presure *(CVP)* responses over time. Transfusion significantly increased fetal central venous pressure at 8 and 10 minutes in the furosemide group and at each measurement between 6 and 20 minutes in the control group. **B,** Fetal mean arterial pressure *(MAP)* responses over time. Transfusion significantly increased fetal mean arterial pressure at each measurement between 4 and 120 minutes in the furosemide group and at each measurement between 6 and 120 minutes in the control group. **C,** Fetal heart rate *(HR)* responses over time. Transfusion significantly decreased fetal heart rate at each measurement between 4 and 10 minutes in the furosemide group and at each measurement between 4 and 20 minutes in the control group. Furosemide (2 mg/kg) or control saline solution was given at time zero and again at 5 minutes. Transfusion started at time zero and was completed at 10 minutes. All values are expressed as mean ± SEM.

control group. Hemorrhage resulted in a similar decrease in fetal hematocrit in the two groups (Table I). The two treatment groups were similar with regard to baseline maternal and fetal hemodynamic, blood gas, and acid-base measurements before transfusion on day 2 (Table II).

There was no significant difference between groups in the fetal hemodynamic response to transfusion (Fig. 1). There was a transient decrease in fetal central venous pressure between baseline and 2 minutes in the furosemide group, but the decrease was not statistically significant (Fig. 1, *A*). At 10 minutes, fetal central venous pressure had increased from 4.9 ± 0.5 to 6.2 ± 0.5 mm Hg in the furosemide group ($p = 0.01$) and from 3.9 ± 0.2 to 5.8 ± 0.3 mm Hg in the control group ($p = 0.0001$). Fetal mean arterial pressure increased from 42 ± 1 to 50 ± 1 mm Hg in the furosemide group ($p = 0.0001$) and from 40 ± 1 to 46 ± 1 mm Hg in the control group ($p = 0.0007$) (Fig. 1, *B*). At 10 minutes, fetal heart rate had decreased from 187 ± 2 to 169 ± 5 beats/min in the furosemide group ($p = 0.004$) and from 188 ± 4 to 170 ± 5 beats/min in the control group ($p = 0.0008$) (Fig. 1, *C*).

There was no significant difference between groups in the fetal arterial hematocrit, pH, or Po_2 responses to transfusion (Fig. 2). Specifically, transfusion significantly increased the fetal hematocrit at 15, 60, and 120 minutes in both groups ($p = 0.0001$) (Fig. 2, *A*). Transfusion did not significantly change fetal pH in either group (Fig. 2, *B*). At 120 minutes, fetal PO_2 had increased from 17 ± 1 to 19 ± 1 mm Hg in the furosemide group ($p = 0.03$) and from 19 ± 1 to 21 ± 2 mm Hg in the control group ($p = 0.05$) (Fig. 2, *C*). Finally, there was a small but significant decrease in PCO_2 at 15 minutes ($p = 0.01$) and at 60 minutes ($p = 0.005$) in the furosemide group, but not in the control group (Fig. 2, *D*).

Comment

Blood volume rapidly returns toward normal after hemorrhage in fetal lambs.[9, 10] Brace and Cheung[10] subjected 12 fetal lambs to hemorrhage (31 ± 2% of the

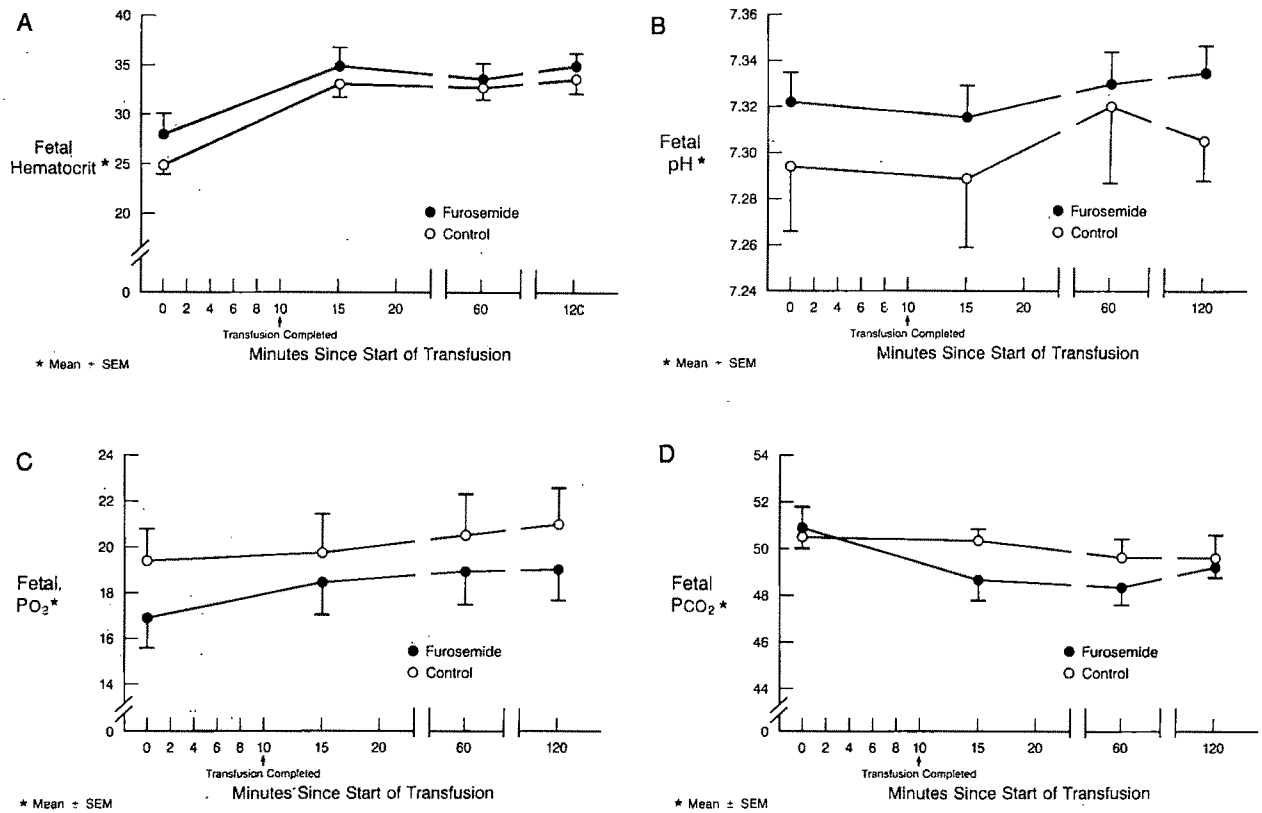

Fig. 2. A, Fetal hematocrit responses over time. Transfusion significantly increased fetal hematocrit at 15, 60, and 120 minutes in both groups ($p = 0.0001$). **B,** Fetal pH responses over time. Transfusion did not significantly change fetal pH in either group. **C,** Fetal P_{O_2} responses over time. Transfusion increased fetal P_{O_2} at 60 minutes ($p = 0.02$) and at 120 minutes ($p = 0.03$) in the furosemide group and at 120 minutes ($p = 0.05$) in the control group. **D,** Fetal P_{CO_2} responses over time. There was a small but significant decrease in P_{CO_2} at 15 minutes ($p = 0.01$) and at 60 minutes ($p = 0.005$) in the furosemide group, but not in the control group. Furosemide (2 mg/kg) or control saline solution was given at time zero and again at 5 minutes. Transfusion started at time zero and was completed at 10 minutes. All values are expressed as mean ± SEM.

initial blood volume over 2 hours). At the end of hemorrhage blood volume was reduced by only 14 ± 1%. Further, blood volume returned to normal by 3 hours after hemorrhage, and was increased 5 ± 2% above control at 24 hours after hemorrhage. The authors noted that "the restitution of blood volume occurred primarily because of a movement of fluid into the fetal circulation as indicated by a reduction in hematocrit."[10] In the present study, transfusion occurred approximately 18 hours after hemorrhage. Thus we presume that the fetal lambs were nearly normovolemic at the time of transfusion.

In the present study, rapid transfusion of approximately 20 ml/kg of packed red blood cells resulted in only modest increases in fetal central venous and arterial pressures. In addition, there was a decrease in fetal heart rate of approximately 18 beats/min, and an increase in fetal P_{O_2} of approximately 2 mm Hg. Brace[11] observed similar changes after intravascular transfusion of approximately 29 ml/kg of packed red blood cells over 30 minutes in anemic fetal lambs. Both Brace and we have speculated that the decreased fetal heart rate resulted from activation of the baroreceptors. The increased fetal P_{O_2} may have resulted from increased umbilical blood flow after transfusion. (This is consistent with the observation that transfusion of anemic human fetuses causes an acute decline of the umbilical artery systolic/diastolic ratio.[6] The increased diastolic flow velocity may reflect increased umbilical blood flow.)

Heretofore, one of us (C. P. W.) has consistently given furosemide (2 mg/kg estimated fetal weight) before and again during direct intravascular transfusion of anemic human fetuses. This rationale was on the basis of the observation that in adults, intravenous administration of furosemide rapidly increases venous capacitance and decreases cardiac filling pressures.[7] We speculated that furosemide might facilitate fetal adaptation to the abrupt increase in intravascular volume, first by dilating the fetal capacitance vessels, and later

by decreasing plasma volume by means of a diuresis. But in this study, furosemide did not significantly alter the hemodynamic response to rapid transfusion of the anemic fetal lamb. The hemodynamic changes were modest, with or without furosemide. We suggest three potential reasons for the absence of a difference between groups in the hemodynamic response to transfusion. First, it is possible that furosemide does not significantly dilate the capacitance vessels of fetal lambs. We did not study the hemodynamic effects of furosemide alone. But Lumbers and Stevens[12] noted that furosemide (2 mg/kg) significantly increased fetal diastolic arterial pressure when it was given to hypotensive fetal lambs. They did not evaluate the effect of furosemide on venous capacitance. Second, there are conflicting data with regard to the effect of furosemide on the urine output of fetal lambs.[12, 13] But third and most important, blood volume quickly returns toward normal after volume loading in fetal lambs.[14] Brace[11] noted that transfusion of anemic fetal lambs increased fetal blood volume by only 50% of the transfused volume because of a loss of plasma from the circulation.

One should be cautious before extrapolating results of any animal study to clinical practice. In addition, we note that the fetal lambs in this study were presumed to be healthy and nonhydropic. They had significant, but not severe, anemia.[2, 5, 15] Further, on day 1 of each experiment, fetal blood was replaced with normal saline solution. We did not determine fetal plasma protein concentrations, and we do not know whether hypoproteinemia occurred. (There is evidence that hypoproteinemia is an important factor in the pathophysiology of fetal hydrops.[16, 17]) Nonetheless, results of this study are consistent with observations made during transfusion of anemic human fetuses. Weiner et al.[18] observed that rapid intravascular transfusion of approximately 90 ml of packed red blood cells to nonhydropic anemic human fetuses increased umbilical venous pressure (corrected for amniotic fluid pressure) from 6.7 ± 1 to 10.9 ± 1 mm Hg. Nicolaides et al.[2] transfused 5 to 150 ml of packed red blood cells to anemic human fetuses at a rate as high as 15 ml/min without obvious evidence of fetal cardiovascular compromise. Nonetheless, Berkowitz et al.[5] argued that exchange, rather than direct, intravascular transfusion may be indicated in selected cases.

We conclude that rapid transfusion of the anemic fetal lamb resulted in modest increases in fetal central venous pressure and mean arterial pressure. Second, furosemide did not significantly alter the hemodynamic response to rapid transfusion.

Intrauterine growth retardation and the circulatory responses to acute hypoxemia in fetal sheep

Barry S. Block, MD,[a] Donald H. Schlafer, DVM, PhD,[b] Richard A. Wentworth, PhD,[c] Lois A. Kreitzer, MS,[b] and Peter W. Nathanielsz, MD, PhD[c]

Chicago, Illinois, and Ithaca, New York

Intrauterine growth retardation has been produced experimentally by umbilical placental embolization for 9 days (early intrauterine growth retardation) in pregnant sheep. Fetuses with early intrauterine growth retardation had a 20% decrease in mean body weight and 33% decrease in placental blood flow. However, the regional blood flow distribution was not significantly different at rest between the embolized and normally grown fetuses despite the 39% decrease in fetal arterial oxygen content. The purpose of this study was to determine the circulatory responses to acute hypoxemic stress in the early development of intrauterine growth retardation. We found that the regional blood flow distribution was not significantly different during imposed acute hypoxemia between the seven fetuses with early intrauterine growth retardation and seven nonembolized normally grown fetuses. We conclude that growth-retarded fetuses are able to meet basal metabolic oxygen requirements and to respond normally to imposed acute hypoxemia until the placental circulatory reserve capacity is depleted. (AM J OBSTET GYNECOL 1989;161:1576-9.)

Key words: Pregnancy, obstetrics, hypoxia, microspheres

Fetuses with intrauterine growth retardation (IUGR) tolerate the acute stress of labor poorly because of malnutrition and chronic hypoxemia.[1] Ethical constraints prevent studies of growth retardation or imposed hypoxemia in human fetuses; however, corresponding studies have been performed with experimental animals. Creasy et al.[2] embolized the maternal uteroplacental vascular bed for 21 to 28 days in sheep and reduced mean fetal body weight by 30% (late IUGR) and total placental blood flow by 53% in embolized fetuses, compared with nonembolized normally grown fetuses. They found that fetuses with late IUGR, at rest, had a redistribution of the circulation that provided preferential perfusion to the vital organs. This blood flow distribution was similar to the distribution seen in normally grown fetuses in response to acute hypoxemia,[3] with the exception that the proportion of combined ventricular output perfusing the placenta was decreased in fetuses with late IUGR at rest.[2] In response to imposed acute hypoxemia fetuses with late IUGR developed a more pronounced blood flow response to all vital organs except the placenta.[4]

Fetal umbilical placental embolization for a period of 9 days has previously been shown to reduce fetal weight by 20% (early IUGR) and to reduce total placental blood flow by 33%.[5] In contrast to fetuses with late IUGR, fetuses with early IUGR had a regional blood flow distribution at rest that was similar to that of nonembolized normally grown fetuses, despite the 39% decrease in fetal arterial oxygen content. Growth-retarded fetuses adapted to chronic oxygen deficiency by decreasing growth rate and thereby decreasing oxygen requirement. Thus a 33% reduction in total placental blood flow restricted normal fetal growth, but did not exceed the placental circulatory reserve capacity necessary to maintain basal metabolic oxygenation. The purpose of this study was to determine the circulatory responses to acute hypoxemic stress during the early development of fetal growth retardation.

Material and methods

Mixed-breed Rambouillet-Columbia pregnant ewes of known gestational ages were used in this study. Surgery was conducted with the ewes under halothane general anesthesia after a 24-hour fast. The maternal abdomen was prepared according to aseptic technique and the uterus was exposed through a midline abdominal incision. A pelvic limb of the fetus was exteriorized and polyvinyl catheters were advanced into the descending fetal aorta via the femoral artery, into the inferior vena cava via the femoral vein, and through a separate incision, the ascending aorta via the fetal ca-

6/6/15672

rotid artery and the superior vena cava via the jugular vein. A polyvinyl amniotic fluid catheter was placed and the unterine incision was closed. Vinyl-insulated multistranded wire electrodes (Cooner Wire Co., Chatsworth, Calif.) were sewn into the uterus at two separate sites and the abdominal incision was closed. All catheters and the electrodes were exteriorized through the flank of the ewe. The maternal neck was prepared according to aseptic technique and polyvinyl catheters were placed in the carotid artery, jugular vein, and trachea.[6] Antibiotics were given to both ewe and fetus intravenously postoperatively for 4 days. The ewe received 250 mg ampicillin and 900 mg chloramphenicol intravenously twice daily. The fetus received 50 mg chloramphenicol intravenously and intraamniotically twice daily.

The fetal umbilical placental circulation was embolized by the general procedure previously described.[5] Briefly, on the sixth day after surgery, the fetuses were assigned to either the control or the embolized group. In the embolized group fetuses were injected over a 3-minute period into the descending aorta with carbonized latex 15 μm microspheres (8 to 16 million) in dextran that were suspended with sterile saline solution, q.s. to 5 ml, once or twice daily. The goal was to maintain an oxygen tension 5 to 7 mm Hg below control values in that fetus on the 2 days before embolization began. In the control group fetuses were injected over a 3-minute period into the descending aorta with a similar volume of dextran, q.s. to 5 ml in sterile saline solution twice daily.

Blood gases and pH were measured with an automated analyzer (ALB2, Radiometer, Copenhagen, Denmark) and corrected to a temperature of 39° C. Blood pressure and amniotic fluid pressure were determined with strain-gauge transducers (P23Db, Statham/Gould, Oxnard, Calif.) and recorded continuously on a polygraph (Dynograph R611, Beckman, Fullerton, Calif.). The percent of oxygen saturation of hemoglobin was measured with a hemoximeter (OSM2, Radiometer, Copenhagen). Arterial oxygen content was calculated as follows: O_2 content (ml/dl) = 1.34 (ml/gm Hgb) × [Hgb] (gm/dl) × Hgb O_2 saturation, where O_2 represents oxygen and Hgb represents hemoglobin.

Fetal arterial blood pressure was corrected by subtracting amniotic fluid pressure. Fetal heart rate was derived from the arterial pressure pulse by a cardiotachometer (9857B input coupler, Beckman, Fullerton, Calif.). Uterine electromyographic activity was displayed continuously. Fetal combined ventricular output and regional blood flow distribution were measured with 15 μm radionuclide-labeled microspheres (New England Nuclear, Boston) while the uterus was quiescent by methods previously described.[4]

The experimental protocol began after 5 days of recovery and 9 days of embolization. The protocol included 30 minutes of baseline recordings; then the first carotid arterial blood gas, pH, and regional blood flow determinations were performed. While the recordings continued 6 L/min of nitrogen was infused into the maternal trachea for 20 minutes and the second blood gas, pH, and regional blood flow determinations were performed. At the end of the experiment the ewe was killed and the uterus and its contents were removed, dissected, and weighed. The placental blood flow was calculated as the sum of the individual cotyledon and noncotyledonary membrane blood flows. The tissues were then carbonized and counted with an automated γ-counter and multiple-channel pulse height analyzer (Gamma Trac 2250, T.M. Analytic, Elk Grove Village, Ill.).

A two-factor analysis of variance for repeated measures and the Newman-Keuls test[7] were used to compare the mean values in the basal and hypoxemia periods for embolized and nonembolized normally grown (control) fetuses. The mean values for gestational age, birth weight, and total placental blood flow in the embolized and nonembolized normally grown fetuses were compared with the two-sample Student t test.[8] The level of significance chosen was $p < 0.05$. The values are expressed as the mean ± 1 SD.

Results

There were 12 singleton and two twin gestations (one in each group) included in this study. The gestational ages at the conclusion of the study were similar (128 ± 3 and 130 ± 4 days) in the seven embolized and seven control fetuses, respectively. Fetal umbilical placental embolization reduced the mean fetal body weight of the embolized fetuses 20% (2.99 ± 0.25 vs. 3.73 ± 0.58 kg, $p < 0.05$) and the total placental blood flow 31% (421 ± 82 vs. 606 ± 160 ml/min, $p < 0.05$) in the embolized fetuses compared with nonembolized normally grown fetuses. The brain-to-thymus weight ratio also was significantly increased in embolized fetuses (6.4 ± 2.2 vs. 3.3 ± 1.5, $p < 0.05$). Surprisingly, neither the fetal crown-rump length (46.2 ± 6.9 vs. 45.5 ± 3.7 cm) nor the brain-to-liver weight ratio (0.42 ± 0.09 vs. 0.43 ± 0.08) was significantly different in the embolized fetuses compared with the nonembolized normally grown fetuses.

The fetal arterial blood gas, pH, hemoglobin, heart rate, and arterial blood pressure values in the basal and hypoxemia study periods for the embolized and nonembolized normally grown fetuses are listed in Table I. Both the mean arterial oxygen tension and oxygen content were reduced significantly in the basal period in the embolized fetuses, and the oxygen content in both groups was reduced by approximately 50% during induced hypoxemia. The mean fetal arterial pH, hemoglobin, and carbon dioxide tension remained within

the normal range in both groups during induced hypoxemia. There was no significant difference in arterial blood pressure between the two groups in the basal or hypoxemia study periods. In addition, there was no significant difference in the bradycardiac fetal heart rate response between the embolized and nonembolized normally grown fetuses in response to acute hypoxemia.

The fetal combined ventricular output and regional blood flow distribution for the embolized and nonembolized normally grown fetuses are listed in Table II. In the basal study period the combined ventricular output and individual organ blood flow values were not significantly different, when calculated on either a weight-specific or percentage of combined ventricular output basis, between the embolized and nonembolized normally grown fetuses. In response to acute imposed hypoxemia, the combined ventricular output and blood flow to the placenta, on a weight-specific basis, were not significantly different between the embolized and nonembolized normally grown fetuses. Both the absolute blood flow and the proportion of combined ventricular output perfusing the adrenal gland, brain, and heart increased significantly in both groups in response to acute imposed hypoxemia.

Comment

Clearly, the ability to maintain normal growth and respond to adverse intrauterine conditions is related to the fetus' ability to adequately perfuse the placenta.

Fetal umbilical placental embolization decreased total placental blood flow and arterial oxygen content and produced a 20% reduction in fetal growth. At rest the regional blood flow distribution in fetuses with early IUGR was similar to the distribution in nonembolized normally grown fetuses. Thus the fetus with early IUGR with subnormal growth was able to meet basal metabolic oxygen requirements despite the 39% decrease in arterial oxygen content. In response to acute hypoxemia, the regional blood flow distribution in the fetus with early IUGR was not significantly different from the normally grown fetus. These findings suggest that the placental circulatory reserve capacity was adequate to maintain basal metabolic oxygenation in fetuses with early IUGR both at rest and in response to acute hypoxemia.

The regional blood flow response to acute hypoxemia in the nonembolized normally grown fetuses, characterized by preferential perfusion to the vital organs, is similar to the blood flow response previously reported.[3] In addition, the fetal arterial oxygen tension, oxygen content, blood pressure, and heart rate values for the nonembolized normally grown fetuses were similar to the values previously reported.[3, 4] The method of fetal umbilical-placental embolization was different from the method of maternal uteroplacental embolization. The explanation for choosing fetal embolization has been discussed in detail.[5] Briefly, we produced a significant degree of fetal hypoxemia by modification of a technique to increase placental vascular resistance and produce primary fetal placental vascular compromise described by Trudinger et al.[9]

To minimize concerns about natural growth retardation in twins, only the use of singleton gestations was planned. However, two ewes were noted at surgery to have twin gestations and they were assigned to different groups. Because the subsequent weight of the control and embolized twin fetuses at necropsy were similar (110% and 94%, respectively) to the mean weight of others in their group, they were not excluded from the study.

We have demonstrated that fetuses have a considerable capacity to adapt to chronic oxygen deficiency produced by decreased placental blood flow by decreasing growth rate and thereby decreasing oxygen requirement. The effects of chronic hypoxemia alone, produced without reduction in placental blood flow, have been previously reported. Kitanaka et al.[10] have shown that the fetus adapts to chronic hypoxemia produced by low oxygen infusion in a normobaric chamber for 21 to 28 days by maintaining fetal arterial oxygen content without reducing fetal weight. The effect of imposed acute hypoxemia on chronically hypoxemic normally grown fetuses has not previously been reported. However, the response to imposed acute hypoxemia in growth-retarded fetuses has previously been reported.[4] Maternal uteroplacental embolization for 21 to 28 days produced a 30% reduction in mean fetal body weight. These fetuses with late IUGR, in contrast to fetuses with early IUGR, have a distribution of combined ventricular output at rest similar to normally grown fetuses in response to acute hypoxyemia. In response to acute imposed hypoxemia, fetuses with late IUGR had a more pronounced blood flow response to all vital organs that normally grown fetuses, with the exception that the proportion of combined ventricular output perfusing the placenta did not change significantly in fetuses with late IUGR. These findings suggest that the 53% decrease in total placental blood flow exceeded the placental circulatory reserve capacity.

We conclude that the growth-retarded fetus adapts to chronic oxygen deficiency by decreasing growth rate and thereby decreasing oxygen requirement. The growth-retarded fetus is thus able to meet basal metabolic oxygen requirements and to respond normally to imposed acute hypoxemia until the placental circulatory reserve capacity is depleted.

We thank Tami Myers and Vivian Surman for their technical assistance.

Prostaglandin E_2 metabolism in the human fetal membranes

Paul Y. C. Cheung, BSc, and John R. G. Challis, PhD, DSc
London, Ontario, Canada

Prostaglandins play a pivotal role in the initiation and maintenance of labor, but the sources that contribute to the production of primary prostaglandins (prostaglandin E_2 and prostaglandin $F_{2\alpha}$) remain controversial. In decidua, prostaglandin $F_{2\alpha}$ may be formed de novo or from prostaglandin E_2 through 9-ketoreductase activity, although it has been suggested that metabolism to 13,14-dihydro-15-ketoprostaglandin E_2 through 15-hydroxyprostaglandin dehydrogenase is dominant. To examine this possibility, and to determine changes with labor, we examined interconversions of prostaglandin E_2 to prostaglandin $F_{2\alpha}$, 13,14-dihydro-15-ketoprostaglandin E_2 and 13,14-dihydro-15-ketoprostaglandin $F_{2\alpha}$ by dispersed cells of decidua, chorion, and amnion obtained from patients at term elective cesarean section or after spontaneous labor. Incubations were performed with increasing concentrations (1 to 100 ng/ml) of prostaglandin E_2 for 2 and 4 hours, and products were measured by radioimmunoassay. The 13,14-dihydro-15-ketoprostaglandin E_2 was measured as 11-deoxy-13,14-dihydro-15-keto-11β,16ψ-cycloprostaglandin E_2. Basal output of prostaglandin E_2 increased between cesarean section and spontaneous labor from 190.6 ± 109 pg/10^5 cells (±SE) to 605.2 ± 346.8 in amnion, nondetectable to 24.5 ± 11.2 in chorion, and 18 ± 16 to 69 ± 25.8 in decidua. For both cesarean section and spontaneous labor patients there was very little conversion of prostaglandin E_2 by the amnion, substantial conversion to 13,14-dihydro-15-ketoprostaglandin E_2 by the chorion, and some conversion to 13,14-dihydro-15-ketoprostagalandin E_2 by the decidua. Percentage conversions did not change with labor. Prostaglandin $F_{2\alpha}$ was formed by all tissues but only in trace amounts. All tissues from one cesarean section patient showed substantial conversion of prostaglandin E_2 to prostaglandin $F_{2\alpha}$, but very little 13,14-dihydro-15-ketoprostaglandin E_2 or 13,14-dihydro-15-ketoprostaglandin $F_{2\alpha}$ formation, indicating either a decrease or deficiency in the 15-hydroxyprostaglandin dehydrogenase activity. We conclude that conversion of exogenous prostaglandin E_2 to prostaglandin $F_{2\alpha}$ can occur in intrauterine tissues, but this does not normally contribute significantly to the prostaglandin $F_{2\alpha}$ output by the human decidua and fetal membranes. (Am J Obstet Gynecol 1989;161:1580-5.)

Key words: Prostaglandin, fetal membranes, labor, metabolism

Prostaglandins (PGs) are involved in the initiation and maintenance of labor.[1,2] Any tissues capable of synthesizing or metabolizing primary PGs (PGE_2 and $PGF_{2\alpha}$) in utero would ultimately affect the concentrations of these PGs reaching the myometrium, the presumed site of PG action.[3,4] Because of their anatomical location, the human fetal membranes are highly suited for this purpose.

PGE_2 can be acted on by two enzymes, 15-hydroxyprostaglandin dehydrogenase (PGDH), leading to formation of 15-keto-PGE_2 and then to 13,14-dihydro-15-keto-PGE_2 (PGEM) or 9-ketoreductase to form $PGF_{2\alpha}$.[5] $PGF_{2\alpha}$ can then be metabolized by PGDH to 15-keto-$PGF_{2\alpha}$ and then to 13,14-dihydro-15-keto-$PGF_{2\alpha}$ (PGFM). PGDH activity has been demonstrated in all three tissues of the human fetal membranes with the order of activity as chorion > decidua > amnion.[2] Although 9-ketoreductase has been characterized extensively in the decidua,[6,7] it has not been investigated to the same extent in the amnion or chorion. Most of these studies have used homogenate or cytosolic preparations to study the characteristics of these enzymes. It has been suggested that inasmuch as the specific activity of PGDH is higher than the specific activity of 9-ketoreductase in decidual cytosolic fractions, PGE_2 would be preferentially metabolized to PGEM rather than to $PGF_{2\alpha}$.[7]

We have extended these studies to investigate the relative formation of PGEM, PGFM, and $PGF_{2\alpha}$ from exogenous PGE_2 by dispersed-cell preparations of separated human fetal membranes in vitro. We determined the potential for $PGF_{2\alpha}$ formation from PGE_2 by the amnion, chorion, and decidua, and examined whether this was altered with spontaneous labor.

women at term undergoing elective cesarean section (n = 6) or at spontaneous delivery (n = 6). Tissues were collected immediately after delivery in Dulbecco's phosphate buffered saline solution (pH 7.4). The amnion was separated manually from the choriodecidua. The tissues were then washed several times with Dulbecco's phosphate buffered saline solution to remove clotted blood. The chorion and decidua were then gently separated with fine forceps.

Cell dispersal. Cells were prepared with collagenase digestion as described by Skinner et al.[8] The rinsed tissues were cut into pieces (1 cm^2) and placed in separate 250 ml Erlenmeyer flasks. Freshly prepared collagenase (0.1%, Type I, Sigma Chemical Co., St. Louis, Mo.) and trypsin inhibitor (0.05%, Type I-S, Sigma Chemical Co.) in Dulbecco's phosphate buffered saline solution (30 ml) were added to each flask, and the flasks were tightly stoppered. The tissues were incubated for approximately 1 hour at 37° C in a shaking water bath with vigorous shaking every 15 to 25 minutes.

When the suspensions appeared uniform, cells were collected by centrifugation at 125 g for 10 minutes. The cells were then washed twice with Dulbecco's phosphate buffered saline solution with centrifugation at 125 g for 10 minutes and resuspended in 20 ml of Eagle's minimum essential medium (pH 7.4 with glutamine, without sodium bicarbonate) (Flow Laboratories, Mississauga, Ontario, Canada). Cell viability was assessed by exclusion of trypan blue dye. An aliquot (10 μl) of the cell suspension was added to Hematall isotonic diluent (10 ml), treated with 0.3% potassium cyanide (Hematall LA-Hgb reagent, Fisher Diagnostics, Unionville, Ontario, Canada), and the cells were counted with a Coulter counter. The cell suspension was then diluted so that the concentration of viable cells was 4×10^5 per milliliter of Eagle's minimum essential medium.

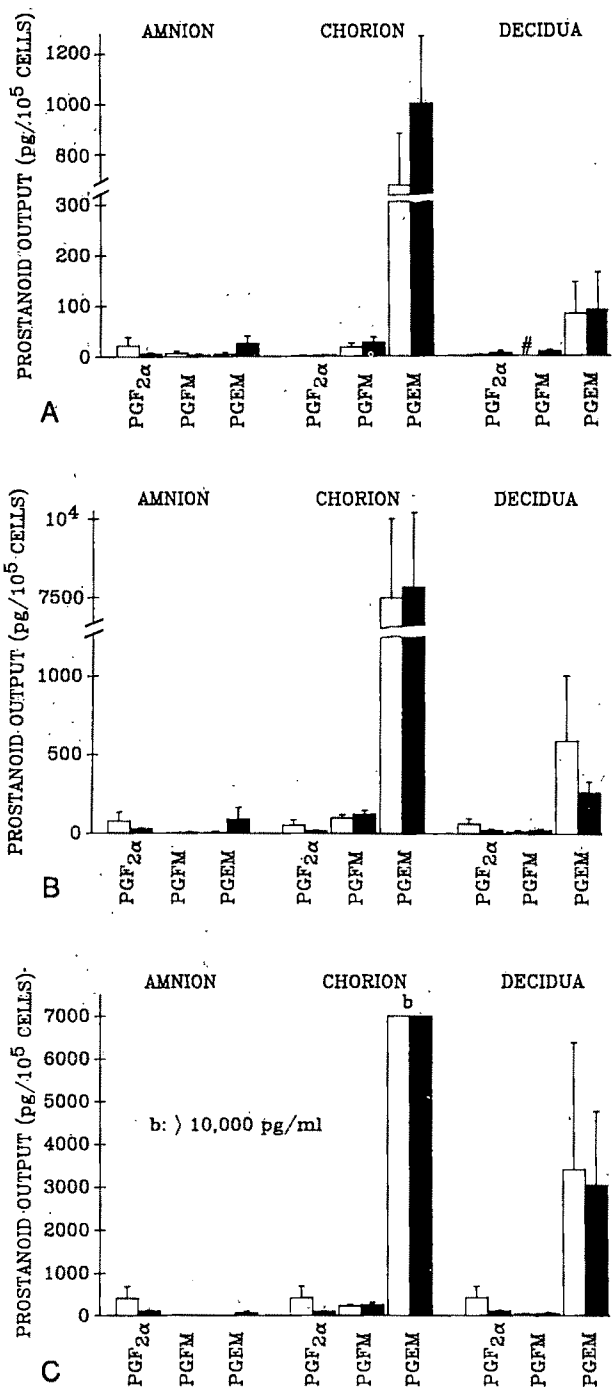

Fig. 2. Output of $PGF_{2\alpha}$, PGFM, and PGEM in presence of **A**, PGE_2, 1 ng/ml; **B**, PGE_2, 10 ng/ml; **C**, PGE_2, 100 ng/ml by amnion, chorion, and decidual cell preparations. Values are mean ± SE for five patients at term elective cesarean section (□) and six patients at spontaneous delivery (■). (#, Nondetectable.)

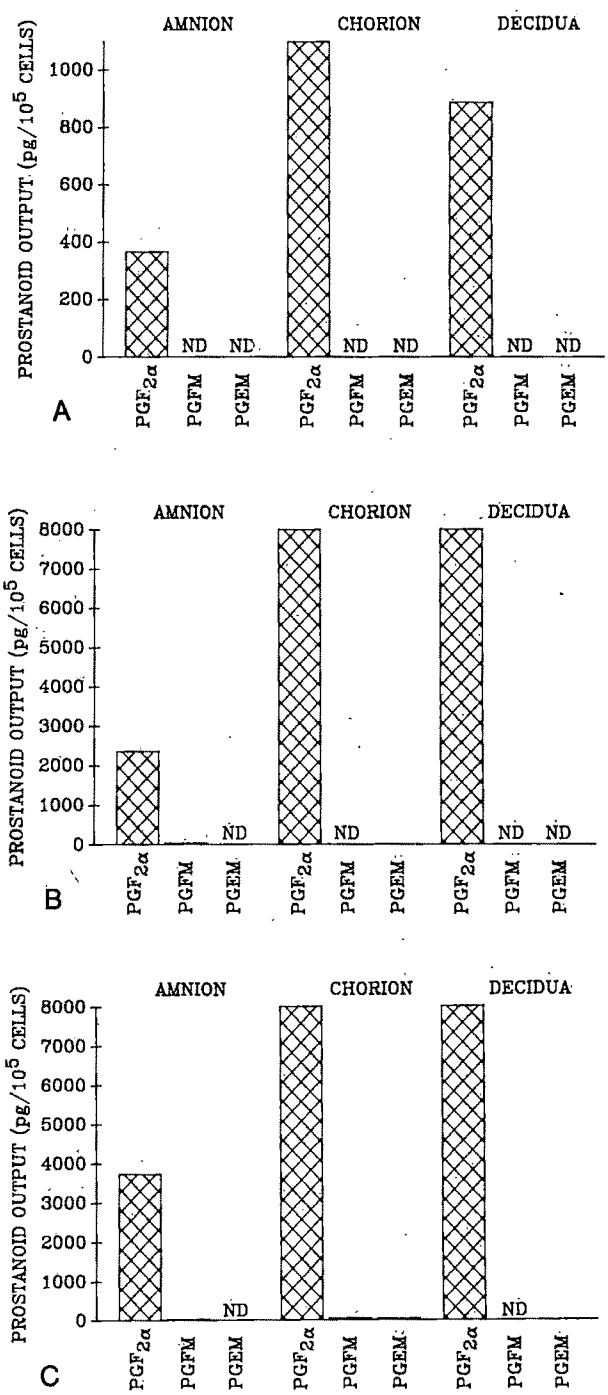

Fig. 3. Output of $PGF_{2\alpha}$, PGFM, and PGEM in presence of **A**, PGE_2, 1 ng/ml; **B**, PGE_2, 10 ng/ml; **C**, PGE_2, 100 ng/ml by amnion, chorion, and decidual cell preparations from one patient at term elective cesarean section. Output of $PGF_{2\alpha}$ by chorion and decidua in panels **B** and **C** were >8065 pg/10^5 cells. *ND*, Nondetectable.

Experimental protocol. Cell suspensions (0.5 ml) were added to polystyrene culture tubes (12 × 75 mm, Canlab, Toronto, Ontario, Canada). PGE_2 or vehicle control was added in 0.5 ml Eagle's minimum essential medium to the respective culture tubes so that the final cell concentration was 2 × 10^5 per milliliter and the final PGE_2 concentration was 0, 1, 10, 100 ng/ml. The cells were then agitated in a shaking water bath at 37° C for 2 and 4 hours under air. All incubations were performed in triplicate. Incubations were terminated

by freezing at −70° C. Controls included in this experiment were cells with media at time zero, test media incubated without cells for 2 and 4 hours, and cells with media but without added PGE_2 to obtain basal PG output at 2 and 4 hours. Frozen cell suspensions were thawed, mixed well, and centrifuged (1000 *g* for 10 minutes) before assay. The concentration of PGE_2 in media from cells at time zero was subtracted from that in media and cells at 2 and 4 hours (basal output) to determine the net basal output over that time. Net basal output was subtracted from total PG output in the presence of added PGE_2 to determine net stimulated output, and is expressed per 10^5 cells.

Overall mean cell viability after collagenase dispersal was 88.9% ± 5.4%. We have determined previously that there was no difference in viability between tissues, nor between cells obtained at elective cesarean section and spontaneous delivery.[9]

Prostaglandin assays. PGE_2, $PGF_{2\alpha}$, and PGEM were measured directly from the incubation media by specific radioimmunoassay. PGEM was measured as 11-deoxy-13,14-dihydro-15-keto-11β,16ψ-cycloprostaglandin E_2 by a commercial assay system from Amersham International (Amersham, United Kingdom). The same amount of medium was included in the assay standard curve. To measure PGFM, the media was first acidified and then extracted with diethyl ether. The extract was dried under a stream of nitrogen and assayed for PGFM.

The interassay and intra-assay coefficients of variation (%) for all four assays were 8.0 ± 2.3 and 3.3 ± 0.6 for PGE_2, 9.3 ± 3.3 and 5.7 ± 1.7 for PGEM, 7.7 ± 1.0 and 4.5 ± 0.3 for $PGF_{2\alpha}$, and 11.3 ± 1.6 and 2.8 ± 0.7 for PGFM.

Antibody specificity was calculated as 50% binding/binding in the absence of nonradioactive prostaglandin displacement. $PGF_{2\alpha}$ cross-reacted 0.18% with the PGE_2 antibody. There was <0.01% cross-reaction for the $PGF_{2\alpha}$ and PGFM antibody with PGs other than $PGF_{2\alpha}$ and PGFM, respectively. The PGEM antibody had <0.001% cross-reactivity with PGE_2, $PGF_{2\alpha}$, or PGFM.

Data analysis. Differences between cesarean section and spontaneous labor patients were sought with the Student *t* test.

Results

It became evident as the study progressed that one patient in the cesarean section group responded quite differently from the rest of the patients. Results for this individual are presented separately. For all other patients, the general response patterns at 2 hours and at 4 hours were similar, and results are presented for the 2-hour incubations only.

Basal PG output. Basal output of PGE_2 (Fig. 1) by amnion was greater than that for other prostanoids, and increased with cells from patients at spontaneous delivery. In chorion, the output of PGEM exceeded that of other PGs but did not change with labor. Net basal output of $PGF_{2\alpha}$ at cesarean section and of PGE_2 at spontaneous delivery from decidual cells was greater than that of PGFM or PGEM, but did not change with labor.

Effects of added PGE_2. The percent recovery of PGE_2 added to the medium at 1 ng/ml, incubated for 2 hours, and measured by radioimmunoassay was 90.8 ± 13.8% (n = 11). Table I shows the recovery of PGE_2, $PGF_{2\alpha}$, PGEM, and PGFM in the medium as a percentage of added PGE_2 after subtraction of net basal PG output. At both cesarean section and spontaneous delivery, recoveries from chorion were not significantly different from 100%, with PGEM being the major product. However, with amnion and decidual cell preparations, recoveries ranged between 30% to 55%, and most activity remained in PGE_2.

The profiles of PGs formed from added PGE_2 were similar at the three different concentrations of added potential substrate (Fig. 2). In amnion, conversion to $PGF_{2\alpha}$ was present, and on average higher at cesarean section than at spontaneous delivery. There was essentially no conversion to PGEM or PGFM by amnion cells at either cesarean section or spontaneous delivery. In chorion there was appreciable conversion to PGEM, but only trace amounts of $PGF_{2\alpha}$ and PGFM were detected. The formation of PGEM in chorion was not significantly different between cesarean section and spontaneous delivery patients. In the decidua there was negligible (<1.0%) formation of $PGF_{2\alpha}$ from added PGE_2. The major product was PGEM, although its formation was variable and did not differ significantly between cesarean section and spontaneous delivery patients.

PG output in one cesarean section patient. The pattern of basal and stimulated output of PGs was quite different in one of the cesarean section patients. In this patient, net basal output of PGE_2, $PGF_{2\alpha}$, and PGEM, and PGFM was undetectable in most tissues (Table II). After addition of PGE_2 (1 to 100 ng/ml) there was substantial formation of $PGF_{2\alpha}$ by amnion (up to 35%), chorion (up to 100%), and decidua (up to 80%), and minimal, if any, formation of PGEM or PGFM by any one of amnion, chorion, and decidual cell preparations (Fig. 3).

Comment

The possibility has been raised that conversion of PGE_2 to $PGF_{2\alpha}$ by intrauterine tissues, especially decidua, might contribute to the increase in $PGF_{2\alpha}$ and PGFM found in amniotic fluid and in maternal plasma during late pregnancy, and may contribute to the stimulus to myometrial contractility at parturition.[7] However, we found that although some $PGF_{2\alpha}$ is formed

Table II. Basal PG output at term cesarean section in one patient (pg/10^5 cells)

Tissue	*PGE_2*	*PGEM*	*$PGF_{2\alpha}$*	*PGFM*
Amnion	13	ND	ND	ND
Chorion	ND	ND	ND	ND
Decidua	ND	ND	ND	18

ND, Nondetectable.

from PGE_2 by all intrauterine tissues, quantitatively this was extremely small, particularly in comparison with the substantial metabolism of PGE_2 to PGEM. Therefore our results are in accord with the conclusions of Niesert et al.[7] and Kredentser et al.[10] that the activity of decidual 9-ketoreductase is unlikely to be a significant factor in the determination of the increase in the production of $PGF_{2\alpha}$ at parturition. Although previous studies have demonstrated PGE_2 9-ketoreductase activity in human decidual cytosol,[4, 7] the present results suggest that the major pathway of decidual $PGF_{2\alpha}$ production is through de novo synthesis. Our study provides new information on the output of PGEM by amnion, chorion, and decidua in the basal state and after added PGE_2 in vitro. We found that PGEM was the major prostanoid produced by chorion, and that in both chorion and decidua (but not in amnion) its output was considerably enhanced after addition of PGE_2. These observations are in accord with high PGDH activity in chorion, somewhat lower activity in decidua, and minimal activity in amnion.[2]

Although we recovered most of the added PGE_2 in PGE_2, PGEM, $PGF_{2\alpha}$, and PGFM for chorion, there was poor quantitative recovery from amnion and decidual cells. In the absence of cells, PGE_2 recovery was good. It seems likely that PGE_2 or its metabolites were taken up and retained to a greater extent by amnion and decidual cells than by chorion. However, because we were interested in relating PG output in vitro to secretion in vivo, we measured PG concentrations in the supernatant only. It is also possible that 15-keto-PGE_2 or 15-keto-$PGF_{2\alpha}$, which were not measured in this study, accumulate in the amnion and decidual cells, although previous studies of PG metabolism in these tissues[11] suggest that this is unlikely to account for the poor total recoveries. It is also possible that the rate of PG entry into cells varies between the tissues. Finally, we did not attempt to adjust cofactors in these experiments. PGDH is a nicotinamide adenine dinucleotide, oxidized form–dependent enzyme, whereas 9-ketoreductase uses nicotinamide adenine dinucleotide phosphate, reduced form.[6, 7] It remains possible that under our incubation conditions nicotinamide adenine dinucleotide phosphate, reduced form, availability is rate-limiting, resulting in an apparent predominance of PGDH activity, despite the demonstration of 9-ketoreductase in decidual cytosol preparations.

Previous studies suggested that 9-ketoreductase activity could be inhibited by progesterone, estradiol, and cortisol, and enhanced by calcium ion or oxytocin.[6] However, the concentrations of steroids used in those studies were high (1 mmol/L), and it is unlikely that endogenous steroid production by the cell types we used in vitro[12] would be sufficient to affect the activity of this enzyme. Further, if the influence of 9-ketoreductase is minimal in vivo, it seems unlikely that steroid modulation would have any physiological significance.

We found one patient in the cesarean section group in whom there was minimal PGDH activity in all tissues, and substantial conversion of PGE_2 to $PGF_{2\alpha}$. Thus, in the absence of PGDH, high levels of 9-ketoreductase were expressed. This patient was delivered as a repeat cesarean section in the current pregnancy. It is of interest that she had had three successive miscarriages at 16 to 20 weeks' gestation. Further detailed studies of this patient and her offspring are under way. The extremely low or undetectable PGDH activity in all tissues of this patient is intriguing. Erwich and Kierse,[13] from a study of placental PGDH activities in monozygotic and dizygotic pregnancies, have suggested that the level of PGDH is controlled by the fetus. A direct fetal effect could account for the results in chorion and amnion. However, the similar absence of PGDH in decidua raises the possibility that either an inhibitor or the lack of a stimulator to PGDH from the trophoblast-derived structures might also exert regulatory influences on the enzyme.

This patient clearly shows that 9-ketoreductase can be expressed in human amnion, chorion, and decidua. However, our results overall suggest that this enzyme does not normally contribute significantly to $PGF_{2\alpha}$ output by the fetal membranes or decidua at term.

Increased placental progesterone may cause decreased placental prostacyclin production in preeclampsia

Scott W. Walsh, PhD, and Stephanie Coulter, BS
Houston, Texas

Placentas obtained from women with preeclampsia produce more thromboxane and less prostacyclin than normal. They also produce more progesterone than normal. This study tested whether a progesterone concentration equivalent to that in the medium after in vitro incubation of placentas from women with preeclampsia ($\geq 1.5 \times 10^{-5}$ mol/L) could cause an imbalance of increased thromboxane and decreased prostacyclin production by normal placentas. Fresh term placental tissues were incubated for 48 hours in the absence or presence of various concentrations of progesterone and/or estradiol. Prostacyclin and thromboxane were determined by radioimmunoassay of their stable metabolites, 6-keto-prostaglandin $F_{1\alpha}$ and thromboxane B_2. A progesterone concentration of 1.5×10^{-5} mol/L significantly ($p < 0.001$) inhibited prostacyclin production, compared with control, but lower concentrations did not. Estradiol at concentrations present in the medium after incubation of either normal or preeclamptic placental tissue did not significantly affect prostacyclin production, nor did it prevent progesterone at 1.5×10^{-5} mol/L from inhibiting prostacyclin. Thromboxane production was not affected by either progesterone or estradiol. *Conclusion:* In vitro addition of progesterone at a concentration equivalent to that in the medium after incubation of preeclamptic placentas inhibited prostacyclin production by normal placentas to a rate characteristic of preeclampsia. However, it did not increase thromboxane. *Speculation:* Increased trophoblast progesterone in preeclampsia may act by a paracrine mechanism to inhibit prostacyclin synthesis in placental vasculature. Progesterone's selective inhibition of prostacyclin without affecting thromboxane may be due to the compartmentalization of thromboxane production to trophoblast and stroma and prostacyclin production to placental vasculature. (AM J OBSTET GYNECOL 1989;161:1586-92.)

Key words: Progesterone, prostacyclin, thromboxane, preeclampsia, human placenta

Placentas obtained from women with preeclampsia produce more thromboxane and less prostacyclin than normal.[1] Prostacyclin, a potent vasodilator and inhibitor of platelet aggregation, opposes the vasoconstrictive and platelet aggregating effects of thromboxane. In vitro incubation of placental tissues obtained from women with mild preeclampsia results in progesterone concentrations that are 30% to 70% greater than normal.[2] The concentrations of estradiol in the incubation medium are the same as normal. This study was done to test the hypothesis that in vitro addition of progesterone at a concentration equivalent to that in the medium after incubation of placental tissue from women with preeclampsia can cause an imbalance of increased thromboxane and decreased prostacyclin production by normal placentas.

Material and methods

Fourteen term placentas were obtained within 5 minutes of vaginal ($n = 11$) or cesarean section ($n = 3$) delivery from healthy, normotensive women. The mode of delivery does not affect in vitro placental prostacyclin or thromboxane production rates.[1, 3] Institutional approval to use human placental tissues was obtained. Each placenta was placed in a sterile plastic bag, covered with ice, brought immediately to the laboratory, and processed under sterile conditions in a clean bench laminar flow type of hood. The umbilical arteries were gently flushed with Dulbecco's modified Eagle's medium (DMEM) (Gibco, Grand Island, N.Y.) until the chorionic plate arteries and veins were visibly clear of blood. Tissue samples were taken from various sites and always from the interior of the placenta to exclude contamination with chorion, decidua, large blood vessels, or bacteria after a vaginal delivery. Placental tissues were placed in DMEM that was oxygenated with 95% oxygen and 5% carbon dioxide. Tissues were gently cut and washed repeatedly until blanched of blood, then gently cut again into small pieces and blotted dry with sterile gauze with a consistent technique used for each

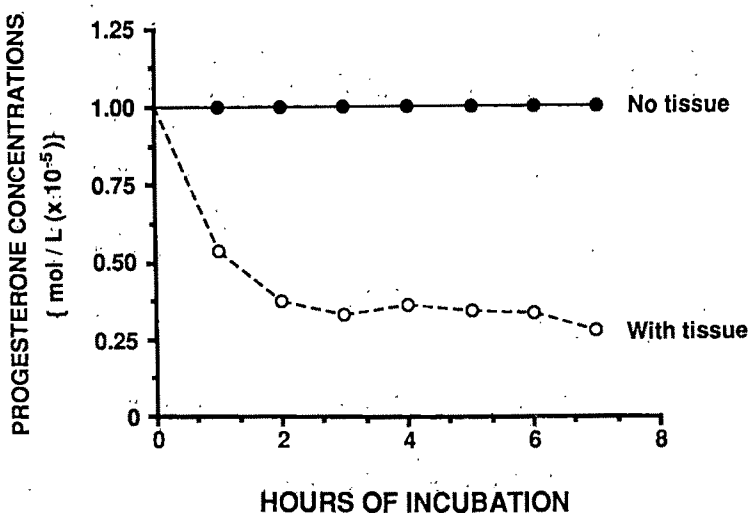

Fig. 1. Concentrations of progesterone in the incubation medium in the presence or absence of approximately 350 mg of human placental tissue. The molar concentration of progesterone added was 1×10^{-5} mol/L.

piece of tissue. Care was taken to assure as little trauma to the tissues as possible. Approximately 350 mg of tissue pieces was placed into 7 ml of DMEM in 2 × 3 six-well culture dishes (35 mm diameter for each well) (Costar, Cambridge, Mass.). Control wells were run in quadruplicate for each placenta and treatment wells were run in duplicate. Tissues were oxygenated with 95% oxygen and 5% carbon dioxide during 48 hours of incubation at 37° C in a Dubnoff metabolic shaker that was located inside a sterile hood.

The shaking incubator creates a shear stress on the tissues that is important for prostacyclin and thromboxane production. The use of 95% oxygen is necessary to assure viability of the inner cells of the tissue pieces. Cell viability of the tissue cultures is >95% as previously published.[3] Reduction of oxygen from 95% to 20% results in a significant decrease in prostacyclin production.[3]

The placenta both synthesizes and metabolizes progesterone and estradiol, but in vitro placental steroid synthesis is low in the absence of added precursor.[2] Therefore metabolism is greater than synthesis. For this reason progesterone and 17β-estradiol concentrations were determined in the incubation medium in the presence and absence of 350 mg of placental tissue. When the original incubation concentrations of progesterone were 1×10^{-4}, 1×10^{-5}, and 1×10^{-6} mol/L, the final incubation concentrations were 1.5×10^{-5} mol/L (85% reduction), 2.8×10^{-6} mol/L (72% reduction) and 4.5×10^{-7} mol/L (55% reduction), respectively. The rate of placental progesterone metabolism is shown in a representative figure for a starting concentration of 1×10^{-5} mol/L (Fig. 1). In the absence of placental tissue the concentrations of progesterone remain stable, but in the presence of placental tissue progesterone concentrations rapidly decline during the first 2 hours of incubation before reaching equilibrium and relatively stable concentrations. Placental metabolism of 17β-estradiol was similar to that of progesterone, but because physiologic concentrations of estradiol did not significantly affect prostacyclin or thromboxane production either alone or in combination with progesterone, its molar concentrations in the incubation medium are presented only as 10^{-x} for the sake of clarity, simplicity, and emphasis on progesterone. Progesterone and 17β-estradiol were initially diluted in 100% ethanol to a concentration of 10 mg/ml. Subsequent dilutions were made from these solutions with DMEM. The ethanol percentages in the experimental solutions were ≤0.586%.

Single 200 μl samples were collected at time 0 and at 8, 20, 32, and 48 hours of incubation from each incubation well. The time 0 sample was collected after all tissues were weighed and placed into their respective incubation wells and just before the shaking incubator was started. Sample volume was not replaced with fresh DMEM to avoid dilution of the incubation media. The production rates of thromboxane A_2 and prostacyclin were estimated by determining the concentrations in the incubation media of their stable metabolites, thromboxane B_2 (TXB_2) and 6-keto-prostaglandin $F_{1\alpha}$ (6-keto-$PGF_{1\alpha}$). The validation of each radioimmunoassay was published previously.[1, 3, 4] The concentrations of TXB_2 and 6-keto-$PGF_{1\alpha}$ in each sample were corrected for the volume of the incubation medium remaining at the time of sampling.

Data are expressed as picograms per milligram of wet tissue. The advantages of expressing the data as

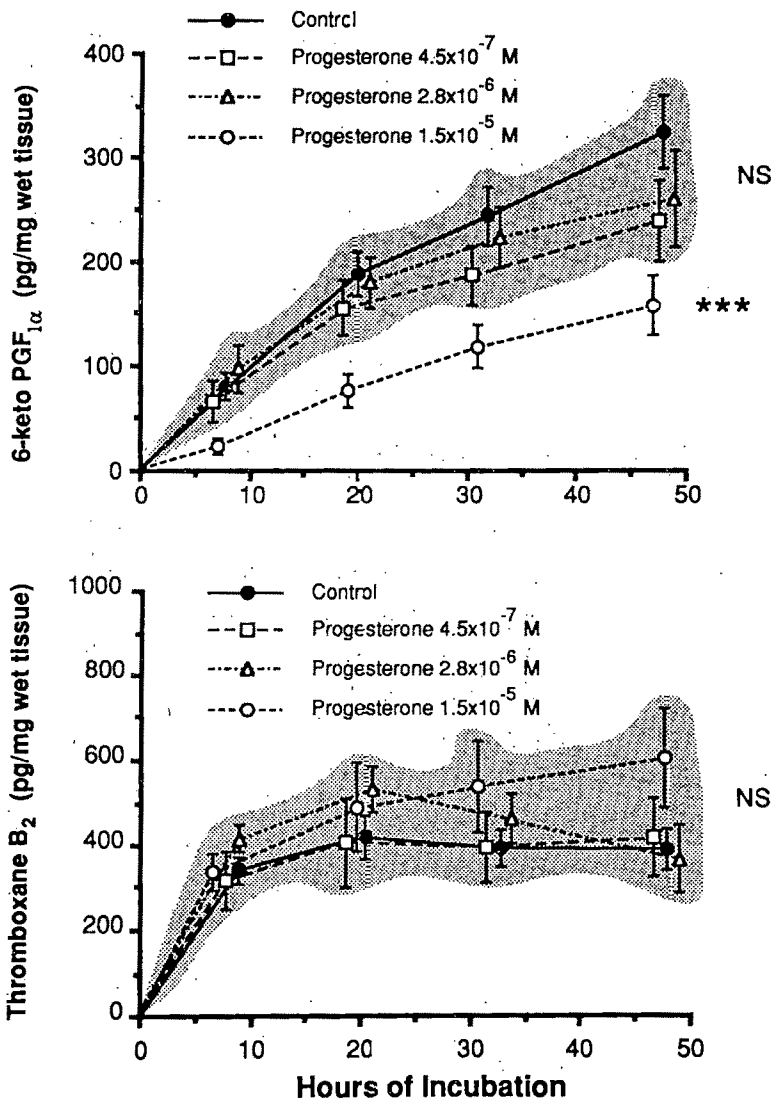

Fig. 2. Placental production of prostacyclin and thromboxane as estimated by the concentrations of their stable metabolites, 6-keto-$PGF_{1\alpha}$ and TXB_2, respectively, in the absence or presence of various concentrations of progesterone. The progesterone concentration of 1.5×10^{-5} mol/L is equivalent to that present in the medium after incubation of preeclamptic placental tissue.[2] Data represent mean ± SE (n = 14 for 6-keto-$PGF_{1\alpha}$, n = 10 for TXB_2). *Triple asterisk*, $p < 0.001$; *NS (shaded area)*, nonsignificant ($p > 0.05$).

per milligram of wet tissue, rather than as per milligram of dry tissue, protein, or deoxyribonucleic acid, are that it is simple and time efficient and it allows calculation of the total production rate for each placenta. We have validated the expression of the data as per milligram of wet tissue weight by comparing it with other methods. Comparison of picograms per milligram of wet tissue with picograms per microgram of protein results in significant and positive correlation coefficients for whole placental tissue of $r = 0.86$ for TXB_2 and $r = 0.95$ for 6-keto-$PGF_{1\alpha}$.[4] Correlation coefficients in five experiments for milligrams of wet tissue versus milligrams of dry tissue ranged from $r = 0.81$ to $r = 0.91$; for expression of the data as picograms per milligram of wet tissue versus picograms per milligram of dry tissue the correlation coefficients were $r = 0.94$ to $r = 0.98$ for TXB_2, and $r = 0.97$ to $r = 0.98$ for 6-keto-$PGF_{1\alpha}$.

Statistical differences between the concentration regression lines from 0 to 48 hours for 6-keto-$PGF_{1\alpha}$ or TXB_2 were assessed by two-way analysis of variance with orthogonal comparisons and the multivariate general linear hypothesis method. This is a revised version of a multivariate least-squares regression analysis allowing any linear contrasts on vectors of dependent and independent variables. A statistical computer software package was used.[5] Regression lines were considered significantly different at $p < 0.05$.

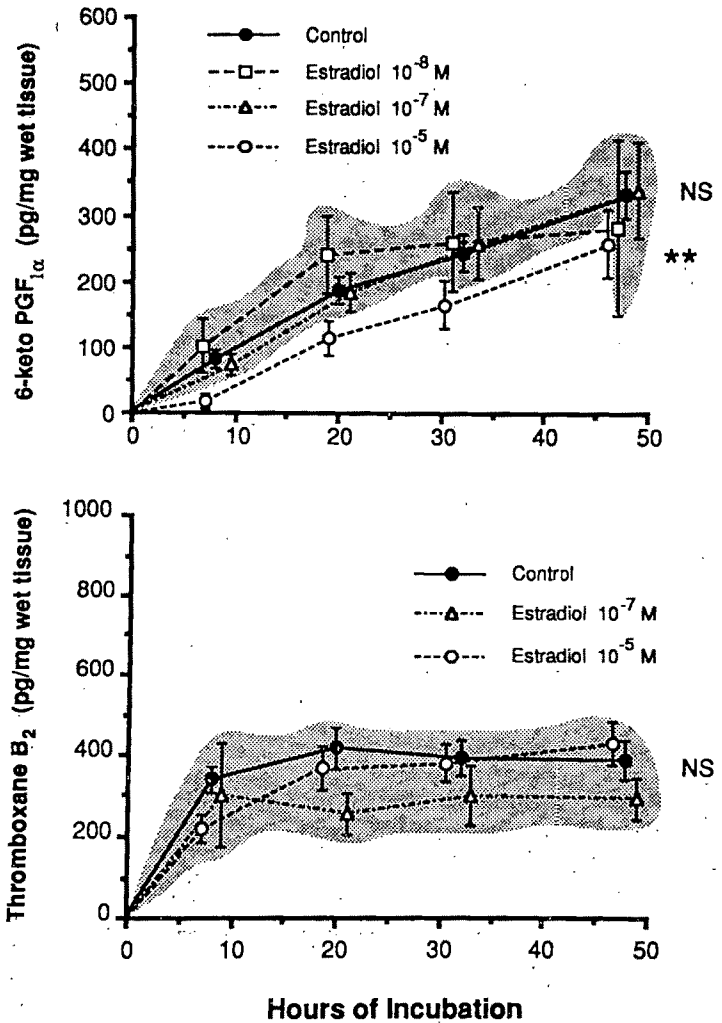

Fig. 3. Same as legend to Fig. 2 except placental tissues were incubated in the absence or presence of various concentrations of 17β-estradiol. The estradiol concentration of 10^{-5} mol/L is a supraphysiologic dose. *Double asterisk*, $p < 0.01$; *NS (shaded area)*, nonsignificant ($p > 0.70$).

Results

A progesterone concentration of 1.5×10^{-5} mol/L significantly inhibited placental prostacyclin production as indicated by significantly lower ($p < 0.001$) concentrations of 6-keto-$PGF_{1\alpha}$ in the incubation medium as compared with control (Fig. 2). Addition of lower concentrations of progesterone did not significantly affect 6-keto-$PGF_{1\alpha}$ concentrations compared with control ($p > 0.05$). An estradiol concentration of 10^{-5} mol/L significantly lowered ($p < 0.01$) 6-keto-$PGF_{1\alpha}$ concentrations, but addition of lower amounts of 10^{-7} and 10^{-8} mol/L did not significantly alter ($p > 0.70$) prostacyclin production (Fig. 3).

When progesterone was added to the incubation medium together with various amounts of estradiol, the progesterone concentration of 1.5×10^{-5} mol/L still significantly inhibited placental prostacyclin production because the concentrations of 6-keto-$PGF_{1\alpha}$ in the incubation medium were significantly lower ($p < 0.001$) than control (Fig. 4). Similar to the results obtained when progesterone was added alone, progesterone at lower concentrations in conjunction with estradiol did not significantly alter ($p > 0.10$) prostacyclin production.

Neither progesterone nor estradiol, either alone or in combination, significantly affected placental thromboxane production as indicated by the concentrations of TXB_2 (Figs. 2 to 4). Statistical probability levels were: 1.5×10^{-5} mol/L progesterone, $p > 0.07$; 2.8×10^{-6} mol/L progesterone, $p > 0.20$; 4.5×10^{-7} mol/L progesterone, $p > 0.98$; 10^{-5} and 10^{-7} mol/L estradiol, $p > 0.4$; progesterone plus estradiol, $p > 0.5$ for all doses. The TXB_2 data represent $n = 10$ rather than $n = 14$ because the TXB_2 radioimmunoassays for some of the experiments were not valid because of heat-damaged TXB_2 standards during shipment in August.

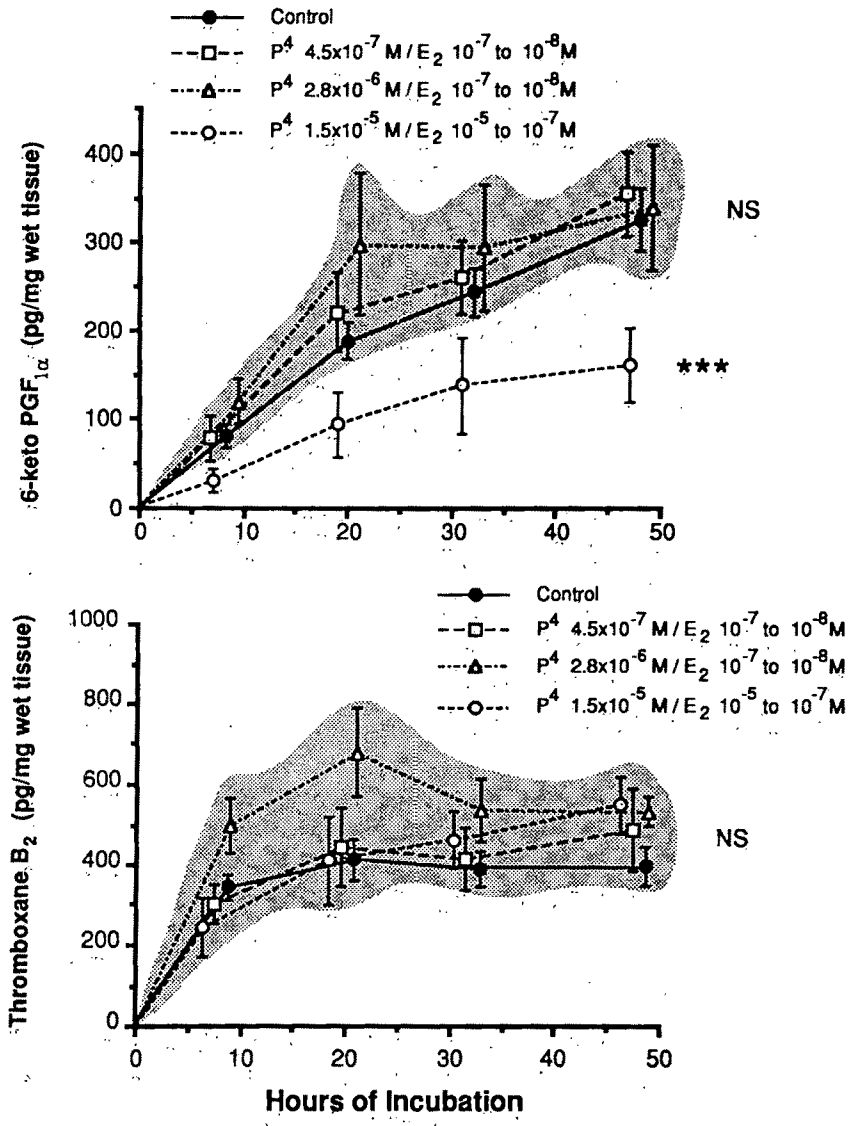

Fig. 4. Same as legend to Fig. 2 except placental tissues were incubated with various combinations of progesterone (P^4) plus estradiol (E_2). *Triple asterisk*, $p < 0.001$; *NS (shaded area)*, nonsignificant ($p > 0.10$).

In three experiments the concentrations of 6-keto-$PGF_{1\alpha}$ and TXB_2 were evaluated between 0 and 8 hours of incubation (i.e., at 1, 2, and 4 hours) in addition to the other sampling times. The concentrations of 6-keto-$PGF_{1\alpha}$ were linear and those of TXB_2 were curvilinear during this time interval. The inhibitory effect of progesterone at 1.5×10^{-5} mol/L on 6-keto-$PGF_{1\alpha}$ was present as early as 1 hour of incubation in two of three placentas.

Comment

Addition in vitro of progesterone at a concentration equivalent to that present in the incubation medium of preeclamptic placentas[2] significantly inhibited prostacyclin production by normal placentas to a rate characteristic of preeclampsia (Fig. 5).[1,3] Lower concentrations of progesterone did not significantly affect placental prostacyclin production (Figs. 2 and 4). Estradiol did not significantly alter prostacyclin production except at a concentration considerably higher than that present in the medium after incubation of either normal or preeclamptic placental tissue (Fig. 3).[2] The inhibitory effect of progesterone on placental prostacyclin production confirms the data of Myatt et al.[6] and Jogee et al.[7] These investigators found that progesterone, either alone or in combination with estradiol, suppressed prostacyclin production by dispersed term placental cells in culture. We speculate that increased trophoblastic production of progesterone in preeclampsia acts by a paracrine mechanism to locally inhibit prostacyclin production in the placental vasculature.

The concentration of 1.5×10^{-5} mol/L of proges-

terone used in this study, although higher than that in the maternal systemic circulation, could be physiologic for the placenta if one considers that progesterone exerts its effect in a paracrine, rather than an endocrine, manner. The in vitro production rates for progesterone previously reported,[2] on which the present study was based, are very similar to those obtained by in vivo studies in pregnant women when they are converted from nanograms per milligram of placental tissue per hour to milligrams per placenta per day. The in vitro progesterone production rates with pregnenolone or pregnenolone sulfate added as precursor ranged from 184 to 268 mg/day. This compares favorably with in vivo production rates reported for pregnant women of 100 to 250 mg/day.

The inhibitory effect of progesterone on placental eicosanoid production was selective because it inhibited prostacyclin but not thromboxane production. Since both prostacyclin and thromboxane are cyclooxygenase metabolites of arachidonic acid, this raises the question as to the mechanism whereby progesterone selectively inhibits prostacyclin without inhibiting thromboxane production in the human placenta. One possibility is that progesterone can selectively inhibit prostacyclin synthesis. The human placenta contains a protein that inhibits prostaglandin synthesis,[8] and progesterone, but not estradiol, inhibits the release of arachidonic acid from human endometrial and decidual cells within 15 minutes, presumably by inhibiting phospholipase activity.[9] We are not aware, though, of any evidence that progesterone can specifically inhibit prostacyclin synthase.

An alternate possibility for the selective inhibitory effect of progesterone on prostacyclin production is that prostacyclin and thromboxane are compartmentalized in the human placenta.[4, 10] Thromboxane is primarily produced in the trophoblastic and stromal tissues of term placentas, whereas prostacyclin is primarily produced in the placental vasculature. Therefore a testable hypothesis is that progesterone receptors are present only in the placental vasculature, resulting in an inhibitory effect on prostacyclin without affecting thromboxane production by the trophoblast and stromal tissue. This hypothesis is consistent with the low number of progesterone-specific receptors present in the human placenta.[11]

All of the doses of progesterone tested theoretically should have saturated the progesterone-specific receptors in the placenta. Despite this, progesterone significantly inhibited prostacyclin production only at the 1.5×10^{-5} mol/L dose. Myatt et al.[6] and Jogee et al.[7] also found significant inhibition of prostacyclin by a progesterone dose of 10^{-5} mol/L in dispersed term placental cells in culture. These observations, together with the finding of Wilson et al.[9] that progesterone

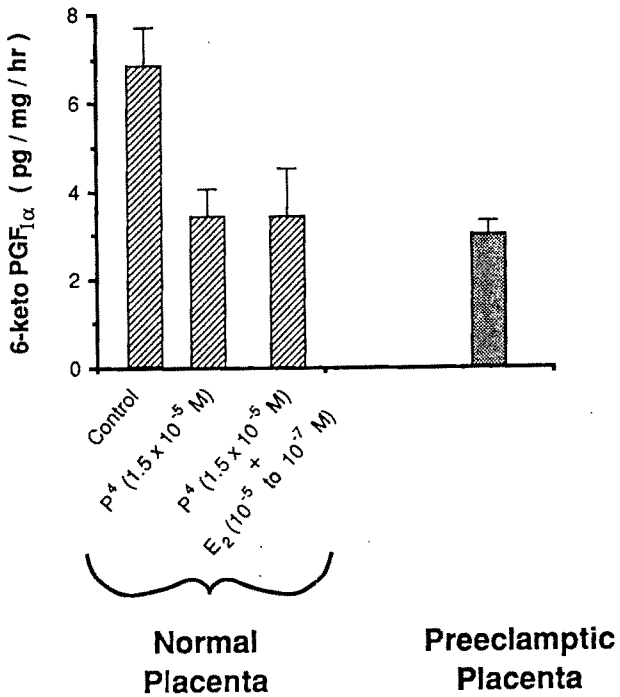

Fig. 5. Prostacyclin production rates (expressed as picograms of 6-keto-$PGF_{1\alpha}$ per milligram of wet tissue per hour) in placental tissues obtained from normal and preeclamptic pregnancies. At an in vitro concentration of progesterone equivalent to that in the medium after incubation of preeclamptic placentas,[2] prostcyclin production by normal placentas was inhibited to a rate characteristic of preeclampsia.[1, 3] Data represent mean ± SE.

rapidly inhibits phospholipase activity, suggest that progesterone can exert effects by a mechanism that may be separate from translocation of the progesterone-specific cytosol receptor to the nucleus with subsequent stimulation of transcription and translational processes.

This study was conducted to test the hypothesis that a progesterone concentration equivalent to that in the medium after in vitro incubation of preeclamptic placentas can cause an imbalance of increased thromboxane and decreased prostacyclin production by normal placentas. The data presented support one half of the hypothesis, that higher than normal placental progesterone concentrations can inhibit placental prostacyclin production, leading to an imbalance between thromboxane and prostacyclin. However, abnormally increased placental thromboxane production in preeclampsia appears to be independent of progesterone.

We acknowledge the expert technical assistance of Mr. Peter Brath.

Aspirin differentially affects thromboxane and prostacyclin production by trophoblast and villous core compartments of human placental villi

D. Michael Nelson, MD, PhD, and Scott W. Walsh, PhD

St. Louis, Missouri, and Houston, Texas

Low-dose aspirin has been used as prophylactic treatment for preeclampsia and fetal growth retardation, but the physiologic mechanisms for the beneficial effect of this therapy are unknown. We studied the effects of aspirin on eicosanoid production by different compartments of normal term human placental villi. Duplicate parallel incubations ($n = 7$) of whole villi, villous core tissues, and trophoblast were established on Millicell platform dishes in minimum essential medium in the presence or absence of 1×10^{-4} or 1×10^{-5} mol/L aspirin. Production rates of thromboxane A_2 and prostacyclin were estimated by radioimmunoassay of their stable hydrolysis products, thromboxane B_2 and 6-keto-prostaglandin $F_{1\alpha}$, respectively. Our results indicate that 1×10^{-4} mol/L aspirin inhibits thromboxane production in whole villi and villous core tissues denuded of their trophoblast layer but not in isolated trophoblast cells. The same concentration of aspirin also inhibits prostacyclin production in the isolated villous core but not in whole villi and not in isolated trophoblast. We conclude that aspirin can selectively inhibit thromboxane production in whole placental villi and differentially affects thromboxane and prostacyclin production by the trophoblast and villous core compartments. (Am J Obstet Gynecol 1989;161:1593-8.)

Key words: Human placenta, thromboxane, prostacyclin, aspirin

The opposing physiologic effects of prostacyclin and thromboxane have led to speculation with regard to the role of these eicosanoids in normal and abnormal pregnancy.[1-3] Prostacyclin is a potent vasodilator and inhibitor of platelet aggregation, whereas thromboxane causes vasoconstriction and stimulates platelet aggregation. Local production in tissues is the key to the effects of these eicosanoids, since it is controversial whether thromboxane or prostacyclin are circulating hormones.[2] Many of the sequelae of preeclampsia can be explained by the action of unopposed thromboxane.[3] Low-dose aspirin has been used as a prophylactic treatment for preeclampsia,[4] other forms of hypertension in pregnancy,[5] and fetal growth retardation[6, 7] in women at increased risk to develop these conditions. The pathophysiologic mechanisms for the beneficial effect of this therapy are not known, but one proposed mechanism involves a preferential inhibition of thromboxane production by low-dose aspirin without a limitation of prostacyclin production.[8]

Human placental villi produce both thromboxane[3, 9] and prostacyclin.[3, 10] We have described a method to separate trophoblast from villous core stroma to compare in vitro eicosanoid production by these two villous compartments with eicosanoid production by intact villi.[11] In this article we report the effects of aspirin on eicosanoid production by the different compartments of human placental villi.

Material and methods

Human term placentas from seven uncomplicated pregnancies (38 to 41 weeks) were obtained immediately after delivery. All women were normotensive throughout pregnancy, were not taking medications, and denied smoking, alcohol use, or aspirin ingestion at the end of pregnancy. The method for isolation of trophoblast and villous core has been published in detail.[11] Briefly, villous tissue was rinsed repeatedly with a modified minimum essential medium to remove blood from the intervillous space and the tissue was treated 10 minutes at 37° C with the proteolytic enzyme dispase (Collaborative Research, Inc., Lexington, Mass.). After enzyme inactivation with ethylenediaminetetraacetic acid, trophoblast components released into the supernatant were harvested and dispase-treated villi were rinsed with three changes of minimum

essential medium. Histologically the dispase-treated tissues consisted of villous core components denuded of the trophoblast layer; the trophoblast pellet contained both syncytial and cellular trophoblast.

Duplicate cultures of intact whole villi, villous core tissues, and trophoblast were established in the presence or absence of 1×10^{-3}, 1×10^{-4}, or 1×10^{-5} mol/L aspirin (Sigma Chemical, Co. St. Louis). All incubations were on Millicell platform dishes (Millipore Products Division, Bedford, Mass.) in serum-free minimum essential medium at 37° C in a 5% carbon dioxide and air atmosphere. Confirmation of viability under these conditions by tritiated leucine incorporation and trypan blue exclusion has been previously described.[11]

Aliquots of media obtained at 2, 4, 20, and 48 hours were analyzed for thromboxane A_2 and prostacyclin by specific radioimmunoassay of their stable hydrolysis products thromboxane B_2 and 6-keto-prostaglandin $F_{1\alpha}$ (6-keto-$PGF_{1\alpha}$), as previously described.[11] Antibodies to thromboxane B_2 and 6-keto-$PGF_{1\alpha}$ were obtained from Advanced Magnetics, Inc. (Cambridge, Mass). Protein content of cells and tissues was determined by the method of Bradford[12] with bovine serum albumin as a standard.

The results are expressed as picograms of eicosanoid per microgram of protein with the mean ± SE calculated for each preparation at each time point. Statistical differences among regression lines were assessed by two-way analysis of variance with orthogonal comparisons and the multivariate general linear hypothesis method. A statistical computer software package was used.[13]

Results

Preliminary experiments (data not shown). Parallel incubations of whole villi, villous core tissues, and trophoblast were prepared from three placentas, and eicosanoid production was determined in the presence or absence of 1×10^{-3} to 1×10^{-5} mol/L aspirin. These studies showed that aspirin at 1×10^{-3} mol/L nonselectively inhibited ≥ 85% of the thromboxane B_2 and ≥70% of the 6-keto-$PGF_{1\alpha}$ produced by the tissues

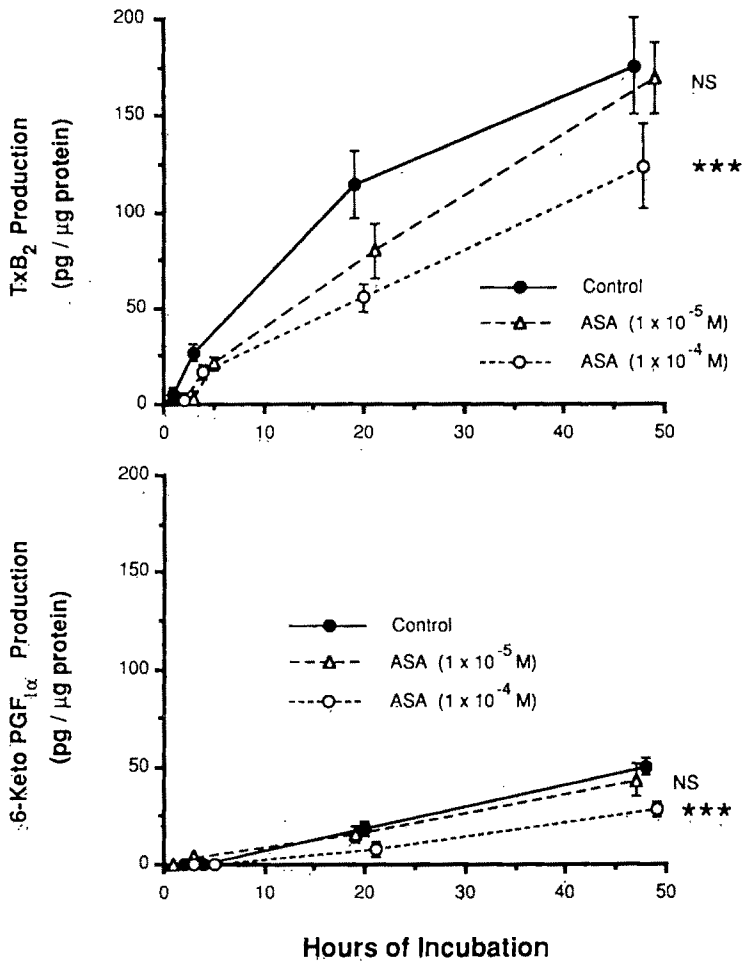

Fig. 2. Mean (±SE) concentrations of thromboxane B_2 *(TxB₂) (upper panel)* and 6-keto-$PGF_{1\alpha}$ *(lower panel)* in culture medium containing dispase-treated villous core tissues incubated in the absence *(control)* or presence of 1×10^{-4} or 1×10^{-5} mol/L aspirin *(ASA)*. Note the different scale for the ordinate compared with Fig. 1. Results are from four placentas with duplicates for each of the parallel incubations. (*NS*, Not significant; *triple asterisks*, $p < 0.001$.)

or cells during the 48-hour incubation. Aspirin at 1×10^{-5} mol/L did not appear to affect eicosanoid production in any of the incubations. We selected 1×10^{-5} and 1×10^{-4} mol/L aspirin for detailed study on the basis of our preliminary results and the results of a study that indicated these molar concentrations of salicylate were present in cord blood of women given a low dose of aspirin during labor.[14]

Eicosanoid production by whole villi. Thromboxane B_2 production by villi incubated with 1×10^{-5} mol/L aspirin was the same as control villi incubated without aspirin ($p > 0.5$; Fig. 1). Aspirin at 1×10^{-4} mol/L significantly inhibited thromboxane B_2 production ($p < 0.001$) by villi compared with villi incubated without aspirin (Fig. 1). Thromboxane B_2 inhibition by 1×10^{-4} mol/L aspirin was significant at 2 hours in culture; thromboxane B_2 levels in the media of the aspirin-treated tissues were only 31% of thromboxane B_2 levels in control incubations. This inhibition of thromboxane B_2 production by villi exposed to 1×10^{-4} mol/L aspirin continued over time: thromboxane B_2 levels were 50% of control villi at 4 hours, 41% of control at 20 hours, and 56% of control at 48 hours.

In contrast to the thromboxane B_2 results, neither 1×10^{-5} mol/L nor 1×10^{-4} mol/L aspirin significantly affected 6-keto-$PGF_{1\alpha}$ production by whole villi compared with villi incubated without aspirin ($p > 0.5$; Fig. 1).

Eicosanoid production by villous core tissues. Explants of villous core tissues produced increased concentrations of eicosanoids compared with whole villi, with a remarkable sixteenfold increase in the thromboxane B_2 concentration by 48 hours (Fig. 2). There was no difference in production of either eicosanoid by villous core tissues incubated with 1×10^{-5} mol/L aspirin compared with control tissues incubated without aspirin ($p > 0.2$; Fig. 2). However, 1×10^{-4} mol/L aspirin significantly inhibited both thromboxane

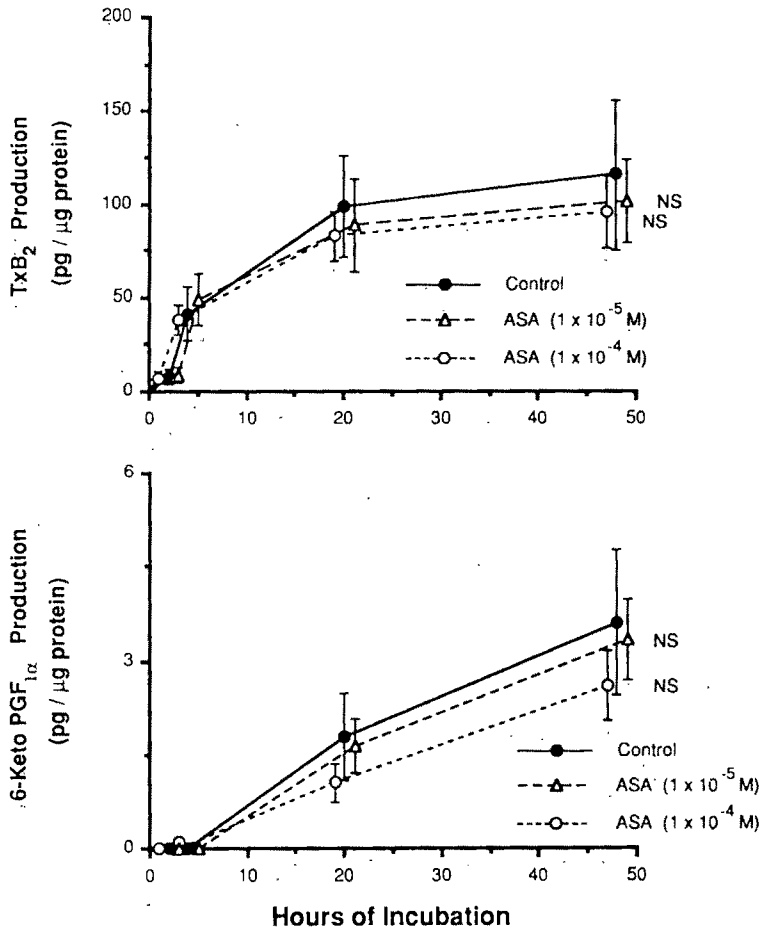

Fig. 3. Mean (±SE) concentrations of thromboxane B_2 *(TxB2) (upper panel)* and 6-keto-$PGF_{1\alpha}$ *(lower panel)* in culture medium containing trophoblast incubated in the absence *(control)* or presence of 1×10^{-4} or 1×10^{-5} mol/L aspirin *(ASA)*. Note the different scale for the ordinate compared with Fig. 1. Results are from four placentas with duplicates for each of the parallel incubations.

B_2 and 6-keto-$PGF_{1\alpha}$ production by villous core tissues compared with control tissues incubated without aspirin ($p < 0.001$; Fig. 2). Maximal inhibition of thromboxane B_2 production was present after 2 hours of incubation, with thromboxane B_2 levels 41% of control at this time. Inhibition continued throughout the study period, with the medium levels of thromboxane B_2 in the 1×10^{-4} mol/L aspirin-treated tissues 61% of control levels at 4 hours, 49% of control at 20 hours, and 71% of control at 48 hours. The 6-keto-$PGF_{1\alpha}$ production by control and aspirin-treated villous core tissues was not measurable in any of the incubations at 2 or 4 hours, but mean 6-keto-$PGF_{1\alpha}$ levels in media of villous core tissues exposed to 1×10^{-4} mol/L aspirin were 40% of control levels at 20 hours and 56% of control levels at 48 hours.

Eicosanoid production by trophoblast. Thromboxane B_2 was the predominant eicosanoid produced by trophoblast (Fig. 3). Neither concentration of aspirin significantly inhibited the thromboxane B_2 or 6-keto-$PGF_{1\alpha}$ production by isolated trophoblast cells ($p > 0.4$; Fig. 3).

Comment

The results indicate that 1×10^{-4} mol/L aspirin inhibits thromboxane B_2 production in whole villi and in villous core tissue denuded of its trophoblast layer but not in isolated trophoblast cells. The same concentration of aspirin also inhibits prostacyclin production in the isolated villous core but not in whole villi or isolated trophoblast. We conclude that aspirin can selectively inhibit thromboxane B_2 production in whole placental villi and differentially affects thromboxane B_2 and prostacyclin production by the trophoblast and villous core compartments. These results, in combination with our previous findings,[11] suggest that the trophoblast modulates villous core thromboxane B_2 production by a paracrine interaction. We speculate that aspirin mimics this trophoblast-inhibiting effect on thromboxane B_2 production by the placenta.

Whether the derangements in prostaglandin synthesis reported in preeclampsia represent primary or secondary phenomena is controversial.[1, 2] Recent studies have used low doses of aspirin to avoid the development of preeclampsia and fetal growth retardation in women at high risk for these complications of pregnancy.[4, 6-8] The beneficial effects of this treatment are attributed to a selective or preferential inhibition of thromboxane production without a significant alteration of prostacyclin production in different tissue compartments. Wallenburg et al.[4] administered placebo or 60 mg of aspirin daily to a group of women at high risk to develop preeclampsia, judged by their increased vascular sensitivity to infused angiotensin II. They found that aspirin alone was an effective prophylaxis for this complication of pregnancy. Beaufils et al.[5] administered daily 150 mg of aspirin and 300 mg of dipyridamole to a group of women at high risk to develop hypertension in pregnancy (not necessarily preeclampsia) and showed an improved outcome for the pregnancies in the treated group compared with untreated women. Treatment with 1 to 1.6 mg/kg/day aspirin in combination with 225 mg of dipyridamole reduced the risk of recurrence for intrauterine fetal growth retardation in a group of normotensive women with a history of intrauterine growth retardation.[6] Trudinger et al.[7] evaluated the fetal benefits of 150 mg aspirin daily in a group of women whose fetuses had elevated umbilical artery waveform systolic/diastolic ratios. Aspirin therapy was associated with an increase in birth weight, head circumference, and placental weight in the treated patients.

Maternal platelets are a source of thromboxane. Fitzgerald et al.[15] attributed the decrease in urinary metabolites of thromboxane after daily treatment of pregnant women with 40 mg of aspirin to a selective inhibition of the cyclooxygenase responsible for platelet thromboxane production. We have shown that normal placental villi also produce thromboxane, and an equal amount of prostacyclin,[3, 11] whereas villi from preeclamptic women produce a sevenfold excess of thromboxane compared with prostacyclin.[3] In addition, we found that trophoblast isolated from normal villi produced predominantly thromboxane, whereas the villous core compartment from normal villi denuded of the trophoblast layer produced a sixfold to ninefold excess of thromboxane compared with prostacyclin.[11] These data suggest that a trophoblast-derived inhibitor functioning in a paracrine interaction between the trophoblast and the villous core limits thromboxane production to maintain a physiologic balance of thromboxane and prostacyclin in the human placenta in normal pregnancy.

We questioned whether part of the beneficial effect of low-dose aspirin in complicated pregnancies might derive from a differential effect on thromboxane and prostacyclin production by different compartments of placental villi. Results of this study demonstrate that 1×10^{-4} mol/L aspirin selectively inhibits thromboxane production, without affecting prostacyclin production, by whole placental villi. This effect is the result of limiting villous core thromboxane production, because aspirin had no effect on eicosanoid production by isolated trophoblast. We speculate that aspirin may substitute for a trophoblast-derived inhibitor that normally limits villous core thromboxane production. We propose that this inhibitor may be absent in villi from preeclamptic women. Administration of low-dose aspirin would prevent the adverse physiologic effects of unopposed thromboxane in the placenta by differentially affecting eicosanoid production by villi.

The tissue levels of aspirin, or its active metabolite salicylate,[16] that result from the various low-dose aspirin regimens reported are not known. Plasma salicylate concentrations rapidly exceed those of aspirin after oral aspirin ingestion, and aspirin may be a "prodrug" for salicylate.[16, 17] Ylikorkala et al.[14] studied salicylate levels in umbilical cord blood after the administration of a single oral dose of 100 mg of aspirin to mothers in labor. The range of serum salicylate concentrations in the cord blood at delivery was between 1×10^{-5} mol/L to 0.9×10^{-4} mol/L. Tissue levels of salicylate may be as much as tenfold higher than serum levels.[17] We identified a differential effect on eicosanoid production by compartments of placental villi with 1×10^{-4} mol/L aspirin. This concentration should be within the ranges of aspirin and salicylate levels achieved in serum and tissues by clinical protocols that use aspirin as therapy for pregnancy complications.[4-8] Further studies will determine whether the effects of aspirin on eicosanoid production in placental compartments provide insight into the pathophysiology of preeclampsia.

We thank Peter Brath, Edward Curran, and Amy Marlo for their skillful technical assistance, and Dr. Ronald C. Strickler for his review of the manuscript.

In vitro release of endothelium-derived relaxing factor by acetylcholine is increased during the guinea pig pregnancy

Carl Weiner, MD, Ernest Martinez, BA, Liu Kang Zhu, MD, Abdi Ghodsi, BS, and David Chestnut, MD[a]

Iowa City, Iowa

The relaxation of isolated blood vessels by acetylcholine is dependent on the presence of intact endothelium and its release of a smooth muscle relaxing nitroso-like compound. Pregnancy is associated with altered vascular responsiveness to a variety of agents. Because many of these agents stimulate the release of endothelium-derived relaxing factor, we investigated in vitro the effect of pregnancy on acetylcholine-mediated relaxation of guinea pig uterine and carotid artery rings. The presence of intact and functional endothelium was confirmed both by examination under the scanning electron microscope and by vessel relaxation after the addition of acetylcholine. The addition of acetylcholine to the vessel bath produced dose-dependent relaxation of both carotid and uterine artery segments obtained from pregnant and nonpregnant animals after they had been submaximally preconstricted with phenylephrine. There was a significant increase in both response and efficacy to acetylcholine during pregnancy for both uterine and carotid arteries ($p < 0.0001$ for each). The concentrations of endothelial cells (cells per square micrometer) were similar in uterine arteries from pregnant and nonpregnant animals. We conclude that the most likely explanation for these findings is a pregnancy-mediated enhancement of endothelium-derived relaxing factor activity. (Am J Obstet Gynecol 1989;161:1599-605.)

Key words: Endothelium-derived relaxing factor, pregnancy, guinea pig, uterine artery, carotid artery

The response of vascular smooth muscle to a variety of vasoactive agents is altered during pregnancy.[1-3] Some of these alterations are mimicked in the castrated animal by estrogen replacement.[4-6] The relaxation of both large and resistance-size arteries caused by acetylcholine applied either in vitro or intravascularly in vivo depends on the functional integrity of the endothelium, which releases one or more vasodilating nitroso substances.[7-10] In the absence of a functional endothelium, acetylcholine causes vasoconstriction. Endothelium-derived relaxing factor release is stimulated by a variety of agents.[10] The effect of pregnancy acetylcholine-mediated relaxation has not been previously studied directly. However, the infusion of acetylcholine into the guinea pig uterus reduces resistance only during pregnancy or after estrogen treatment.[11-13] This loss of resistance was reported to be independent of vasodilator cholinergic nerves but reduced by protein synthesis inhibition.[13] If endothelium-derived relaxing factor activity were increased during pregnancy, it could account for at least part of the decline in vascular resistance and responsiveness to catecholamines during pregnancy. The present experiments were designed to determine whether the response of either systemic or reproductive organ arteries to acetylcholine is altered by pregnancy.

6/6/15671

Material and methods

The protocol was approved by the University of Iowa Animal Care Committee. Adult female, nonpregnant and pregnant (50 to 60 days' gestation; term, 65 to 68 days' gestation) guinea pigs (600 to 1000 gm) were anesthetized (ketamine hydrochloride, 80 mg/kg administered intraperitoneally; xylazine hydrochoride, 3 mg/kg administered intramuscularly). While 100% oxygen was applied by mask, the common carotid and main uterine arteries were removed en bloc with microsurgical instruments and an operating microscope. The carotid artery was selected to represent the systemic vasculature. The uterine artery was selected because it directly supplies the conceptus. The number of pups supplied by each uterine artery was recorded. These were small arteries. The inner diameter as measured under the operating microscope of the unstretched uterine artery from a nonpregnant guinea pig ranged from 90 to 150 μm. The inner diameter of the remaining vessels studied ranged from 150 to 200 μm.

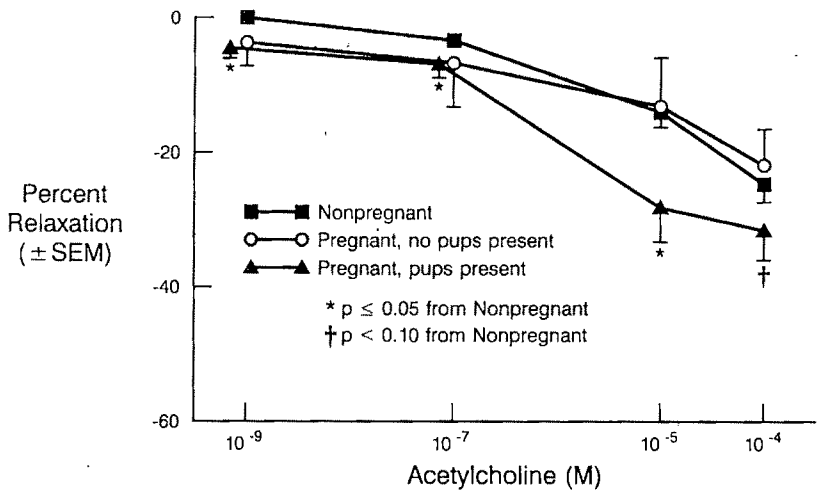

Fig. 1. Acetylcholine-stimulated relaxation of uterine artery preconstricted with phenylephrine was increased during pregnancy. Repetitive measures two-way ANOVA: dose, $p < 0.0001$; pregnancy status, $p < 0.0001$; interaction, $p < 0.0001$. Note that arterial segments from pregnant animals that supply a horn without a pup demonstrated an intermediate pregnancy effect (control, $n = 12$; no pups, $n = 3$; pups, $n = 8$). * and † Compared with nonpregnant animal.

The arteries were immediately placed in iced Krebs-Ringer bicarbonate solution (grams per liter: sodium chloride 6.914, potassium chloride 0.3505, calcium chloride dihydrate 0.328, magnesium sulfate heptahydrate 0.295, monopotassium phosphate 0.164, sodium bicarbonate 2.1, and glucose 2.0) previously aerated with 95% oxygen and 5% carbon dioxide. Under the microscope, the vessels were sharply cleaned of connective tissue, cut into 3 mm rings excluding areas with branches, and suspended on two 50 μm tungsten wire triangles. One triangle was hooked to a stationary rod and the other to a strain gauge transducer (Grass FT 0.03, Quincy, Mass.) for the measurement of isometric force. The rings were suspended in 25 ml dropaway baths filled with Krebs-Ringer solution maintained at 37° C and aerated with 95% oxygen and 5% carbon dioxide.[14, 15] All experiments were performed in the presence of desipramine (10^{-5} mol/L) to block neuronal, and hydrocortisone (10^{-5} mol/L) to block extraneuronal uptake of norepinephrine.[16, 17] Propranolol (10^{-5} mol/L) was added to inhibit β-adrenergic receptors.[18]

After at least 60 minutes of equilibration in the organ chamber, each ring was stretched to the optimal point of its length-tension curve as determined by the tension developed in response to potassium chloride (10^{-1} mol/L) added at each stretch level.[19] The optimal resting tension was defined as that point on the length-tension curve where the maximal constrictive response to potassium chloride was obtained. The arterial ring was then preconstricted with submaximal phenylephrine hydrochloride (10^{-7} mol/L) and endothelium-derived relaxing factor release stimulated by the addition of acetylcholine 10^{-9} to 10^{-4} mol/L) given in random order. The arterial ring was washed twice after each acetylcholine dose and rested for 15 minutes before the phenylephrine was again added to the bath. At the conclusion of the experiment, the rings were sharply opened longitudinally and the dimensions were measured. Then they were blotted dry and weighed. The vascular wall cross-sectional area was calculated so that the isometric force produced in response to phenylephrine could be normalized for muscle mass.[20] The response to acetylcholine was expressed in terms of the percent relaxation obtained from the phenylephrine-induced constriction and the efficacy of acetylcholine. Efficacy was defined as the percent relaxation obtained for that dose divided by the maximum relaxation obtained during the performance of the dose-response curve for the ring (i.e., the percent of the maximum).

To determine the effect of pregnancy on the number of endothelial cells and the effect of the experiment on the structural integrity of the endothelium, rings prepared identically and simultaneously with those used in experimentation and rings actually used in experimentation were placed in glutaraldehyde, mounted, and viewed under the scanning electron microscope. The area denuded of endothelium was estimated and the number of endothelial cells per micron^2 were counted. The pregnancy status of the animal from which the vessels were obtained was unknown to the investigator at the time these evaluations were made.

Drugs. The following drugs were used: acetylcholine hydrochloride, phenylephrine hydrochloride, desipramine, hydrocortisone, and propranolol (Sigma Chemical Co., St. Louis, Mo.); ketamine hydrochloride (Bristol Myers Co., Syracuse, N.Y.); and xylazine (Miles Laboratories, Shawnee, Kan.). All drugs and buffers were

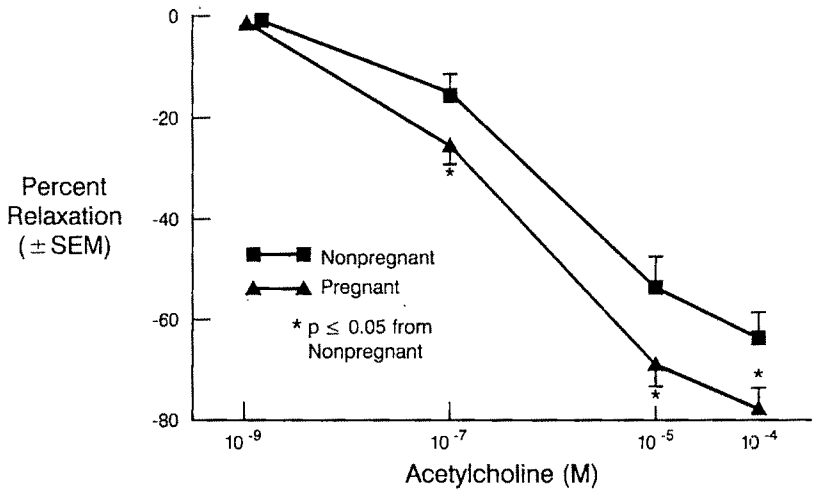

Fig. 2. Acetylcholine-stimulated relaxation of carotid artery preconstricted with 10^{-7} mol/L phenylephrine was increased during pregnancy (n = 13). Repetitive measures two-way ANOVA: dose, $p < 0.0001$; pregnancy status, $p < 0.0001$; interaction, $p = 0.0005$. * and † Compared with nonpregnant animal.

prepared fresh on the day of study with distilled water and were kept on ice. Concentrations are expressed as final molar concentration (mol/L) in the organ bath.

Statistics. Data are expressed as mean ± SEM; n indicates the number of animals. Uterine rings from pregnant animals were subcategorized by the presence or absence of at least one pup in the uterine horn they supplied. Quantitative differences in responses to acetylcholine between animals was a large source of variability. Therefore the effect of pregnancy and dose on the relaxation and efficacy of acetylcholine was determined by a two-way random block repeated measures analysis of variance (ANOVA) with either percent relaxation from the phenylephrine-induced constriction or efficacy as the dependent variable and the dose of acetylcholine and the pregnancy status as the independent variables (blocking by animal). If the mean values for the ANOVA were found to be significantly different, either a Scheffé test or an independent Student t test with appropriate correction for multiple comparisons was applied. Thus, despite the somewhat large SE because of interanimal variability, statistically significant differences between pregnancy and nonpregnant animals could be discerned. Comparisons of means from two groups used where appropriate were either a paired or unpaired Student t test (two-tailed). A p value < 0.05 was considered to indicate a significant difference.

Results

There was a significant dose-dependent acetylcholine-stimulated relaxation of the preconstricted carotid and uterine arterial rings from both pregnant and nonpregnant animals ($p < 0.0001$ for each) (Figs. 1 and 2). The percent of relaxation the preconstricted vessel achieved was greater in vessels from pregnant animals than that achieved in vessels from nonpregnant animals ($p < 0.0001$ for both uterine and carotid artery rings). Further, there was a significant interaction between pregnancy status and acetylcholine dose on the relaxation achieved for both the uterine ($p < 0.0001$) and carotid ($p = 0.0005$) arteries. The maximum relaxation observed for the carotid artery was approximately three times that observed for the uterine artery. The effect of pregnancy on the uterine artery was most pronounced at the lower concentrations of acetylcholine. Pregnancy was also associated with increased efficacy of acetylcholine for both carotid ($p < 0.0001$) and the uterine arteries ($p = 0.0002$) (Figs. 3 and 4). The interaction term between pregnancy status and dose was also significant for both the uterine ($p = 0.03$) and carotid ($p < 0.0001$) arteries.

Differences in such characteristics as vessel weight, area, and the tension developed in response to phenylephrine was examined. The carotid artery rings from the pregnant animal weighed less (1.61 ± 0.03 mg versus 1.83 ± 0.04 mg, $p < 0.0001$) and had a smaller surface area (1.5 ± 0.03 mm² versus 1.70 ± 0.04 mm², $p = 0.0001$) compared with the nonpregnant animal. However, there was no significant difference in the tension developed in response to 10^{-7} mol/L phenylephrine (53.7 versus 54.8 mg/mm², $p = 0.26$). The uterine artery rings from the pregnant animal weighed more (0.41 ± 0.02 mg versus 0.3 ± 0.01 mg, $p < 0.0001$) and had more surface area (0.85 ± 0.05 mm² versus 0.55 ± 0.02 mm², $p < 0.0001$). There was a significant increase in the tension developed in response to phenylephrine in the uterine artery during preg-

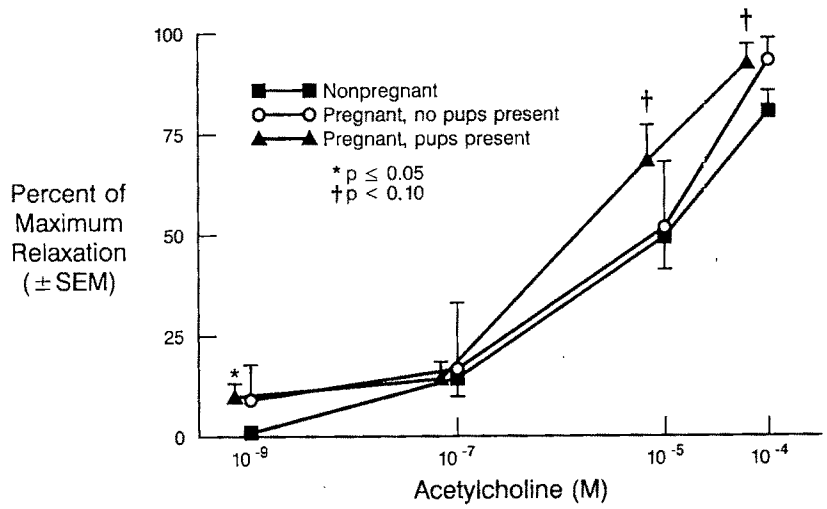

Fig. 3. Efficacy of acetylcholine for uterine artery (defined as percentage of relaxation per dose acetylcholine divided by maximum relaxation achieved in that arterial ring) preconstricted with phenylephrine (10^{-7} mmol/L) was increased during pregnancy (control, $n = 12$; no pups, $n = 3$; pups, $n = 8$). Repetitive measures two-way ANOVA: dose, $p < 0.0001$; pregnancy status, $p = 0.0002$; interaction, $p = 0.03$. * and † Compared with nonpregnant animal.

nancy (30 ± 2.7 mg/mm² versus 21 ± 2.3 mg/mm², $p = 0.01$).

Despite the small diameter of the uterine vessels, they were successfully suspended on the tungsten wire with minimal trauma (Fig. 5). There were no differences observed under the scanning electron microscope between uterine artery rings from pregnant (23 rings, 7 animals) and nonpregnant (16 rings, 5 animals) guinea pigs in terms of either the number of endothelial cells per square micrometer (pregnant, 13.2 ± 0.5; nonpregnant, 12.3 ± 0.6) or the percentage of surface area estimated visually to be denuded of endothelium both at the start and completion of the experiments (each <1%). However, because the surface area of the uterine rings from the pregnant animal was significantly larger than that of the nonpregnant animal, the calculated total number of endothelial cells per ring was also higher during pregnancy (pregnant, 12,205 ± 588; nonpregnant, 9904 ± 937; $p = 0.035$). Rings from both pregnant and nonpregnant animals revealed an apparent loss of endothelium (cells per square micrometer) during the course of the experiment (12 arteries from pregnant, before = 14.3 ± 0.5, after = 12.1 ± 0.7, $p = 0.02$; 8 arteries from nonpregnant, before = 14.1 ± 0.4, after = 10.4 ± 0.7, $p = 0.0003$). This may reflect a small degree of either tissue swelling or stretching during the course of the experiment inasmuch as the area denuded did not increase over the course of the experiment.

Comment

Numerous investigations during the past decade have documented the importance of the endothelium in a host of functions.[10, 21] In vitro studies of vascular smooth muscle function that did not specifically confirm endothelial integrity may have resulted in misleading conclusions concerning vascular responsiveness. For example, acetylcholine-mediated and serotonin-mediated relaxation is dependent on the presence of functional endothelium. In the absence of endothelium, the addition of a low concentration of either causes constriction rather than dilation.[10, 22]

The effect of pregnancy on endothelium-derived relaxing factor has not been studied directly. Bell and colleagues[11, 12] observed that acetylcholine produced hyperemia of the isolated guinea pig uterine horn only during pregnancy or after estrogen supplementation. Two recent reports have dealt with the effect of estrogen on endothelium-derived relaxing factor in the castrated rabbit. Gisclard et al.[23] reported that treatment with 17β-estradiol increased endothelium-dependent relaxation to acetylcholine (3×10^{-9} to 3×10^{-6} mol/L) in the femoral artery. In agreement with the present study, the enhancement was most obvious at the lower concentrations. Miller et al.[24] reported that treatment with 17β-estradiol enhanced acetylcholine-mediated relaxation of the uteroovarian artery obtained from castrated rabbits but did not alter the acetylcholine-mediated relaxation of either the carotid artery or the aorta from the same animal.

In studies by both Gisclard and Miller, the quantity of estrogen given increased the circulating estradiol concentration to estrus-like concentrations and did not alter norepinephrine sensitivity[24] as is typical of pregnancy.[25] Whereas their observations clearly demonstrate an estrogen affect on acetylcholine-mediated endothelium-dependent relaxation, their model does not necessarily mimic pregnancy. In the present study,

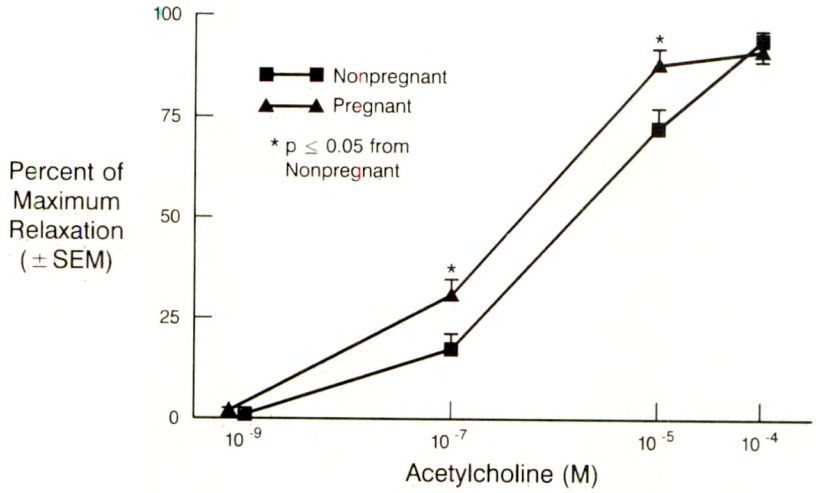

Fig. 4. Efficacy of acetylcholine for carotid artery preconstricted with phenylephrine (10^{-7} mmol/L) was enhanced during pregnancy ($n = 13$). Repetitive measures two-way ANOVA: dose, $p < 0.0001$; pregnancy status, $p < 0.0001$; interaction, $p < 0.0001$. * and † Compared with nonpregnant animal.

we documented a significant enhancement of acetylcholine-mediated relaxation and sensitivity for both the uterine and carotid arteries. That the response of these vessels was altered suggests that the stimulus that leads to the alteration is systemic rather than confined to the uterine vasculature at least by late pregnancy, as was studied here. We cannot explain the observation that the response of rings from uterine arteries that supplied a horn without a pup showed an effect intermediate to the nonpregnant and pregnant animals with a pup present.

Could our observations be a result of increased release of prostacyclin during pregnancy? Though the small diameter of the uterine artery precluded reproducible mechanical disruption of the endothelium without smooth muscle damage, and neither saponin nor indomethacin were used in the present investigation, the relaxation stimulated was very short-lived (<30 seconds total). This differs from prostacyclin. In addition, Gisclard et al.[23] documented that the enhancement of acetylcholine-mediated relaxation in the castrated rabbit after 17β-estradiol was unaltered by indomethacin. Thus the most likely explanation for our observation of increased relaxation and sensitivity to acetylcholine is an alteration of either endothelium-derived relaxing factor release or vessel responsiveness. The observed pregnancy-associated increase in the absolute number of endothelial cells (about 30%) is not likely the sole explanation because there was no significant change in the total number of endothelial cells per unit area. Further investigation is under way to examine this issue.

We cannot, at this time, determine whether the observed changes are a result of either increased release of endothelium-derived relaxing factor per activated muscarinic receptor, increased receptor number, or increased smooth muscle sensitivity to endothelium-derived relaxing factor. Each is plausible. In uterine artery from a castrated rabbit, 17β-estradiol replacement does not alter the endothelium-dependent re-

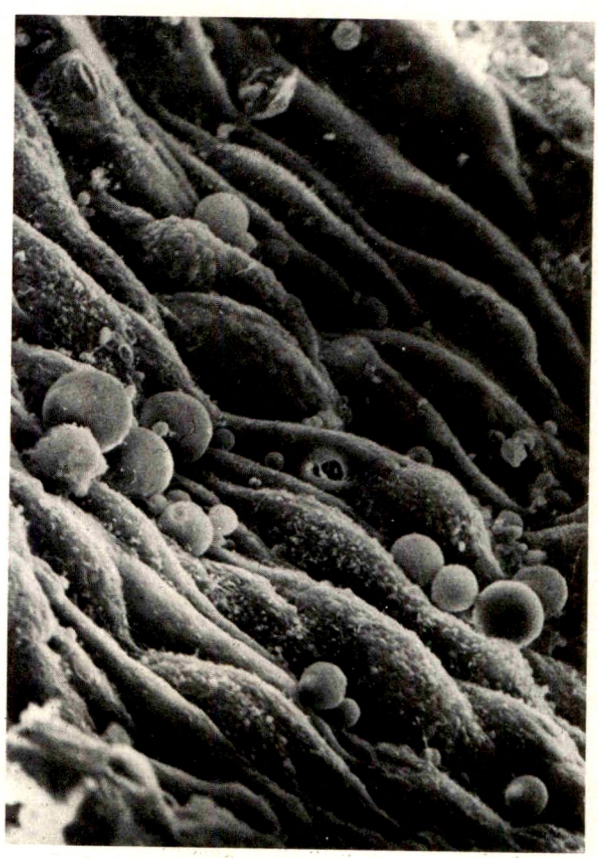

Fig. 5. Representative scanning electron microphotograph of uterine artery from nonpregnant animal after experiment. Note anatomically confluent endothelium.

sponses to the calcium ionophore A23187.[23] This would argue against increased sensitivity of the vascular smooth muscle to endothelium-derived relaxing factor, assuming A21387 and acetylcholine release the same factor (which is controversial[26]). And, as previously noted, estrogen replacement does not mimic pregnancy per se. Endothelial cells contain muscarinic receptors[27] and estrogens augment the number of muscarinic receptors in the rat hypothalamus.[28] Therefore one possible explanation of increased release of endothelium-derived relaxing factor in response to acetylcholine during pregnancy may be an estrogen-mediated increase in the number of endothelial cell muscarinic receptors. Blockade of these receptors prevents acetylcholine-stimulated release of endothelium-derived relaxing factor.

α-Adrenergic receptors appear to be involved in estrogen-induced rat uterine hyperemia.[29] The affinity and subtypes of β-adrenergic receptors is affected by estrogen treatment of rabbits and rats.[30, 31] Because the arterial rings in this study were preconstricted with phenylephrine, the observed effect of pregnancy may reflect an alteration of adrenergic responsiveness. The degree of vessel preconstriction might alter endothelium-derived relaxing factor release, and in this study there was a small but statistically significant difference in the force generated by the uterine arteries of pregnant and nonpregnant animals in response to phenylephrine (10^{-7} mol/L). Changes in disposition can be ruled out because neuronal and extraneuronal uptake of catecholamines were blocked. In conclusion, we believe the most likely explanation for the finding of increased acetylcholine-mediated arterial relaxation during pregnancy is a pregnancy-mediated enhancement of endothelium-derived relaxing factor activity.

Effect of pregnancy on uterine and carotid artery response to norepinephrine, epinephrine, and phenylephrine in vessels with documented functional endothelium

Carl P. Weiner, MD,[a] Ernest Martinez, BA,[a] David H. Chestnut, MD,[b] and Abdi Ghodsi, BS[a]

Iowa City, Iowa

The effect of pregnancy on arterial sensitivity to vasoconstrictors is controversial. Some of the controversy may reflect methodologic differences. Vessel reactivity in vitro is altered by both the tension placed on the segment and the presence or absence of functional endothelium. We investigated the effect of pregnancy on guinea pig uterine and carotid arteries to norepinephrine, epinephrine, and phenylephrine. Each vessel segment was stretched to the optimal point along its length-tension curve, and functional endothelium was documented by acetylcholine-stimulated relaxation. A significant dose-response relationship was observed in each vessel for each agent (each $p < 0.0001$). Pregnancy was demonstrated to be associated with a significant reduction in both uterine artery response and sensitivity to norepinephrine, epinephrine, and phenylephrine. However, there was no consistent pregnancy-associated effect on carotid artery response and sensitivity. (Am J Obstet Gynecol 1989;161:1605-10.)

Key words: Pregnancy, catecholamines, endothelium, vascular smooth muscle, in vitro, guinea pig

Many pregnancy-mediated alterations of physiology are known, although the cause(s) are not always clear. Recently we reported enhanced endothelium-derived relaxing factor activity during pregnancy in the uterine and carotid arteries of the guinea pig.[1] Various agents including catecholamines, prostacyclin, histamine, serotonin, and bradykinin stimulate endothelium-dependent relaxation through endothelium-derived relaxing factor release.[2] It is also known that the degree of stretch placed on the vessel (shear or tangential) and the rate of flow through the vessel alters the release of endothelium-derived relaxing factor and consequently the response of the smooth muscle to various vasoconstrictors.[3-6] Prior in vivo study on the effects of catecholamines on uterine blood flow demonstrated decreased sensitivity to norepinephrine and epinephrine during pregnancy.[7-10] Results of the few studies on the effect of catecholamines on isolated vessels obtained from pregnant animals[11-13] seem at odds with the in vivo observations. To our knowledge in no instance has both functional endothelium been confirmed and the vessel placed at its individual optimal resting tension before in vitro experimentation. The purpose of this investigation was to determine the effect of pregnancy on arterial responsiveness in vitro to norepinephrine, epinephrine, and phenylephrine in a vessel stretched to its optimal resting tension and with its endothelium documented to be functionally intact.

Material and methods

This study was approved by the University of Iowa Animal Use Committee. Adult female nonpregnant

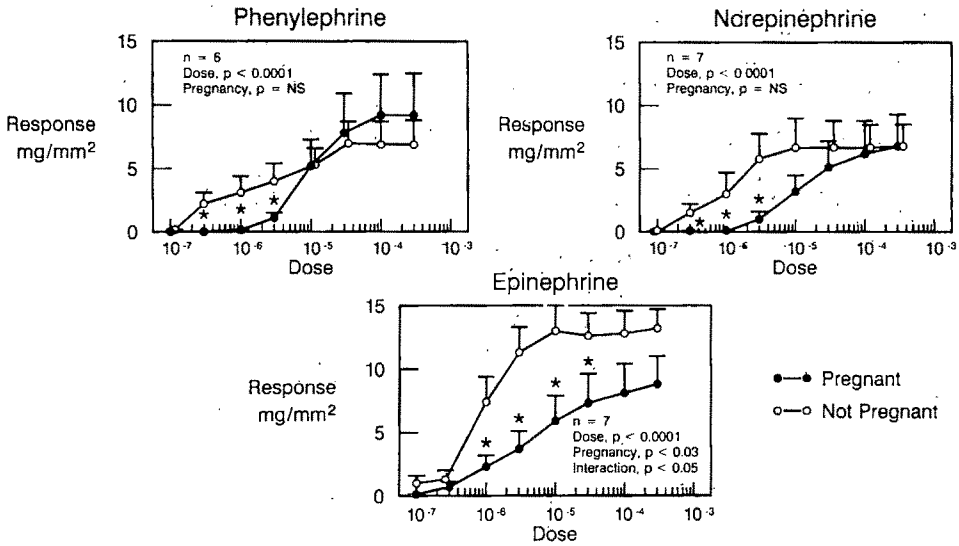

Fig. 1. Uterine artery force (milligrams per square millimeter) developed in response to phenylephrine, norepinephrine, and epinephrine. Dose reflects final molar concentration of drug in vessel bath. *p* Values for dose, interaction, and pregnancy result from two-way analysis of variance with dose and pregnancy status as independent variables. *Asterisk* reflects sensitivity (comparison of pregnant and nonpregnant animals' responses for individual doses).

and pregnant (50 to 60 days, term 65 to 68 days) guinea pigs (600 to 1000 gm) were anesthetized (ketamine 80 mg/kg intraperitoneally, xylazine 3 mg/kg intramuscularly). While 100% oxygen was applied by mask, the common carotid and main uterine arteries were removed en bloc with microsurgical instruments and an operating microscope. The common carotid artery was considered unlikely to be altered by pregnancy and served as a control vessel. The main uterine artery was selected because it directly supplies the conceptus and is thus most likely to be altered by pregnancy. The unstretched inner diameter of the uterine artery from the nonpregnant guinea pig ranges from 90 to 150 μm and would be considered resistance-sized, although in the guinea pig it is a conduit vessel.

The vessels were immediately placed in iced Krebs-Ringer bicarbonate solution (composed of sodium chloride, 6.914 gm/L; potassium chloride, 0.3505 gm/L; calcium chloride dihydrate, 0.328 gm/L; magnesium sulfate heptahydrate, 0.295 gm/L; potassium phosphate, monobasic, 0.164 gm/L; sodium bicarbonate, 2.1 gm/L; and glucose, 2.0 gm/L). Under the microscope, the arteries were cleaned sharply of connective tissue, cut into 3 mm rings, and suspended on two 50 μm tungsten triangles. One triangle was attached to a stationary rod and the other to a strain-gauge transducer (Grass FT 0.03) for the measurement of isometric force.[14, 15] The arterial segments were suspended in a 25 ml drop-away vessel chamber filled with Krebs-Ringer solution aerated with 95% oxygen and 5% carbon dioxide and maintained at 37° C. All experiments were performed in the presence of desipramine (10^{-5} mol/L) to block neuronal uptake and hydrocortisone (10^{-5} mol/L) to block extraneuronal uptake of catecholamines.[16, 17] Propranolol (10^{-5} mol/L) was added to inhibit β-adrenergic receptors.

After at least 60 minutes in the vessel bath, each ring was stretched to the optimal point of its length-tension curve as determined by the tension provoked by potassium chloride (10^{-4} mol/L) added at each stretch level. The optimal resting tension was defined as that point on the length-tension curve where the maximal response to potassium chloride was obtained. The presence of functional endothelium at the beginning (and end) of the experiment was documented by adding acetylcholine (10^{-4} mol/L) to the ring after preconstricting it with submaximal phenylephrine (10^{-7} mol/L). On the basis of prior study,[1] at least 20% relaxation was considered indicative of functional endothelium. In this same study, anatomic integrity of the endothelium was shown under the scanning electron microscope.

The following drugs were used in the experiments: acetylcholine chloride, norepinephrine hydrochloride, epinephrine hydrochloride, phenylephrine hydrochloride, desipramine, hydrocortisone, and propranolol hydrochloride (Sigma Chemical Co., St. Louis); ketamine hydrochloride (Bristol Myers Co., Syracuse, N.Y.); xylazine (Miles Laboratories, Shawnee, Kan.). All drugs and buffers were prepared fresh with distilled water on the day of study and kept on wet ice. All concentrations were expressed as the final molar concentration in the organ bath. After demonstrating functional endothelium, serial cumulative dose-response curves[18] were performed on each ring using norepinephrine, epinephrine, and phenylephrine applied in a random

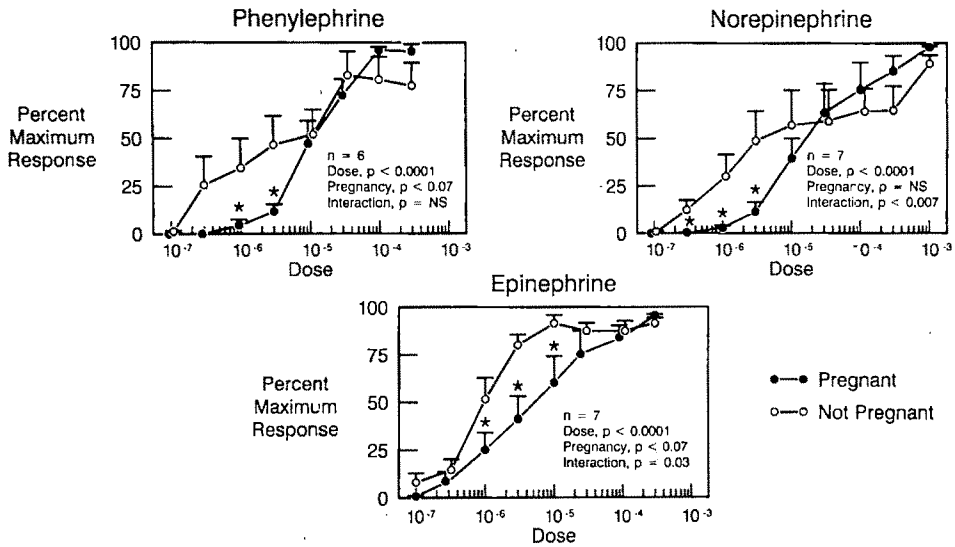

Fig. 2. Efficacy of phenylephrine, norepinephrine, and epinephrine on uterine artery. Dose reflects final molar concentration of drug in vessel bath. *p* Values for dose, interaction, and pregnancy result from two-way analysis of variance, with dose and pregnancy status as independent variables. *Asterisk* reflects sensitivity (comparison of pregnant and nonpregnant animals' responses for individual doses).

order (each 10^{-8} to 10^{-4} mol/L). At the conclusion of the experiment, the vessel segments were cut open longitudinally, the dimensions were measured, and the segments were blotted dry and weighed. The vessel wall cross-sectional area was calculated so that the isometric force generated could be normalized for muscle mass.[19] The response to an agent was expressed in terms of the force generated by each dose of the study agent (milligrams per square millimeter) and the force generated divided by the maximum force generated during the performance of that dose-response curve, i.e., the percent of the maximum.

Data are expressed as mean ± SEM; *n* indicates the number of animals. There were significant differences in the responses between animals. Therefore the effect of pregnancy and dose on vessel constriction was determined by a two-way random block analysis of variance with either response or percent response as the dependent variable and dose and pregnancy as independent variables (blocking by animal). If the mean values were found to be significantly different, a *t* test with Bonnferoni correction was used to reflect differences in sensitivity between pregnant and nonpregnant animals. Thus, despite relatively large standard errors as a result of interanimal variability, statistically significant differences between treatment groups and their dose response curves could be discerned. The comparisons were considered statistically different if $p \leq 0.05$.

Results

For each of the three agents studied a significant drug dose-response relationship was documented in uterine and carotid arteries obtained from pregnant and nonpregnant guinea pigs ($p < 0.0001$ for all). The response and sensitivity of the uterine artery were decreased during pregnancy for phenylephrine, norepinephrine, and epinephrine (Figs. 1 and 2). Each agent showed a higher ED_{30} (30% effective dose) during pregnancy ($p < 0.05$). There were no persistent differences observed for the response of carotid arteries obtained from pregnant and nonpregnant animals for any of the three agents (Fig. 3). However, there was a slight increase in the percent maximum response of norepinephrine for the carotid artery at the high end of the dose range ($p = 0.04$) during pregnancy (Fig. 4).

Comment

Although it is frequently stated that the sensitivity of the uterine artery to a variety of vasoconstrictors is reduced in vivo during pregnancy,[7-10] the finding is not universal in in vitro studies. Van Nimwegen and Dyer[11] compared strips of uterine artery obtained from nonpregnant women to those obtained from pregnant sheep. The tension on the strip was not standardized. They observed that norepinephrine and epinephrine in vessels from pregnant and nonpregnant donors were *equal* in vasoconstrictor activity. This particular technique has a high probability of damaging the endothelium. Assali et al.[12] compared uterine artery responsiveness to norepinephrine in vessels obtained from pregnant and nonpregnant sheep. They observed an *increase* in the response of the uterine artery during pregnancy to norepinephrine. In this study the investigators used vessels from different portions of the uterine arcade in an attempt to control for the changes in

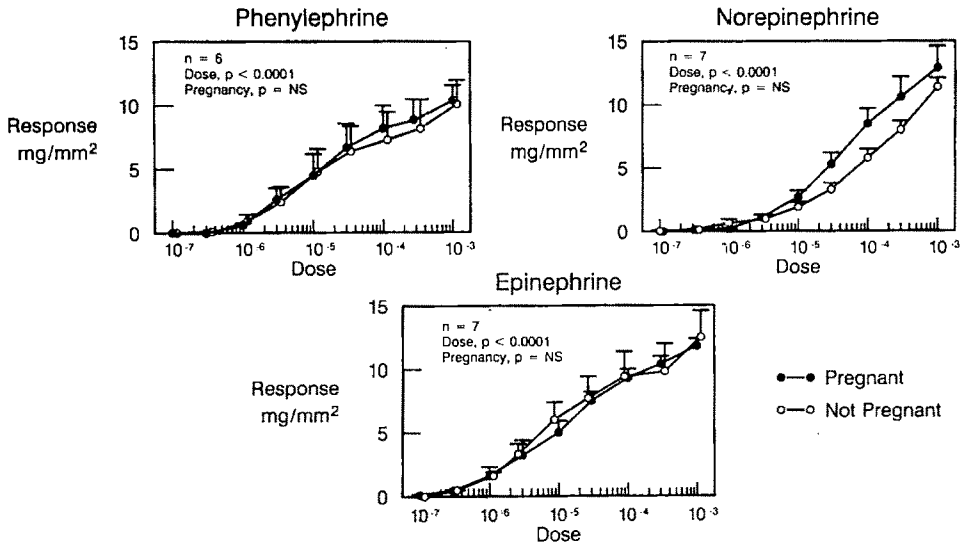

Fig. 3. Carotid artery force (milligrams per square millimeter) in response to phenylephrine, norepinephrine, and epinephrine. Fig. 4. Efficacy of phenylephrine, norepinephrine, and epinephrine in carotid artery. Dose reflects final molar concentration of drug in vessel bath. *p* Values for dose, interaction, and pregnancy result from two-way analysis of variance, with dose and pregnancy status as independent variables. *Asterisk* reflects sensitivity (comparison of pregnant and nonpregnant animals' responses for individual doses).

size of the uterine artery that occur with pregnancy, assuming that the segments would respond similarly if pregnancy were not a factor. Each of the aforementioned studies was performed before the general realization of the importance of the endothelium in vascular responsiveness. In 1985 Nunotani et al.[13] reported that the response of the uterine artery in the sow to norepinephrine was *enhanced* during pregnancy.[13] Functional endothelium was not documented. Our study of the guinea pig uterine artery with documented functional endothelium and stretched to its optimal resting tension supports the in vivo reports of decreased sensitivity to catecholamines during pregnancy.

The cause of this diminished sensitivity is unclear. Some investigators have suggested that it is mediated

by either estrogen or an estrogen-like substance.[20, 21] α-Adrenergic receptors are involved in estrogen-induced rat uterine hyperemia.[22] The affinity and subtypes of α-adrenergic receptors are affected by estrogen treatment of rabbits and rats.[23, 24] Thus the observed effect of pregnancy may reflect an alteration of adrenergic responsiveness, but this view is controversial.[21] In general, these studies have focused on receptor number, affinity, coupling, etc. However, there are other possibilities. There is an increase in uterine artery production of prostacyclin[25] and endothelium-derived relaxing factor[1] during pregnancy and catecholamines are capable of stimulating their release.[2] Thus altered α-receptor activity would not be necessary if α-stimulation was countered by the release of a vasodilatory substance. Further study is necessary to elucidate the roles of these agents in uterine artery responsiveness to catecholamines.

The effects of pregnancy on the response of systemic vessels to vasoconstrictors are also controversial. Both increases and no change in the sensitivity of the femoral artery to norepinephrine have been reported.[11, 26] Another study reported decreased responsiveness of the perfused tail artery of the rat to norepinephrine during pregnancy.[27] In our study, there was no consistent pregnancy-associated alteration in carotid artery response to the three agents studied.

The uterine artery undergoes rapid growth during pregnancy in association with a twentyfold to fortyfold increase in blood flow.[28] The increased diameter is not simply the result of passive dilation. Vascular smooth muscle hypertrophy and hyperplasia are fairly well documented in the uterine artery of a variety of species during pregnancy.[1, 28] We recently demonstrated an increase in uterine artery mass and endothelial number in the pregnant guinea pig.[1] This increase in smooth muscle content might theoretically be associated with an increase in the force-generating capacity of the vessel. However, this was not reproducible when the force generated by the arterial ring was corrected for cross-sectional area.

In summary, we observed that there is a pregnancy-related decrease in both the force generated and efficacy in the uterine artery to phenylephrine, norepinephrine, and epinephrine during pregnancy and that there is no consistent change in the force-generating capacity and efficacy of the guinea pig carotid artery during pregnancy when the endothelium is functional and the arterial segment is stretched to its optimal resting tension.

Evaluation of pulsed Doppler echocardiography for measurement of aortic blood flow in the fetal lamb

Jean-Claude Veille, MD,[a] Michael Tavill, BA,[a] Mark Sivakoff, MD,[b] Ilan Cohen, MD,* Moshe Ben-Ami, MD,* Yuh-Cheng Yang, MD,* and Vasil Jovkovsky, MD*

Cleveland, Ohio

The purpose of this study was to assess the accuracy of a quantitative, range-gated, two-dimensional Doppler echocardiography method for measurement of blood flow in the fetal lamb descending aorta. Comparison was made between this method and measurements determined by an electromagnetic flowmeter placed directly on the aorta in the chest of the fetus. Stroke volume was manipulated acutely either by the removal of blood, the addition of fluid by injection, or by pharmacologic means. During each procedure, descending aortic blood flow was estimated by the Doppler ultrasonography method and compared to the flowmeter recording. The size of the lumen of the aorta determined by echocardiography was correlated with direct measurement during surgery and at autopsy. A total of 359 flow measurements were obtained in 15 fetuses. Doppler ultrasonographic flow studies and electromagnetic flowmeter measurements were found to be highly correlated ($r = 0.93$). The study demonstrates the accuracy and reliability of the two-dimensional pulsed Doppler echocardiography method for measurement of blood flow in the descending aorta in the fetal lamb. (Am J Obstet Gynecol 1989;161:1610-4.)

Key words: Pulsed Doppler echocardiography, fetal lamb

Doppler ultrasonography for measurement of cardiac output has been shown to be an accurate, reliable, noninvasive method in both adults and children. Several studies report a good correlation between cardiac output determined by Doppler ultrasonography and cardiac output measurements obtained with the Fick method[1] or thermodilution.[2, 3] Although quantitative ultrasonographic assessment of the human fetal cardiac function has been published,[4, 5] validation of this noninvasive technique is insufficient.

The purpose of this study was to evaluate the accuracy of blood flow rates measured in the fetal lamb descending aorta with range-gated, two-dimensional pulsed Doppler ultrasonography by comparing them to measurements obtained simultaneously with an electromagnetic flowmeter that had been previously placed on the descending aorta.

Material and methods

Experimental animals. A total of 15 fetal lambs were studied (mean body weight 3252 gm ± 846 gm) at a mean gestational age of 135.5 days ± 2.1 days (SD). Food was withheld from the ewe for 48 hours and water was withheld for 24 hours before surgery.

Lactated Ringer's solution (1000 ml) was given through a large bore catheter (No. 14) placed in the external jugular vein. General anesthesia was induced

with ketamine 4 mg/kg and was maintained with ketamine 3 mg/kg per hour administered intravenously. Ventilation was continued through a tracheostomy with inspired gas of ≥50% oxygen in nitrous oxide. Muscle relaxation was achieved with 0.15 mg/kg of pancuronium bromide.

Electromagnetic probe placement. The sheep was shaved and a midline incision was made to expose the uterus. An area distal to the cotyledons (usually close to the uterine septum) was chosen to avoid bleeding and abruptio placentae. A purse-string suture was placed around the myometrium with 1-0 chromic catgut. A second purse-string suture was placed around the amnion to decrease the loss of amniotic fluid. The fetal lamb was then partially delivered to the level of the sternum. A temporary suture was placed to secure the chest and the back of the fetus to the myometrium. Care was taken to avoid compression of the umbilical cord during the surgery. The fetal external jugular vein was identified and a large caliber (inner diameter 3.0 mm) plastic tube was introduced into the lumen of the vessel and advanced to the level of the atrium. The tube was fixed by sutures to the skin of the neck. The chest was opened at the level of the fifth rib and the pleura was carefully incised to expose the descending aorta. The adventitia was opened longitudinally, the size of the vessel was measured, and a precalibrated cuff-type electromagnetic flow probe (In Vivo Metric System, Healdsburg, Calif.) with a lumen diameter of either 8 mm or 10 mm was placed distally and adjacent to the ductus arteriosus and secured with ligatures. A water-inflatable occluder of a corresponding diameter was secured distally to the electromagnetic flowmeter. Occlusion of the vessel was accomplished transiently by the injection of water into the tubing with a 3 ml syringe. All occluders were checked at the time of the surgery. Both the tubing and cable were externally fixed to the chest wall. The chest was closed and the fetus was returned completely to the uterine cavity. The purse-string sutures were tied after introduction of normal saline solution (0.9% wt/vol) into the amniotic cavity to restore the amniotic fluid loss. The maternal skin incision was closed.

Electromagnetic study. Returning signals were displayed on a Carolina Medical Electronics flowmeter (model FM 501, Burlington, N.C.), properly grounded to the sheep, and mean flow was transcribed on a two-channel recorder (Gould, Cleveland, Ohio). The flow probes used were previously calibrated for their linearity and sensitivity with an in vitro preparation. The flow probe was attached to a segment of external jugular vein from a sheep that had been put to death, and 500 ml of heparinized blood was introduced at a constant rate into a closed circuit circulation system. The flow rate was checked with a beaker and stopwatch technique. A gradual restriction to flow was applied distal to the segment of vessel to vary flow rate. The vessel was maintained distended and wet to ensure a good electrical contact between the vessel and the flow probe. An excellent linear correlation

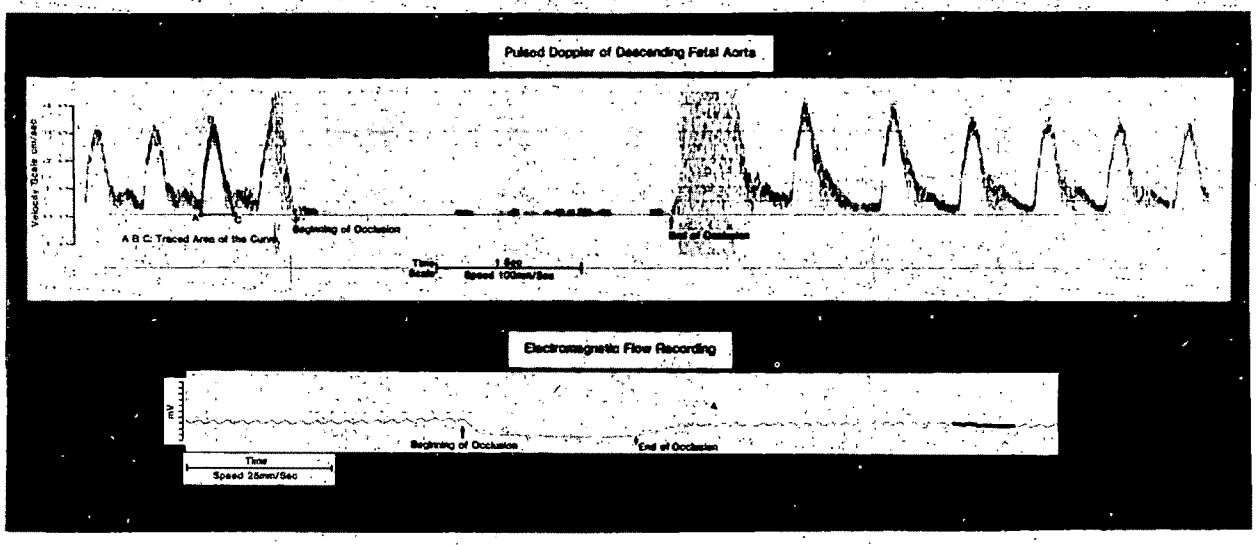

Fig. 2. Typical Doppler tracing of descending aorta of fetal sheep. Waveform was analyzed by placement of digital pen on point *A* of curve and tracing curve out (i.e., joining point *A* to *B* to *C*). This was done to obtain time velocity integral. Quantity of blood flowing through that vessel was calculated with use of area of that vessel. Results are expressed in cubic centimeters per beat.

was shown between voltage and flow for both flow probes ($r = 0.98$, $p < 0.01$, $n = 35$) for probe No. 10, and $r = 0.97$, $p < 0.01$, $n = 27$ for probe No. 8).

Doppler ultrasonography and blood flow measurement. The probe (Ultra Mark 8 mechanical sector, Advanced Technology Laboratories, Bothell, Wash.) was placed (scan heads with either 3 or 5 MHz frequencies, Fig. 1) on the maternal abdominal wall and the descending fetal aorta was identified. The size of the vessel was evaluated on a still frame during systole (inner to inner walls). Comparison between aortic measurements obtained by ultrasonography and those at autopsy was 7.4 mm ± 2 mm and 7.5 mm ± 2 mm, respectively. By placing the probe parallel to the vessel with the two-dimensional echocardiographic image, thereby keeping the angle close to zero, it was possible to keep the sample volume as small as possible. The Doppler ultrasonographic frequency shift was automatically corrected for the angle. The velocity scale was increased to provide maximum magnification of the Doppler ultrasonographic display. A hard copy was obtained with a strip chart recorder set at a speed of 100 mm/sec.

Experimental protocol. Twenty milliliters of blood or fluid was rapidly removed or added at a time through the large bore catheter placed in the external jugular vein of the fetal lamb. After completion of each withdrawal, simultaneous recordings of the two-dimensional Doppler ultrasonographic and electromagnetic flow measurements were obtained. A 30-second vessel occlusion was obtained at each recording to establish a dynamic calibration baseline zero. An average of 20 to 25 data points were obtained per animal. Pharmacologic agents atropine, epinephrine, or ritodrine (0.01 mg increments) were injected directly into the fetus to affect heart rate and thus the quantity of blood ejected per beat through that particular vessel.

Digitizing protocol. An average of the three cardiac cycles that immediately preceded the vessel occlusion was analyzed. The Doppler ultrasonography curve area was traced with a tablet digitizer and a stylus tip (Digisonics, Houston, Tex.) to include points A, B, and C (Fig. 2). The ascending part of the curve was usually a fine line that was easily traced. The middle of the most dense spectral display was traced. All signals below the baseline were not included in the tracing analysis (Fig. 2). This area under the curve is defined as the time velocity integral. The size of the vessel was obtained by two-dimensional echocardiography. The area of the vessel was computed by multiplying half of the diameter by π (½ of diameter^2 × π). The actual volume of blood that flowed through that vessel per heart beat was computed automatically by multiplying time velocity integral and the area of the vessel. Intraobserver variability for the tracing of the curves was limited because measurements were obtained by two investigators (J. C. V., M. S.).

Statistical analysis. A commercially available statistical package (Northwest Statpak, Portland, Ore.) was used to calculate the correlation coefficient between the actual flow measurement obtained with the electromagnetic flow probe and the pulsed Doppler ultrasonography measurement.

Results

A total of 359 measurements of the quantity of blood flow through the descending fetal aorta were ob-

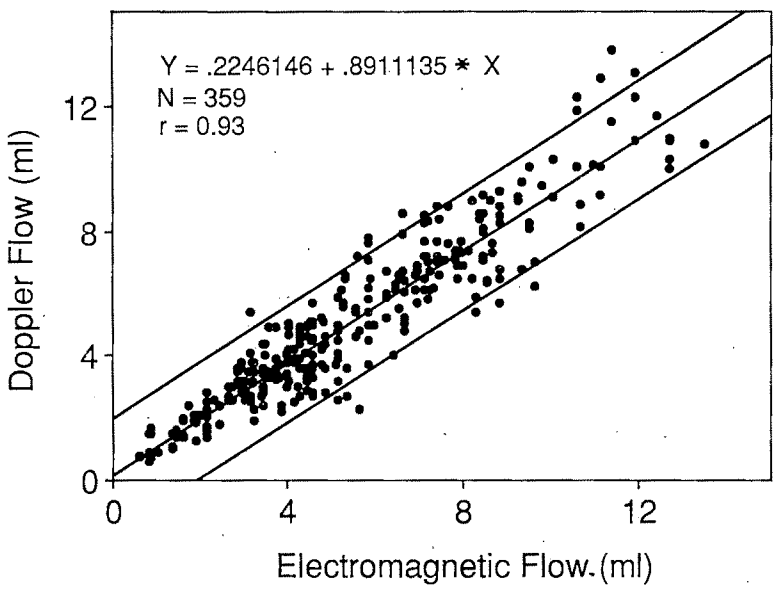

Fig. 3. Linear relationship between quality of blood flowing through fetal descending aorta per beat. Note that values are in ml (or ml/beat) because heart rate is not taken into consideration.

tained simultaneously over a range of 2 to 15 ml/beat with two-dimensional pulsed Doppler echocardiography and electromagnetic flow probe on 15 fetal lambs. There was an excellent direct linear correlation between electromagnetic flow and Doppler ultrasonography readings ($r = 0.93$, $p < 0.001$; Fig. 3) Interobserver variability (i.e., between two observers) and intraobserver variability (i.e., same curve traced by the same observer at different times) were found to be <5%.

Comment

This study suggests that two-dimensional pulsed Doppler ultrasonography can be used to reliably measure the quantity of blood flow in the descending aorta of the fetal lamb. Estimation of flow with this noninvasive technique gave an accurate calculation of flow, as compared to an invasive method such as an electromagnetic flowmeter. In this study, the electromagnetic flow probe was used as our reference standard. Although probes were "factory" precalibrated and had an electronic zero, we recalibrated all the flowmeters with a beaker and stopwatch technique with both a mechanical and electronic zeroing to correct for any possible signal drift. Furthermore, the phasic nature of the studies of blood flow pattern rendered a dynamic calibration necessary, especially when studying low flow rates.[6] Each period of analysis was coupled with a mechanical zero for reference. Care was taken not to constrict or kink the segment of the blood vessel that was being analyzed. The transducers used were chosen to maintain contact around the vessel to thereby minimize movement of the transducer. In our earlier experiments poor electromagnetic signals and gross artifacts occurred because of poor vessel contact. Careful scrutiny of placement and fixation of the electromagnetic flowmeter yielded more consistent results. The acute nature of these experiments did not allow for fibrosis to occur as a means of securing the flow probe. Nonetheless, the consistency of the signals attested to the constant contact between the flow probe and the vessel. As mentioned earlier, all the occlusions were placed downstream to the transducer to prevent additional breaks in the contact between flow probe and vessel. During the calibration of the flow probe, we checked its accuracy over the whole range of its scale to determine its sensitivity. Its reliability was found to be excellent at both low and high flow velocity. As we removed blood from the fetus and reinjected saline solution, the fetal hematocrit was altered and thus could have affected the sensitivity of the flow probe.[7, 8] Notwithstanding the above comments, we showed that the flow measurements obtained with electromagnetic flowmeters were precise and reproducible, and that we were justified in their use as our reference standard.

Estimation of the quantity of blood flow with the use of Doppler ultrasonography greatly depends on the ability to accurately measure the size of the vessel (i.e., its cross-sectional area) and to keep the angle between the ultrasound beam and the direction of the blood flow as close to zero as possible. With the use of various focal depths (maximum display depth, 25 cm) we were able to measure the descending aortic diameter with reliable accuracy. A small error in measurement of the vessel size could result in a large flow error because the

diameter is squared to calculate the area and the flow through the vessel under study.[9] Maintenance of the angle as low as possible gave the best and most reliable Doppler ultrasonographic tracings as judged by best correlation with electromagnetic measurements. In all analyses, the angle was kept close to 20°. Such deviation in the angle should not alter estimation of the quantity of blood flow, as the cosine of the angle is close to 1,[10] and error of measurements will be <6%.[11]

With pulsed Doppler ultrasonography we were able to place the sample volume in close proximity to the electromagnetic flow probe. This is a major advantage in the use of such a technique, as the precise location and depth of sample are known. Even with such positioning, there was some spectral dispersion of the Doppler ultrasonography velocity curve. Although the middle of the most dense portion of the velocity shift was traced, there was an element of subjectivity in locating this zone. By standardization of these tracings we improved the reproducibility and correlation with electromagnetic flow probe measurements.

Despite certain theoretical and practical difficulties in the use of two-dimensional Doppler echocardiography to quantify flow through deep vessels such as those of the intrauterine fetus, we have shown that these can be overcome. Our results indicate that this method can reliably determine, in a noninvasive manner, the quantity of blood flow through the descending aorta in the ovine fetus.

We thank Dr. Mark Morton of the Department of Cardiology at Oregon Health Sciences University for his indispensable help and Dr. Merrill Adams for his technical assistance.

Lymph flow rate response to angiotensin II is decreased in pregnant sheep

Guillermo J. Valenzuela, MD, and Lawrence D. Longo, MD
Loma Linda, California

Pregnancy in humans is associated with a number of physiologic changes including interstitial fluid retention (edema) and a decrease in the systemic vascular response to infused angiotensin II. In nonpregnant sheep angiotensin II increases the lymph flow rate by what appears to be a direct effect on the lymphatic vessels. The purpose of this study was to test the hypothesis that during pregnancy the lymph flow rate response to angiotensin II infusion is decreased in relation to that of the nonpregnant state. We speculate that a decrease in lymph flow may explain the interstitial fluid retention observed during human pregnancy. In nine nonpregnant and five pregnant chronically catheterized ewes, we infused angiotensin II at rates of 0.1, 10, and 1000 ng/kg/min during a 5-minute period, with intervals of at least 15 minutes between doses. At the highest angiotensin II dose, peak lymph flow rate increased 286% in pregnant ewes compared with an increase of 344% in the nonpregnant sheep ($p < 0.05$). No changes occurred in the intravascular volume, plasma or lymph protein concentration, or venous pressure. The arterial pressure responses to angiotensin II were decreased in pregnant sheep ($p < 0.05$). These results are compatible with a model for fluid retention in pregnancy in which a decreased lymph flow rate plays a significant role in interstitial fluid retention. (Am J Obstet Gynecol 1989;161:1615-9.)

Key words: Angiotensin II, fluid balance, pregnancy, lymph flow

Human pregnancy is associated with a number of cardiovascular changes, including increases of approximately 40% in blood volume, about 50% in cardiac output, and the retention of several liters of fluid in the interstitium.[1] The fluid distribution across the capillaries follows the balance between the hydrostatic and oncotic pressures on both sides of the capillaries as described by Starling's law.[2] The resulting forces are modified by the area of the surface of interchange and the protein permeability of the capillary walls.[3] Fluid and protein, representing ~30% of the total protein mass in the intravascular system, are transferred into the interstitium and returned to the systemic circulation by the lymphatic system. Thus one may speculate that relatively small changes in the lymph flow rate could produce significant retention of protein and fluid, thus altering the forces that affect the interstitial space oncotic and interstitial fluid pressure. We have previously postulated that angiotensin II may have a direct effect on lymphatic flow in nonpregnant ewes,[4] a concept supported by the findings of Dabney et al.[5] of the effects of angiotensin II in the dog's hind-paw lymphatics. During pregnancy, several animal species, including sheep[6] and man,[7] experience a decrease in systemic arterial pressure response to angiotensin II infusion, despite the fact that circulating levels of angiotensin II in the pregnant sheep during angiotensin II infusion are not statistically different from those in nonpregnant animals.[8] Therefore we tested the hypothesis that lymph flow response to angiotensin II infusion is decreased in pregnancy as compared with nonpregnant controls. Such a finding would suggest that during pregnancy the lymphatic system behaves in a manner similar to that of the systemic vascular system with a decreased responsiveness to vasoactive hormones. We hypothesize that if lympahtic contractility is decreased and if at the same time interstitial compliance is increased, more protein and fluid would remain within the interstitium and appear clinically as edema.

Material and methods

We used nine nonpregnant and five pregnant ewes, with body weights of 30 to 80 kg. The animals were obtained from a local breeder and housed in individual pens with artificial light (14 hours of light and 12 hours of dark) and ambient temperature of 22° C. The data on the nonpregnant animals have been described in detail elsewhere.[4]

Surgery was performed with the animals under general anesthesia as described in detail elsewhere.[4] Briefly, anesthesia was induced with intravenous Biotal (500 mg) and maintained by inspiration of 1.5% halothane

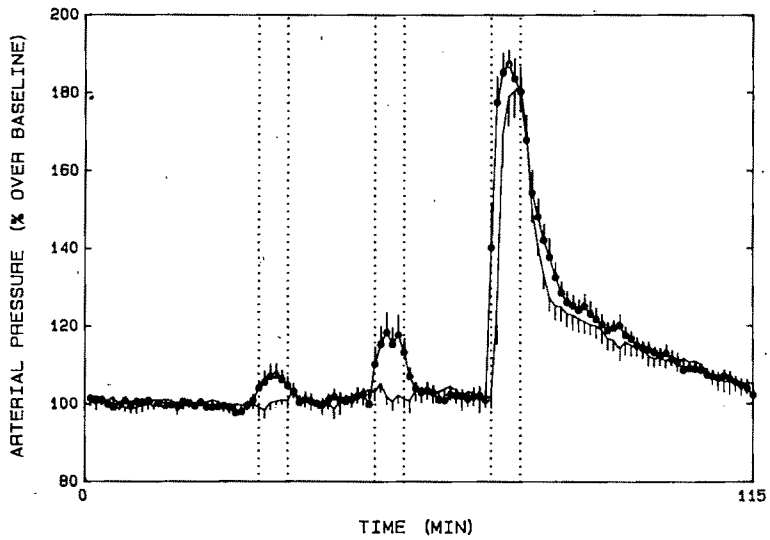

Fig. 1. Mean ± SEM arterial pressure (expressed as percent over baseline) is presented for pregnant (●——●) and nonpregnant (——) animals. Angiotensin II infusion is represented by interval between vertical *dotted lines*; the doses used were 0.1, 10, and 1000 ng/min/kg, respectively. The nonpregnant animals responded with higher arterial pressures ($p < 0.05$).

balanced with oxygen. Tygon catheters (inside diameter 1.27 mm) were placed through a neck incision in the thoracic duct, and one catheter was also placed in one of the internal jugular vein tributaries. The connection between these two vessels was made externally so as to allow the lymph to circulate undisturbed while allowing us easy access to the lymphatic vessels at the time of the experiments. We also catheterized a femoral artery and vein. Splenectomy was performed through a left flank incision. An incision was made 2 cm parallel to the left rib cage, centered about the midaxillary line. Once the incision was made into the peritoneal cavity, the loose fascial planes attached to the splenic capsule were released by blunt dissection. The spleen was then delivered through the incision, stretching the pedicle containing the splenic artery and vein; this pedical was then doubly clamped and tied with 1-0 nylon sutures. Occasionally other small vascular connections at the inferior pole were also ligated. Average blood loss from splenectomy was <50 ml, and the procedure added <10 minutes to the surgery. Postoperatively the animals received heparin, 30,000 IU intravenously daily and 15,000 IU subcutaneously twice a day.

Experimental protocol. The experiments were conducted 4 to 14 days after surgery. We measured lymph flow rate by draining the lymph into a continuously weighed vial ~30 cm below the level of the thoracic duct. The rate was calculated every 10 seconds from the differential of the vial's weight by the use of an online program. We returned the lymph to the animal every 10 minutes, by infusing the vial's content into the jugular vein. Samples for hematocrit and plasma and lymph protein concentration were obtained during the control period and immediately before and after each of the angiotensin II infusions. Protein concentrations were determined by a hand-held refractometer (American Optical, Buffalo). Arterial and venous pressures were measured continuously and averaged every 30 seconds; the values were stored for later analysis.

After a control period of 30 minutes, we infused angiotensin II at a dose of 0.1 ng/kg animal weight per minute for 5 minutes into the jugular vein. Then after a 15-minute observation period, we infused a dose of 10 ng/kg/min for 5 minutes followed by an observation period of 30 minutes. We then administered a third angiotensin II infusion at a rate of 1000 ng/kg/min for 5 minutes. Finally, all functions were measured for 40 minutes.

Data analysis. The data are presented as average ± SEM. To eliminate interanimal variability, the arterial pressure and the lymph flow rate are presented as percent over initial control. Group comparisons were performed by unpaired t test, and the changes with time for each variable were tested with a two-way analysis of variance (separated for pregnant and nonpregnant animals). The lymph flow rate responses were also analyzed by measuring the total area under the curve for pregnant and nonpregnant animals. We plotted the responses to angiotensin II infusion and cut out and weighed the area under the curve for both pregnant and nonpregnant ewes. Also we measured the amount of lymph collected during the first 10 minutes after the angiotensin II infusion for pregnant and nonpregnant animals.

Results

The values for pregnant and nonpregnant animals during the control period are presented in Table

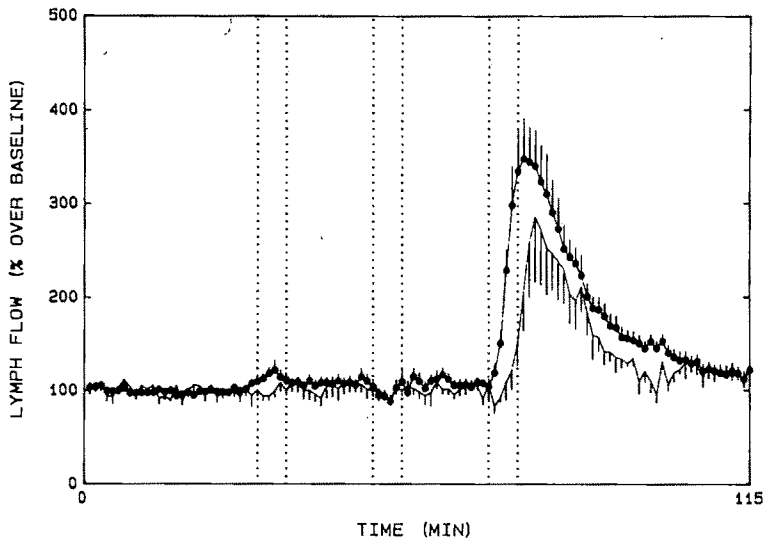

Fig. 2. Average ± SEM lymph flow rates (expressed as milliliters per minute over baseline) responses to angiotensin II are presented in nonpregnant (●——●) and pregnant (——) animals. Vertical *dotted lines* represent angiotensin II infusion doses of 0.1, 10, and 1000 ng/min/kg. There was no effect at lower doses, but at higher doses the response was significantly lower for pregnant ewes ($p < 0.05$).

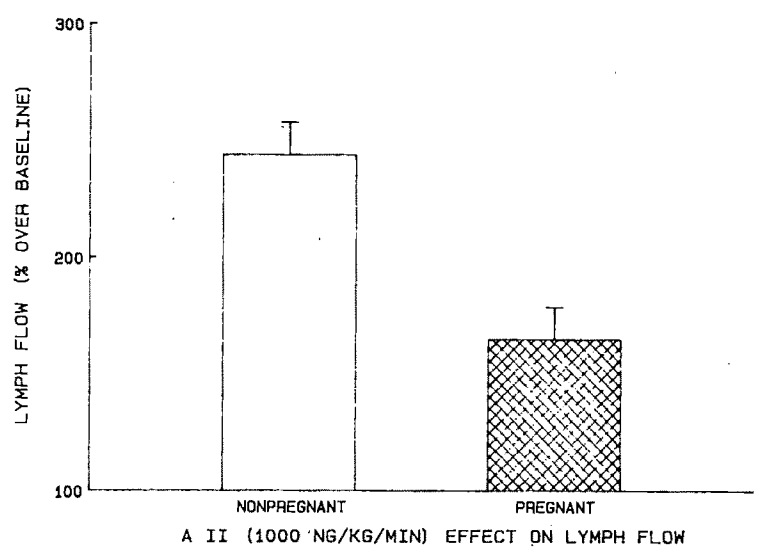

Fig. 3. Excess of lymph flow in response to the higher angiotensin II infusion dose (expressed as % over baseline) for pregnant and nonpregnant animals. The difference is significantly lower for pregnant animal ($p < 0.05$).

I. During the control period the arterial pressure was significantly higher for the nonpregnant ewes ($p < 0.05$). There were no statistical differences between the groups for lymph flow rate, venous pressure, hematocrit, plasma, or lymph protein concentration.

Fig. 1 presents the percent change of arterial pressure over baseline in association with angiotensin II infusion for both pregnant and nonpregnant ewes; there was a statistically higher pressor response at all angiotensin II doses in the nonpregnant animals ($p < 0.05$). Fig. 2 presents the lymph flow response for both groups expressed as the percent change over baseline. There was no change in the lymph flow rate at the two lower doses of angiotensin II even though arterial pressure was elevated in the nonpregnant animals. In absolute terms, after the maximum angiotensin II dose, lymph flow rate increased from a baseline of 2.46 ± 0.69 to 2.98 ± 0.7 ml/min in pregnant animals, as compared with the change from baseline of 2.93 ± 0.15 to 5.07 ± 0.57 ml/min for the nonpregnant group ($p < 0.05$). The ratio of the total area under the curve for nonpregnant/pregnant response was 1.65 ($p < 0.05$). The excess lymph flow during the first 10 minutes after angiotensin II infusion at the highest dose was also greater for the nonpregnant animals (Fig. 3) ($p < 0.05$).

Table I. Values during 30-minute control period

	Nonpregnant (mean ± SEM)	*Pregnant (mean ± SEM)*	*p Value*
Arterial pressure (mm Hg)	100.3 ± 3.7	84 ± 4.2	<0.05
Venous pressure (mm Hg)	7.9 ± 1.1	9.1 ± 0.7	NS
Lymph flow (ml/min)	2.93 ± 0.15	2.46 ± 0.69	NS
Hematocrit (%)	28.84 ± 1.17	26.24 ± 3.66	NS
Plasma protein (gm/dl)	6.3 ± 0.8	6.8 ± 0.2	NS
Lymph protein (gm/dl)	4.4 ± 0.5	5.1 ± 0.6	NS

There were no changes with time for venous pressure, hematocrit, plasma protein, or lymph protein in association with angiotensin II infusion for the pregnant or nonpregnant ewes ($p > 0.1$).

Comment

An understanding of fluid dynamics during pregnancy is important because appropriate fluid retention is associated with improved perinatal outcome.[9, 10] Furthermore, many clinical conditions such as preterm labor, heart disease, kidney disease, and preeclampsia are characterized by alterations of the total amount of fluid retained or its distribution. For instance, preterm labor is characterized by an expansion of blood volume less than that of the normal pregnant women who is delivered at term. In contrast, preeclampsia is characterized by a total fluid retention within normal limits, but it is distributed chiefly to the interstitium when the disease is more pronounced.[10]

The present finding of a relatively decreased lymph flow in response to angiotensin II infusion in pregnant animals as compared with nonpregnant animals is relevant to the problem of fluid dynamics during pregnancy. This is because it is compatible with pregnancy-associated hyporesponsiveness of the lymphatics to pressor hormones as a possible mechanism for interstitial fluid retention. For instance, a 5% lower fluid transport by the lymphatics may result in an interstitial fluid retention of ~100 ml/day; thus in a few days it could produce the retention of a significant amount of fluid and protein. One might argue that the increased lymph flow resulted from the increase in arterial pressure observed with the angiotensin II infusion. However, angiotensin II acts on the smaller arterioles and does not affect veins,[11] so we would not expect an effect on the capillary hydrostatic pressure. The lack of venous pressure change can be used as indirect evidence that the hydrostatic capillary pressure was not significantly changed. If the origin of the increase in lymph flow were the intravascular fluid, we would have expected a change in the microhematocrit in splenectomized animals. Furthermore, in experiments in which a greater transfer of fluid is obtained by increasing the local blood flow, there is a delay before the increase in lymph flow is apparent.[12] In addition, there were no changes in interstitial fluid pressure (as reflected by a lack of changes in venous pressure) or in the plasma or lymph protein concentrations (therefore the oncotic pressures remained stable). Thus with these direct and indirect measurements all parameters suggest that the increased lymph flow did not originate from the systemic circulation. Another possibility is that the excess lymph originated by mobilization of interstitial fluid; however, the lack of change in venous pressure strongly suggests that interstitial fluid pressure remained stable during the angiotensin II infusion.

We speculate that the decreased response to angiotensin II seen in pregnancy results in a decrease in lymph flow. Although the absolute values for lymph flow (expressed as milliliters per minute per kilogram) are not different for pregnant and nonpregnant animals in these results or in our previous study,[13] if a correction factor for the placenta, fetus, and amniotic fluid weights is used, the pregnant animals display a 20% lower lymph flow rate. The mechanism may involve a down-regulation of angiotensin II receptors similar to that thought to occur during pregnancy in rabbits.[14] Another possible mechanism could be the release and/or synthesis of compounds with vasodilator capability produced by angiotensin II infusion during pregnancy; it is well known that blocking prostaglandin production produces a disappearance of the angiotensin II resistance of pregnancy.[15]

Mechanisms other than alterations in the lymph flow rate can be postulated to explain edema formation during pregnancy. For instance, estrogen increases capillary permeability, thus augmenting the fluid and protein transferred across the capillary wall. The administration of fluid also produces an increase in the capillary passage of fluid; however, the steady state is maintained by a severalfold increase in the lymph flow rate, resulting in no net fluid retention in the interstitium.[2] For fluid and protein to be retained in the interstitium, it is also necessary that there be changes in the interstitial fluid space compliance. In this manner the interstitial space may contain more fluid without increasing the pressure. Otherwise, the elevation in interstitial fluid pressure would produce an increase in the lymph flow rate. Estrogen infusion produces fluid retention, mainly in the interstitium,[16] and the decrease of physiologic concentration of estrogen by castration in sheep decreases interstitial fluid space compliance.[17] The fluid and protein retention occur until a critical interstitial fluid volume is reached beyond which the interstitial pressure increases at the same rate as that

of a nonpregnant animal. At this time the lymph flow rate and the response to fluid infusion return to normal, as demonstrated by us in the pregnant sheep.[13]

In conclusion, pregnancy in sheep is associated with a decreased lymph flow rate response to angiotensin II infusion, a phenomenon similar to the response observed in the systemic circulation. This hyporesponsiveness may play a role in the fluid retention of pregnancy.

Atrial natriuretic factor: The effects of pregnancy and a high-salt diet on atrial levels

Lony C. Castro, MD, Chander P. Arora, PhD, Jane L. Davis, MD, Calvin J. Hobel, MD, and Hassan Parvez, PhD

Los Angeles, California, and Paris, France

The chronic and relatively acute changes in blood volume that occur during pregnancy and post partum may be associated with alterations in the content of atrial natriuretic factor in the atria. We measured the concentration of atrial natriuretic factor in the right and left atria of virgin, pregnant, and postpartum Sprague-Dawley rats by radioimmunoassay as well as the concentration of atrial natriuretic factor in the atria and plasma of term pregnant rats on a high-salt diet. Neither right nor left atrial concentrations of atrial natriuretic factor were elevated during pregnancy in animals on a normal diet, but both were increased during the first 2 days after delivery. Term pregnant rats on a high-salt diet showed a small increase in atrial natriuretic factor levels in the left atria only, without any change in plasma atrial natriuretic factor levels. We conclude that relatively acute changes in fluid and electrolyte balance are more likely than chronic ones to be associated with alterations in atrial natriuretic factor concentrations in the atria.
(AM J OBSTET GYNECOL 1989;161:1620-3.)

Key words: Atrial natriuretic factor, pregnancy, rats, blood volume

Atrial natriuretic factor (ANF) is a family of peptides secreted by the heart that is involved in fluid and electrolyte homeostasis.[1] The cardiac atria of nonpregnant mammals respond to acute and chronic blood volume expansion with an increase in the synthesis and release of ANF.[2, 3] ANF in turn decreases the blood volume sensed by the atria through its effects on the vascular, renal, and endocrine systems.[4, 5]

Normal pregnancy in both humans and rats is a state of chronic volume expansion,[6, 7] and rats have been widely used as a model to study the interactions between ANF and blood volume. We have previously reported that plasma ANF levels are not elevated in the pregnant rat at term, when blood volume expansion is maximal, but increase during the first 48 hours post partum.[8] This has led us to suggest that factors other than blood volume may play a role in the regulation of the release of ANF during pregnancy and after delivery.

However, atrial ANF content does not always change in parallel with plasma levels as it represents the difference between ANF synthesis and secretion.[9, 10] Therefore, information about the concentration of ANF in the atria in addition to knowledge with regard to plasma levels is necessary to determine whether either pregnancy or the puerperium is associated with an alteration in atrial ANF synthesis.

In this study, we measured the concentration of ANF in the right and left atria of virgin, pregnant, and postpartum Sprague-Dawley rats to determine whether the chronic and relatively acute changes in blood volume associated with pregnancy and the early puerperium alters the concentration of ANF in the atria. Atrial and plasma ANF levels were also measured in a subgroup of pregnant rats placed on a high-salt diet to evaluate whether the atria of the term pregnant rat are able to alter ANF synthesis or secretion in response to a sodium load.

Material and methods

Animals studied. A total of 55 virgin, timed pregnant, and postpartum Sprague-Dawley rats (Simonsen, Gilroy, Calif.) from 10 to 16 weeks old were used in this study. The experimental protocol was approved by the animal research committee. All animals were housed ≥6 days before study in an environment in which light and temperature were controlled. The animals were studied during proestrus (determined by vaginal smear) and on days 11 to 15, 18, and 21 of pregnancy (term was day 21). Post partum they were studied between 0 and 24 hours, 25 to 48 hours, and 30 days after delivery. A total of 48 rats received a "normal" diet that consisted of standard rat chow with free access to tap water. A total of 7 rats received standard rat chow and tap water on days 1 to 16 of preg-

nancy. The drinking water was then replaced with 1% sodium chloride from days 17 to 21 (high-salt diet).

Blood and tissue preparation. After the rats were killed by cervical dislocation, 2 to 2.5 ml of blood was obtained from the abdominal aorta and placed in chilled tubes that contained ethylenediaminetetraacetic acid (1 mg/ml) and aprotinin (500 kallikrein-inhibitor U/ml, Sigma Chemical Co., St. Louis, Mo.). The plasma was separated by centrifugation, extracted on C-18 Sep-Pak cartridges (Waters Associates, Milford, Mass.) and assayed for ANF. The plasma ANF levels measured in the animals on a normal diet have been previously reported.[8]

Immediately after blood sampling the right and left atria were dissected in situ, snap frozen in liquid nitrogen, and stored at −50° C until they were processed. The atria were extracted under acidic conditions to minimize proteolytic degradation. Two milliliters of boiling 1.0 mol/L acetic acid was added to each frozen tissue sample. The tissue was then homogenized, placed in a boiling water bath for 10 minutes, cooled on ice, and centrifuged at 30,000 *g* for 30 minutes at 4° C. Half of the resultant supernatant was used for protein determinations and half was dried in a Speed Vac concentrator (Savant Instruments, Hicksville, N.Y.) and stored at −50° C until determination of ANF content by radioimmunoassay (RIA). To evaluate ANF recoveries in tissue extracts, atrial samples were homogenized in acetic acid and divided. ANF 99-126 (Peninsula Laboratories, Belmont, Calif.) was then added to half of each sample at a concentration that was severalfold greater than that present in the atria. The tissue samples were then processed as described above and the concentration of ANF was determined by RIA.

RIA for ANF. Tissue and plasma concentrations of ANF were measured with a double antibody RIA, the details of which have been previously published.[8] This assay uses a rabbit anti-ANF antiserum that cross-reacts 100% with ANF 99-126. The intra- and interassay variabilities were 4% and 8%, respectively. Extraction recoveries in plasma were 93% ± 3% (n = 10). Extraction recoveries in tissue were 78% ± 1% (n = 6). Results are not corrected for recoveries. Protein concentrations were measured with the Bradford method.[11]

Statistics. Results are expressed as the mean ± SEM. Differences between groups were analyzed with either the one-way or two-way analysis of variance with the Newman-Keuls test or the paired or unpaired Student t test. A p value <0.05 was considered significant.

Results

The ANF concentrations in the right and left atria of virgin, pregnant, and postpartum Sprague-Dawley rats are shown in Figs. 1 and 2, respectively. Neither right nor left atrial ANF concentrations changed significantly during pregnancy and they were not significantly elevated, compared with those in virgin rats. During the first 2 days post partum, atrial ANF levels increased twofold to threefold and returned toward levels present in virgin rats by 30 days post partum. At no time was there any significant difference between right and left atrial ANF concentrations; ANF levels in both atria showed similar patterns of change.

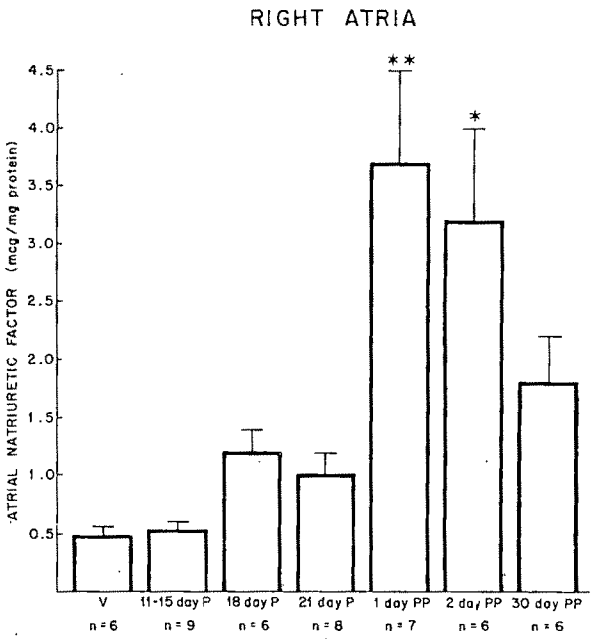

Fig. 1. Concentration of ANF in right atria of virgin *(V)*, pregnant *(P)*, and postpartum *(PP)* Sprague-Dawley rats. *Double star*, $p < 0.01$ versus virgin rats, 11- to 15-, 18-, and 21-day pregnant rats; $p < 0.05$ versus 30-day postpartum rats. *Star*, $p < 0.01$ versus virgin rats, 11- to 15- and 21-day pregnant rats; $p < 0.05$ versus 18-day pregnant rats and 30-day postpartum rats.

Table I shows the effects a high-salt intake over a 4-day period at the end of pregnancy had on atrial and plasma ANF concentrations. The eight pregnant rats on a normal diet represent a subgroup of animals for which plasma ANF values have been previously reported.[8] The high-salt intake produced a modest but significant elevation in left atrial ANF concentration. There was no significant alteration in right atrial or plasma ANF levels.

Comment

Atrial stretch appears to be the primary determinant of ANF release,[12] but other factors such as blood pressure and myocardial work[13] may be important in the regulation of ANF synthesis and secretion in vivo. We previously showed that plasma ANF levels are elevated on days 16 to 18 of pregnancy and during the first 2 days post partum, but are comparable to those in virgin

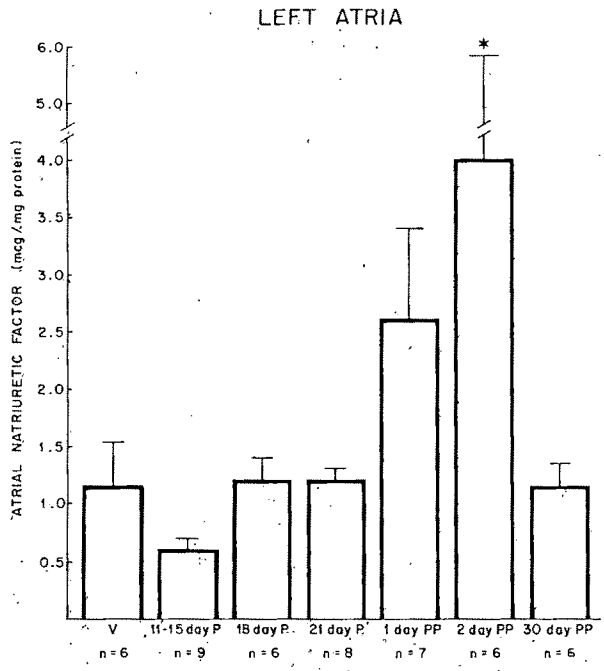

Fig. 2. Concentration of ANF in left atria of virgin *(V)*, pregnant *(P)*, and postpartum *(PP)* Sprague-Dawley rats. *Star*, $p < 0.05$ versus 11- to 15-, 18-, and 21-day pregnant rats.

Table I. 21-day pregnant rats

	Normal diet $n = 8$	*High-salt diet* $n = 7$
ANF, right atria (μg/mg protein)	1.0 ± 0.2	1.2 ± 0.5
ANF, left atria (μg/mg protein)	1.2 ± 0.1	1.8 ± 0.2*
ANF, plasma (pg/ml)	63 ± 6	53 ± 8

*$p < 0.05$ versus left atria, normal diet.

rats on days 11 to 15 and 21 of pregnancy.[8] These findings, coupled with the lack of significant change in the concentration of ANF in the right and left atria during pregnancy reported here, suggest that during the second half of pregnancy any changes in the rate of secretion of ANF are accompanied by similar changes in the rate of ANF synthesis by the atria. These data also suggest that the chronic blood volume expansion present in the term pregnant rat (day 2[7]) is not associated with any significant change in atrial ANF synthesis or secretion when compared to the virgin rat. We previously proposed that this may be a result of the decrease in blood pressure[14] and cardiac index,[15] which have been reported to occur after day 19 of pregnancy. These changes could conceivably result in alterations in myocardial work and atrial stretch opposite to those expected by volume expansion alone. However, our data do not rule out the possibility that in the term pregnant rat an increase in the synthesis and secretion of ANF could be accompanied by an equal increase in ANF clearance or volume of distribution, resulting in tissue and plasma ANF levels that are similar to those in the virgin rat. The data reported here confirms a previously published study[16] that did not show changes in rat atrial ANF content during pregnancy as measured with a bioassay. However, our data are in disagreement with a study[17] in which cardiac ANF levels were found to be elevated at term, whereas plasma levels were decreased. A possible explanation for this difference is that the term pregnant rats in our study were in labor and the accompanying hemodynamic changes may have increased ANF secretion when compared with nonlaboring animals at a similar gestational age.

ANF levels in the atria were elevated during the first 48 hours post partum, a time when plasma ANF levels are known to be high. There are at least two possible reasons for this. After delivery there is closure of the uteroplacental shunt with a probable elevation in blood pressure and increase in myocardial work. The resultant increase in ANF secretion may then be coupled with an even greater increase in ANF synthesis and a concomitant rise in the amount of ANF stored in the atria. Similar changes in the synthesis and secretion of ANF have been reported to occur during the development of spontaneously hypertensive rats.[10] Alternatively, closure of the uteroplacental shunt may be associated with a significant decrease in the clearance of ANF from the circulation. The increase in ANF levels seen in the atria may then reflect a decrease in ANF secretion. Reports that confirm the presence of ANF receptors in the human placenta[18] and of an umbilical arteriovenous difference in plasma ANF levels[19] lend support for the concept of the placental circulation as a possible site of ANF clearance.

The observation that left atrial ANF levels increased after 4 days of sodium loading, whereas plasma levels did not change, suggests that the term pregnant rat retains the ability to respond to relatively short-term changes in sodium intake with alterations in the synthesis of ANF even though ANF secretion did not apparently change. Sodium loading in spontaneously hypertensive rats has been reported to be associated with increased plasma ANF levels only during the first 24 hours after the initiation of the high-salt diet. ANF levels were not elevated thereafter.[20] In a more recent study, pregnant and nonpregnant uninephrectomized rats treated for 3 weeks with deoxycorticosterone and a high-sodium diet showed no alterations in plasma ANF levels; however, the concentration of ANF in the atria was not measured.[21] The dissociation we observed between left and right atrial ANF levels in response to the high-sodium diet is of interest in light of a report

that levels of ANF messenger ribonucleic acid in male Wistar rats are elevated in the right atria but not in the left atria after 1 week of a high-sodium diet.[22] Whether our findings represent a true difference in the response of pregnant versus nonpregnant rats to a sodium load or merely reflect differences in experimental protocols remains to be determined.

Whereas a definitive conclusion about any alteration in ANF synthesis that may occur during pregnancy or post partum will require a knowledge of the levels of ANF messenger ribonucleic acid, it appears that relatively acute changes in fluid and electrolyte balance are more likely than chronic ones to be associated with alterations in atrial ANF concentrations.

Is a decrease in plasma oncotic pressure enough to explain the edema of pregnancy?

Guillermo J. Valenzuela, MD
Loma Linda, California

The balance of fluid across capillaries is given by the Starling equation. Because the plasma protein concentration (one of its components) is decreased in pregnancy, we decided to explore the question as to whether hypoproteinemia with intact protein mass (produced by blood volume expansion) or hypoproteinemia with decreased total protein mass (produced by removal of circulating proteins) alters the oncotic pressure differences across capillaries. We calculated the oncotic pressure difference obtained in seven nonpregnant ewes during periods of normoproteinemia and hypoproteinemia; the influence of fluid infusion under both conditions was also observed. There was an increase in the oncotic pressure difference across the capillary wall during hypoproteinemia produced by a decrease in the total protein mass ($p < 0.01$); however, the response to hypoproteinemia produced by fluid infusion was similar ($p > 0.1$). The venous pressure (used as an index of interstitial fluid pressure changes) did not differ in either hypoproteinemia or fluid infusion. Capillary permeability was decreased during hypoproteinemia, as evidenced by a higher lymph/protein ratio of labeled albumin during the control period ($p < 0.05$). In conclusion, during a state of decreased plasma protein concentration similar to that of pregnancy, the difference in the oncotic pressure and hydrostatic pressure forces acting to prevent transfer of fluid to the interstitium is increased. Therefore other factors that influence fluid transfer across the capillaries must be investigated to explain the edema of pregnancy. (Am J Obstet Gynecol 1989;161:1624-7.)

Key words: Oncotic pressure, fluid balance, edema

Human pregnancy is characterized by many changes in fluid homeostasis including the retention of several liters of fluid in the interstitium.[1] Under normal conditions the fluid balance across the capillaries follows the Starling equation, with hydrostatic capillary pressure and the interstitial fluid oncotic pressure forcing fluid out of the capillary, and the plasma oncotic pressure and interstitial fluid pressure driving the fluid into the capillary. The resulting net movement of fluid and protein is toward the interstitium, from where it is then returned to the systemic circulation via the lymphatics.[2] In the nonpregnant state normal regulatory mechanisms maintain fluid balance with a variability of <1%, despite wide variations in daily water intake[3]; therefore, the interstitial fluid retention seen during pregnancy must be a result of alterations in the components of the Starling equation. Arterial pressure is decreased, whereas central venous pressure is unchanged during pregnancy[4]; therefore, capillary hydrostatic pressure is probably not increased. Thus the edema cannot be explained by hydrostatic forces. For these reasons, we decided to test the hypothesis that a decrease in the plasma oncotic pressure in a nonpregnant animal would be accompanied by a decrease in the oncotic pressure difference across the capillary wall and would favor the retention of fluid in the interstitial space—a finding that would help to explain the edema of pregnancy. The data used in this experiment have been reported in detail elsewhere,[5] with the exception of the calculations that were made for the oncotic pressure measurements, and the data on labeled albumin appearance in the lymph.

Material and methods

The experiments were performed on seven nonpregnant ewes that were obtained from a local breeder and housed in standard laboratory conditions. After general anesthesia was induced the surgery was performed as described in detail elsewhere.[6] The vessels catheterized included the femoral artery and vein, the left thoracic duct lymphatic, a tributary of the internal jugular vein, and the left jugular vein.

Experimental protocol. The experiments were conducted on postoperative day 4 and postoperative day 9. Labeled albumin (10 μCi) (Mallinckrodt, St. Louis, Mo.) was injected and samples from both the plasma

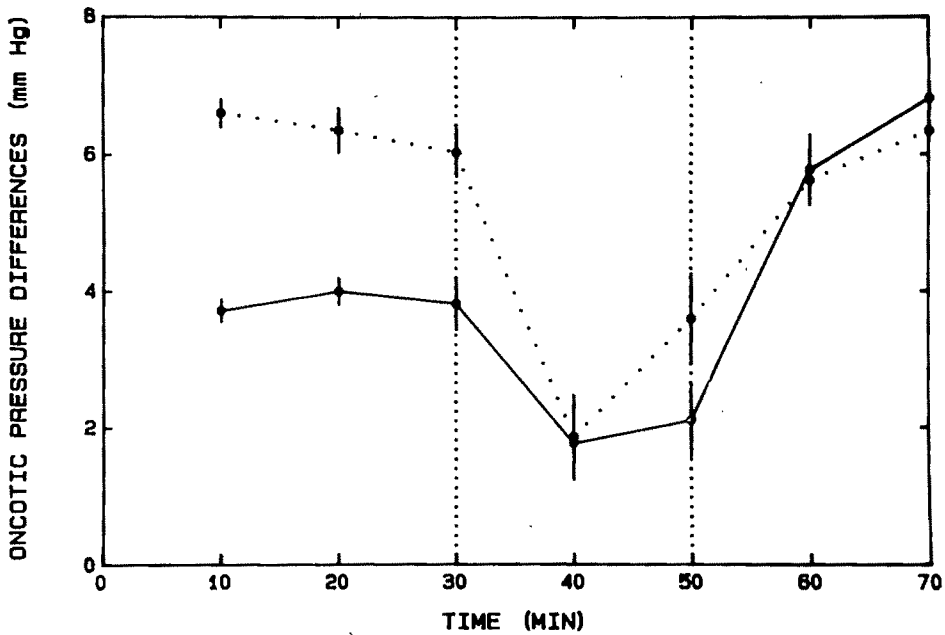

Fig. 1. Differences in oncotic pressure across capillaries are represented during period of normoproteinemia *(continuous line)* and hypoproteinemia *(dotted lines)*. *Vertical lines* represent infusion of fluid. Oncotic pressure differences are significantly higher during hypoproteinemia.

and lymph was obtained at 60 minutes for counts. A normoproteinemic control period of 30 minutes preceded an infusion of 6% of body weight of isosmotic intravenous fluid (Isolyte, Abbott Laboratories, North Chicago, Ill.) administered over 20 minutes. Lymphatic flow measurements and plasma protein samples were obtained every 10 minutes throughout the experiment. There was a 20-minute recovery period. Plasma and lymphatic protein concentration levels were determined by a standard manual refractometer (American Optical, Keene, N.H.). The venous pressure was measured on a continuous basis. Subsequently, the lymphatic fluid was allowed to drain to the exterior for 5 days. A similar protocol of fluid infusion was repeated on postoperative day 9. In four animals, the protein concentrations that were obtained by refractometry were confirmed by measurement of the protein concentrations with the Lowry method in some of the samples.

The different protein fraction concentrations were measured and found unaltered.[5]

Oncotic pressure calculations. In the samples that were obtained during the control period and at the time of peak lymphatic flow, we found that there was no alteration in the protein fraction that was transferred to the interstitium during the hypoproteinemic control period or during the peak fluid infusion period. We calculated the oncotic pressure with the formula developed by Demling et al.[7] in which:

$$\pi_o = 2.47^* (LPC) + 0.51_{,p} = 2.22^* (PPC) + 1.87$$

where π_o = lymphatic oncotic pressure, LPC = lymph protein concentration, π_p = plasma oncotic pressure, and PPC = plasma protein concentration. The albumin counts were expressed as counts per minute per milliliter and the results were expressed as lymph/protein ratio.

Results

The oncotic pressures for plasma during the normoproteinemic and hypoproteinemic period were 21.9 ± 1.4 mm Hg (day 1) and 12.5 ± 1.7 mm Hg (day 5) ($p < 0.01$), and 15.1 ± 1.2 and 7.5 ± 1.4 mm Hg ($p < 0.01$) for the lymph on days 1 and 5, respectively. The average ± SE values for the differences in the oncotic pressure results during the baseline period and during the time of fluid infusions are presented in Fig. 1 (values obtained at 10-minute intervals). The responses to fluid infusion were identical when the normoproteinemic and hypoproteinemic periods were compared ($p > 0.1$). The venous pressures for the normoproteinemic control period and fluid infusion were 9.8 ± 0.1 mm Hg (SE) and 14.6 ± 0.9 mm Hg, whereas the corresponding values for the hypoproteinemic period were 7.4 ± 0.1 mm Hg and 11.6 ± 0.6 mm Hg (a nonsignificant difference when normoproteinemic and hypoproteinemic groups are compared). The labeled albumin lymph/plasma ratio was 0.4 ±

0.01 for the control period and 0.30 ± 0.15 for the hypoproteinemic period ($p < 0.05$).

Comment

Human pregnancy is characterized by many cardiovascular changes including a 40% increase in blood volume and the retention of several liters of fluid in the interstitium.[1] Although the causes for this fluid retention are largely unknown, Longo[8] has proposed that an increase in the circulating concentration of estradiol and other hormones or the placenta acting as an arteriovenous shunt may be the mechanism(s) responsible for these changes. The understanding of fluid balance during human pregnancy is of vital importance because abnormalities in fluid homeostasis are associated with significant perinatal morbidity and mortality.[8, 9] Fluid administration in the nonpregnant state results in fluid transfer to the interstitium, a decrease in the lymphatic oncotic pressure (which decreases the forces moving fluid into the interstitium), and an increase in the plasma oncotic pressure. The interstitial fluid increase results in increased interstitial hydrostatic pressure, and increases the lymphatic flow rate severalfold.[3] Furthermore, the increase in interstitial fluid augments the hydrostatic forces that tend to move the fluid back into the intravascular system. Thus, after a short interval the balance is reestablished. The increase in hydrostatic pressures as a result of the volume alterations also produces an increase in urinary output, which returns volume to baseline. The interesting fact about fluid balance during pregnancy is that there is an alteration of the phenomena described above, with resulting fluid retention. Although there are many vascular changes in the renal circulation, the responses to fluid or salt challenges remain unchanged from the nonpregnant subjects.[10] Furthermore, many maternal diseases such as premature labor and preeclampsia are characterized by alterations in fluid retention or distribution.[8, 9]

Neither pulmonary wedge pressure,[5] nor venous pressure were altered during hypoproteinemia; therefore, we should expect a decrease in the total force retaining the fluid in the intravascular system. The index of pulmonary wedge pressure plus plasma oncotic pressure has been used to predict survival in a host of pathologic states including burns, sepsis, and cardiac failure[11]; this index has also been adopted for use in the management of preeclampsia.[12] The present findings of an increase in oncotic pressure gradient across the capillaries with hypoproteinemia, without a change in the hydrostatic pressure, would leave the pulmonary wedge pressure–oncotic pressure difference unchanged during hypoproteinemia.

The results of the foregoing experiment appear to conflict with the data obtained from Oian et al.[13] who determined the oncotic pressure differences across the capillaries in normal pregnancy and in the preeclamptic state. Our findings also differ from results obtained by Brace and Christian[14] who, with skin segments from pregnant animals, described a decrease in the difference in oncotic pressure across the capillaries in the guinea pig, an animal that displays fluid retention in pregnancy. There were no changes in oncotic pressure noted in sheep, a species that shows only modest changes in blood volume during pregnancy. A major factor that may explain the differences in results is that the aforementioned authors conducted the experiments in skin; however, skin contributes only a modest amount to total body lymphatic circulation. In contrast, our test were performed by obtaining estimates of whole body oncotic pressure differences.

The present finding of a decrease in the lymph/protein ratio of labeled albumin after hypoproteinemia suggests that a decrease in the permeability surface area may be the mechanism responsible for the maintenance of the plasma lymph oncotic pressure difference.

We interpreted the findings of maintained oncotic pressure differences during fluid infusion in a hypoproteinemic state as evidence that the bulk flow across the capillaries does not play a major role in the oncotic pressure difference. For instance, the decrease in lymph flow observed during hypoproteinemia indicates that the fluid transfer across the capillaries is decreased; therefore the convectives component of protein transfer would be decreased. When we increased the bulk flow across the capillaries by the fluid infusion, we found a maintenance of the oncotic pressure difference.

In conclusion, hypoproteinemia does produce an alteration in capillary permeability that protects the oncotic pressure differences. The present results also suggest that convective forces are less important than permeability in the transfer of protein. Therefore, to explain the edema observed during pregnancy it is necessary to postulate that there is an alteration in whole body capillary permeability.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1989 issues from the Publisher, at a cost of $56.00 ($79.00 international) for Vol. 160 (January-June) and Vol. 161 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C.V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146-3318, USA; phone (800) 325-4177, ext. 351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Treatment of oophorectomized guinea pigs with intrauterine 17β-estradiol pellets may modulate myometrial β-adrenergic receptor binding properties

Christos G. Hatjis, MD, David M. Grogan, BA, and Donald R. Koritnik, PhD
Winston-Salem, North Carolina, and Columbus, Ohio

Intrauterine 17β-estradiol pellets can induce an up-regulation of guinea pig myometrial β-adrenergic receptor density and *l*-isoproterenol–dependent adenylate cyclase activity. Does 17β-estradiol influence the ability of β-adrenergic receptors to form a "high affinity" state with *l*-isoproterenol, which is a necessary step for adenylate cyclase activation? Nonpregnant, oophorectomized guinea pigs received intrauterine pellets of either placebo, 17β-estradiol, progesterone, or 17β-estradiol plus progesterone for 1 week. 17β-Estradiol resulted in pharmacologic, whereas progesterone resulted in physiologic plasma 17β-estradiol and progesterone concentrations, respectively. The affinity of myometrial β-adrenergic receptors for *l*-isoproterenol was measured by percentage of inhibition of $-[^{125}I]$cyanopindolol binding. In all groups, the competition curves in the presence of magnesium chloride could be resolved into two affinity states of the β-adrenergic receptor, "high" and "low," respectively. The ratio of their dissociation constants was not influenced by hormonal treatment. However, the relative concentration of β-adrenergic receptors in the high affinity state was significantly higher in the 17β-estradiol–treated group than that in the control group. This correlates with the up-regulation in myometrial adenylate cyclase activity and suggests that myometrial β-adrenergic receptor–adenylate cyclase function may be modulated by 17β-estradiol. (Am J Obstet Gynecol 1989;161:1628-32.)

Key words: Sex steroids, myometrial β-adrenergic receptor affinity states, nonpregnant guinea pigs

Myometrial contractility is regulated by the interaction between the hormonal milieu and the function of several stimulatory and inhibitory membrane receptors.[1] A major class of membrane receptors that inhibits myometrial contractility is the β-adrenergic receptor. Stimulation of β-adrenergic receptors in human or animal myometrium by β-adrenergic receptor agonists results in an increase in adenylate cyclase activity and high levels of intracellular 3′5′-cyclic adenosine monophosphate. The latter is a second messenger that initiates a series of events leading to smooth muscle relaxation.

The β-adrenergic receptor–adenylate cyclase system consists of at least three separate proteins: β-adrenergic receptor, guanosine nucleotide regulatory protein, and the catalytic moiety of the enzyme.[2] We[3] and others[2] have shown that the interactions between β-adrenergic receptor agonists (but not antagonists) and β-adrenergic receptor in mammalian tissues facilitates the binding of magnesium to guanosine nucleotide regulatory protein, resulting in the formation of a stable high affinity state of the receptor. From a functional standpoint there apears to be a direct relationship between the ability to form the high affinity state of the β-adrenergic receptor and the ability to activate adenylate cyclase.[2]

In pregnant guinea pigs at ≥0.9 of term gestation (term, 65 days), there is an up-regulation of the ability of myometrial β-adrenergic receptor to form this high affinity state.[3] We have also reported that in oophorectomized guinea pigs, myometrial β-adrenergic receptor concentration increases after exposure to local 17β-estradiol pellets.[4] Finally, we have shown that myometrial β-adrenergic receptor dependent adenylate cyclase stimulation is higher in oophorectomized guinea pigs after exposure to intrauterine 17β-estradiol pellets, as compared with placebo-treated controls or animals exposed to progesterone pellets alone.[5] Thus we have asked the question whether 17β-estradiol intrauterine pellets may influence the ability of the β-adrenergic receptor to form a high affinity state with *l*-isoproterenol, a necessary step for adenylate cyclase activation. To answer this question

we have performed a series of competition studies in which we have examined the degree of inhibition of $-[^{125}I]$cyanopindolol binding by *l*-isoproterenol in the presence of magnesium chloride with or without guanosine triphosphate in myometrial membranes obtained from oophorectomized guinea pigs treated with either 17β-estradiol, progesterone, 17β-estradiol plus progesterone, or placebo intrauterine pellets.

Material and methods

Material. All chemicals were of reagent grade and of the highest purity available. $-[^{125}I]$cyanopindolol (2.2 Ci/μmol), a specific β-adrenergic receptor antagonist, was purchased from New England Nuclear (Boston, Mass.) on a monthly basis.

Animals. Nonpregnant Hartley nulligravid guinea pigs that weighed 600 to 700 gm were obtained from Perfection Breeders (Douglasville, Pa.). They were housed in the Animal Resources Department facilities (14 hours light, 10 hours darkness per day).

Animal surgery. Details of animal surgery have been previously described in detail.[4] Briefly, under anesthesia induced by ketamine-xylazine bilateral oophorectomies were performed. A total of 14 days later, under anesthesia, hysterotomies were performed and intrauterine pellets of 17β-estradiol (0.75 mg), progesterone (15 mg), 17β-estradiol plus progesterone, or placebo were inserted into the uterine cavities of each horn. Animals were distributed randomly to each of the treatment groups. After 7 days of treatment, the animals were anesthetized again and were killed.

Tissue collection. Details of tissue collection were as previously described.[4] Uterine tissue obtained at death was frozen in liquid nitrogen and stored at −70° C until its use. Freezing did not have any significant effects on β-adrenergic receptor binding characteristics.

Tissue preparation. Details of tissue preparation have been previously described.[3,4] Briefly, uteri were allowed to thaw in ice-cold buffer A containing 0.005 mol/L ethylenediaminetetraacetic acid (EDTA), 0.025 mol/L sucrose, 0.9% sodium chloride, and 0.02 mol/L tris(hydroxymethyl)-aminomethane hydrochloride (Tris HCl), pH 7.5. The uterus was minced with scissors and sonicated with a Brinkmann Polytron homogenizer (Brinkmann Instruments, Westbury, N.Y.). After filtration, the homogenate was centrifuged at 80,000 *g* (15 minutes at 4° C). The supernatant was discarded and the pellet was resuspended in buffer B containing 0.9% sodium chloride, 0.02 mol/L Tris HCl, pH 7.5, and 10 mmol/L magnesium chloride. The suspension was recentrifuged as before. The final pellets were then resuspended in ice-cold buffer B.

Binding studies. An aliquot of the final pellet (5 to 45 μg of protein per tube) was incubated with $-[^{125}I]$cyanopindolol and appropriate drugs as previously described.[3] To determine whether hormonal treatment alters the relative affinities of β-adrenergic receptor to *l*-isoproterenol, a β-adrenergic receptor agonist, we performed a series of drug competition studies. We also examined the interaction between myometrial β-adrenergic receptor and *l*-propranolol, a β-adrenergic receptor antagonist. Binding studies were carried out at 35° C for 45 minutes with various concentrations of *l*-isoproterenol or *l*-propranolol in duplicate. $-[^{125}I]$cyanopindolol was present in concentrations of 8 to 15 pmol/L. The reaction was stopped by dilution with 5 ml of buffer B without magnesium chloride. Binding was assessed by rapid filtration through Whatman GF/C glass fiber filters. Radioactivity was determined in a γ-counter (80% efficiency).

Specific binding of $-[^{125}I]$cyanopindolol was defined as the amount bound in the absence of competing ligand minus the amount bound in the presence of 10 mol/L of DL-propranolol. Specific binding routinely represented ≥90% of the total $-[^{125}I]$cyanopindolol binding. Total $-[^{125}I]$cyanopindolol was <10% to 20% of total $-[^{125}I]$cyanopindolol added and did not change when guanosine triphosphate was added in the incubation.

Inhibition constants were calculated by fitting the data by a nonlinear, iterative, curve-fitting procedure with a generalized model for complex ligand-receptor systems (LIGAND) as initially described by Munson

Table I. Guinea pig uterine weights

Hormonal treatment	*Uterine weight (gm)*
Placebo (n = 3)	0.78 ± 0.01*†
Estradiol (n = 4)	1.99 ± 0.25*
Progesterone (n = 5)	1.27 ± 0.21
Estradiol plus progesterone (n = 4)	1.90 ± 0.12†

Values are mean ± SEM.

and Rodbard.[7] This method provided estimates for the affinity of the ligands for the different states of the β-adrenergic receptor and for the relative proportions of these states. The dissociation constants were designated at K_H and K_L ; for the high and low affinity states, respectively. The corresponding β-adrenergic receptor population were designated as R_H and R_L · $R_T = R_H + R_L$.

Hormonal studies. When the animals were killed, systemic blood was obtained in heparinized syringes by intracardiac puncture. 17β-Estradiol and progesterone concentrations were measured as previously described.[4]

Protein determinations. Protein concentrations in the tubes were determined by the method of Bradford with bovine serum albumin as a standard.[8]

Statistical analysis. Parameters of interest were compared with analysis of variance (one- and two-way). For multiple comparisons, we used the Newman-Keuls test. The null hypothesis was that there was no significant difference in K_H, K_L, K_L/K_H and the proportion of the β-adrenergic receptor in the high affinity state (R_H/R_T) between placebo (control) animals, and animals treated with hormonal pellets. A p value of <0.05 was considered significant.

Results

All animals gained weight satisfactorily during the postoperative periods. After the placement of intrauterine pellets, the vaginal openings in the animals that received 17β-estradiol or 17β-estradiol plus progesterone pellets were noted to open within 24 to 48 hours of treatment. This is consistent with an estrogen-dependent effect.

At the time of death, uterine weights were determined in the treated animals. Table I shows uterine weights for each of the animal groups. There was a

significant increase in uterine weight for animals that received 17β-estradiol or 17β-estradiol plus progesterone pellets.

Hormonal treatment resulted in pharmacologic 17β-estradiol concentrations (Table II). In contrast, progesterone concentrations were in the physiologic range for nonpregnant animals.

Binding curves of the displacement of $-[^{125}I]$cyanopindolol by *l*-isoproterenol were obtained for each one of the animals studied. Fig. 1 shows binding curves from animals treated with placebo, 17β-estradiol, progesterone, and 17β-estradiol plus progesterone pellets in the presence of magnesium chloride. Each point on each curve represents the mean value of percent $-[^{125}I]$cyanopindolol binding at that concentration of *l*-isoproterenol derived from individual binding curves from each animal. In the presence of magnesium chloride a statistically better fit ($p < 0.05$) of the experimental data points was obtained when a two-site model was hypothesized instead of a one-site model. This was on the basis of the analysis of each of the binding curves by LIGAND (generalized model of complex ligand-receptor interaction).[7] Estimates of the dissociation constants for the high (K_H) and low (K_L) affinity states of β-adrenergic receptor, as well as an estimate of the relative percentage of the β-adrenergic receptor capable of forming the high affinity state, were thus obtained. The results from these calculations are shown in Tables III and IV. There were no significant differences with regard to K_H or K_L between groups. The ratio K_L/K_H was not different in the myometria obtained from animals in each of the experimental groups (Table IV). However, in the presence of magnesium chloride there was a significant increase in the percentage of the β-adrenergic receptor capable of forming the high affinity of the receptor in 17β-estradiol–treated animals as compared with placebo controls. Finally, when guanosine triphosphate was added to magnesium chloride, the best fit for the experimental data points was obtained with a one-site model (low affinity). In the presence of magnesium chloride and guanosine triphosphate, the calculated K_I was similar to the K_L.

Table V shows binding parameters for *l*-propranolol. In all cases, the experimental data fit better to a one-site model. There was no difference in K_I between animal groups in the presence of magnesium chloride with or without guanosine triphosphate.

Table IV. *l*-Isoproterenol–"derived" binding parameters for β-adrenergic receptors in myometria of oophorectomized guinea pigs

Hormonal treatment	K_L/K_H	R_H/R_T
Placebo ($n = 3$)	92.14 ± 2.11	0.40 ± 0.06*
Estradiol ($n = 4$)	140.48 ± 47.84	0.57 ± 0.07*
Progesterone ($n = 5$)	87.69 ± 13.78	0.45 ± 0.02
Estradiol plus progesterone ($n = 4$)	101.51 ± 16.13	0.50 ± 0.01

Mean ± SEM; $K_L = K_D$ for low affinity state and $K_H = K_D$ for high affinity state in the presence of 10 mmol/L magnesium chloride.

R_L and R_H corresponding β-adrenergic concentrations: $R_H + R_L = R_T$.

*$p = 0.05$.

Table V. *l*-Propranolol binding parameters for β-adrenergic receptors in myometria of oophorectomized guinea pigs

	Magnesium chloride (10 mmol/L)	*Magnesium chloride (10 mmol/L) plus guanosine triphosphate (250 μmol/L)*
Hormonal treatment	K_I *(nmol/L)*	K_I *(nmol/L)*
Placebo ($n = 3$)	0.74 ± 0.13	1.10 ± 0.38
Estradiol ($n = 3$)	0.66 ± 0.13	0.90 ± 0.34
Progesterone ($n = 5$)	0.54 ± 0.06	0.69 ± 0.13
Estradiol plus progesterone ($n = 4$)	0.43 ± 0.02	0.53 ± 0.04

Values are mean ± SEM.

Comment

In an attempt to further delineate the interaction between sex steroid hormones and myometrial β-adrenergic receptor function, we perfomred a series of experiments in which we studied the ability of the myometrial β-adrenergic receptor to form the high affinity state with *l*-isoproterenol in previously oophorectomized guinea pigs that subsequently were treated with intrauterine pellets that contained either 17β-estradiol, progesterone, 17β-estradiol plus progesterone, or placebo. In the absence of guanosine triphosphate but in the presence of magnesium chloride, myometrial β-adrenergic receptor from all guinea pigs interacted with *l*-isoproterenol and were able to form two affinity states, high and low, respectively. On the addition of guanosine triphosphate, β-adrenergic receptor were converted to the low affinity state. The above were observed in all animals regardless of the hormonal or placebo treatment. In contrast with the results obtained in our previous studies in pregnant and nonpregnant guinea pig myometria,[3] a significant pregnancy effect on K_H of *l*-isoproterenol was not seen in this series of experiments. Moreover, the ability to form a high affinity state of the β-adrenergic receptor as reflected in the increase of the K_L/K_H ratio was not detectable. The latter is in contrast to the results seen in pregnant animals at ≥0.9 of term gestation (term, 65 days).[3] However, we observed a modest but statistically significant 17β-estradiol–dependent increase in the relative concentration of β-adrenergic receptor capable for form-

ing the high affinity state for L-isoproterenol. This was not seen in the animals treated with 17β-estradiol plus progesterone or progesterone alone. Finally, *l*-propranolol recognized one site of myometrial β-adrenergic receptor of uniform affinity.

The K_L/K_H and R_H/R_T ratios might reflect similar attributes of the high affinity state of the myometrial β-adrenergic receptor. In this series of experiments and in our previously reported studies,[3] there is a dichotomy between the effects of hormonal treatment or pregnancy with regard to these two ratios. The reason for these apparently differing observations is not clear. It is plausible that the derived parameters might reflect different aspects of the interaction between the guanosine nucleotide regulatory protein/*l*-isoproterenol. However, they do provide an explanation for the up-regulation of *l*-isoproterenol dependent adenylate cyclase activity in guinea pig myometria of animals treated with 17β-estradiol pellets.[5]

It should be noted that the increase in R_H/R_T ratio was seen only with pharmacologic doses of 17β-estradiol. Interestingly, on addition of progesterone, this ratio was indistinguishable from that seen in the control (placebo-treated) animals. Clearly, this pharmacologic treatment with intrauterine pellets is different from the situation in normal guinea pig pregnancy in that the 17β-estradiol plasma concentrations are severalfold higher than the concentrations seen in normal pregnant animals and the progesterone concentrations are severalfold lower than those seen in pregnant guinea pigs at ≥0.7 gestation. Although there are some similarities in the properties of β-adrenergic receptor interaction with *l*-isoproterenol, one cannot extrapolate from the studies with hormonally treated animals and explain the observations seen in pregnant guinea pigs. Finally, given some inherent uncertainties in the determinations of R_H and R_L, these conclusions must await further studies in which the guanosine nucleotide regulatory protein concentrations are directly estimated. However, the experiments we report herein represent the neccesary first step toward that goal.

This is the first report in which the ability of myometrial β-adrenergic receptor to form a high affinity state with β-adrenergic receptor agonists has been reported in groups of animals treated with intrauterine 17β-estradiol and progesterone. A preliminary study in hormonally treated rabbits via a systemic route did not show a significant effect on this property.[3] In that regard, our observations confirm these studies. However, because the previous investigators did not report on hormonal concentrations, the differing results with regard to the R_H/R_T ratio cannot be readily explained.

From this series of experiments, we suggest that in nonpregnant, oophorectomized guinea pigs, myometrial β-adrenergic receptor interaction with *l*-isoproterenol may be subject to heterologous hormonal regulation by local 17β-estradiol. The effects of 17β-estradiol might be reversible by the addition of progesterone in physiologic doses. These experiments represent the first step toward the further characterization of the interaction of guanosine nucleotide regulatory protein and *l*-isoproterenol as a function of the animal's hormonal milieu at a molecular level.

Pregnancy-induced changes in the interaction of guinea pig myometrial β-adrenergic receptors with *l*-isoproterenol

Christos G. Hatjis, MD, and David M. Grogan, BA
Winston-Salem, North Carolina, and Columbus, Ohio

The ability of myometrial β-adrenergic receptors to form a "high-affinity state" with β-adrenergic receptor agonists might be greater in pregnant guinea pigs at ≥0.9 of gestation than in nonpregnant animals. To determine whether this difference is due to pregnancy in general or is associated only with late pregnancy and to determine whether it persists in the postpartum period, we studied the interaction of *l*-isoproterenol with β-adrenergic receptors in myometrial membranes obtained from nonpregnant (nulligravid) animals, pregnant (primigravid) animals at 0.3, 0.7, and 0.9 to 1.0 of gestation (term 65 days), and postpartum guinea pigs (2 to 3 days). The affinity of myometrial β-adrenergic receptors for *l*-isoproterenol was measured by percent inhibition of −[^{125}I]cyanopindolol binding. In the presence of magnesium chloride, the competition curves could be resolved into two affinity states of the β-adrenergic receptor, "high" and "low," respectively, in all groups. The ratio of the dissociation constant of the "low"-affinity state to that of the "high"-affinity state was significantly higher in pregnant guinea pigs at ≥0.9 of gestation than in nonpregnant or postpartum animals and in pregnant animals of earlier gestations. In the presence of guanosine triphosphate only one (low-affinity) state of the receptor was detectable. Thus it is only in pregnant guinea pigs at ≥0.9 of gestation that the ability of myometrial β-adrenergic receptors to form a high-affinity state is enhanced. (Am J Obstet Gynecol 1989;161:1633-6.)

Key words: Pregnancy and myometrial β-adrenergic receptor affinity states

The β-adrenergic receptor–adenylate cyclase system consists of at least three separate proteins: β-adrenergic receptor, guanosine nucleotide regulatory protein, and the catalytic moiety of the enzyme.[1] We[2] and others[1] have shown that the interaction between β-adrenergic receptor agonists (but not antagonists) and β-adrenergic receptor in mammalian tissues facilitates the binding of magnesium to guanosine nucleotide regulatory protein, resulting in the formation of a stable "high-affinity" state of the receptor. In turn, guanine nucleotides block or reverse the magnesium-dependent formation of the "high-affinity state" of the receptor for the agonists and convert the receptor to a "low-affinity state." From the operational standpoint, in the presence of β-adrenergic receptor agonists, magnesium, and guanosine triphosphate, guanosine nucleotide regulatory protein is activated and stimulates the catalytic moiety of the complex, resulting in the formation of cyclic adenosine 3′,5′-monophosphate. Thus there appears to be a direct relationship between the ability to form the high-affinity state of the β-adrenergic receptor and the ability to activate adenylate cyclase.

We have previously reported that myometrial β-adrenergic receptor–dependent adenylate cyclase stimulation is higher in guinea pigs in late pregnancy[3] (0.9 to 1.0 of gestation; term 65 days) than in nonpregnant or pregnant animals at 0.3 of gestation. Although there was an increase in the concentration of β-adrenergic receptor in this system with pregnancy, neither forskolin-stimulated adenylate cyclase activity,[4] a measure of the catalytic moiety of the system, nor sodium fluoride–dependent stimulation,[3] an indirect measure of guanosine nucleotide regulatory protein activation, appears to be modulated by pregnancy. More recently, we presented data that strongly suggested that the ability to form a high-affinity state of the β-adrenergic receptor was higher in pregnant animals at ≥0.9 of gestation than in nonpregnant controls.[2] We thus asked the question whether this differential regulation of the ability of the myometrial β-adrenergic receptor to form a high-affinity state with *l*-isoproterenol could be seen at an earlier point in gestation or was retained in the postpartum period. To answer the question, we performed a series of competition experiments in which we examined the degree of inhibition of −[^{125}I]cyanopindolol binding by *l*-isoproterenol in the presence of magnesium chloride with or without guanosine triphosphate.

Material and methods

Material. All chemicals were of reagent grade and of the highest purity available. $-[^{125}I]$cyanopindolol (2.2 Ci/mol), a specific β-adrenergic receptor antagonist, was purchased from New England Nuclear, Boston, on a monthly basis.

Animals. Nonpregnant (nulligravid) Hartley guinea pigs weighing 600 to 700 gm and time-dated pregnant (primigravid, nulliparous) guinea pigs at 0.3, 0.7, and 0.9 to 1.0 of gestation (term 65 days) were obtained from Perfection Breeders (Douglasville, Pa.). They were housed in the Animal Resources Department facilities (14 hours light and 10 hours darkness per day).

Tissue collection. Details of tissue collection were as previously described.[2-4] Uterine tissue, obtained at the time the animals were put to death, was frozen in liquid nitrogen and stored at −70° C until its use. Freezing did not have any significant effects on β-adrenergic receptor binding charcteristics.

Tissue preparation. Details of tissue preparation have been previously described.[2-4] Uteri were allowed to thaw in ice-cold buffer A containing 0.005 mol/L ethylenediaminetetraacetic acid (EDTA), 0.025 mol/L sucrose, 0.9% sodium chloride, and 0.02 mol/L tris(hydroxymethylaminomethane) hydrochloride, pH 7.5. The uterus was minced with scissors and sonicated with a Brinkman Polytron device. After filtration, the homogenate was centrifuged twice at 80,000 *g* (15 min-

utes at 4° C). The final pellets were resuspended in ice-cold buffer B containing 0.9% sodium chloride and 0.02 mol/L Tris-HCl, pH 7.5, and 10 mmol/L magnesium chloride.

Binding studies. An aliquot of the final pellet (5 to 45 μg of protein per tube) was incubated with $-[^{125}I]$cyanopindolol and appropriate drugs as previously described.[2] To determine whether pregnancy alters the relative affinities of β-adrenergic receptor to *l*-isoproterenol, a β-adrenergic receptor agonist, we performed a series of drug competition studies. Binding studies were carried out at 35° C for 45 minutes with various concentrations of *l*-isoproterenol in duplicate. $-[^{125}I]$cyanopindolol was present in concentrations of 8 to 15 pmol/L. The reaction was stopped by dilution and binding was assessed by rapid filtration through Whatman GF/C glass fiber filters. Radioactivity was determined in a γ-counter.

Specific binding of $-[^{125}I]$cyanopindolol was defined as the amount bound in the absence of competing ligand minus the amount bound in the presence of 10 mol/L of DL-propranolol. Specific binding routinely represented ≥90% of total $-[^{125}I]$cyanopindolol binding. Total $-[^{125}I]$cyanopindolol binding was < 10% to 20% of total $-[^{125}I]$cyanopindolol added.

Inhibition constants were calculated by fitting the data by a nonlinear, iterative, curve-fitting procedure according to a generalized model for complex ligand-receptor systems (LIGAND) as initially described by Munson and Rodbard.[5] This method provided estimates for the affinity of the ligands for the different states of the β-adrenergic receptor and for the relative proportions of these states. The dissociation constants were designated at K_H and K_L for the high- and low-affinity states, respectively. The corresponding β-adrenergic receptor populations were designated as R_H and R_L. $R_T = R_H + R_L$, where R_T is the total.

Protein determinations. Protein concentrations in the tubes were determined by the method of Bradford[6] with bovine serum albumin used as a standard.

Statistical analysis. Parameters of interest were compared with analysis of variance (one-way and two-way). For multiple comparisons we used nonparameteric tests. The null hypothesis was that there were no significant differences in K_H, K_L, K_L/K_H, and the proportion of the β-adrenergic receptor in the high-affinity state (R_H/R_T) among nonpregnant animals, pregnant animals at various points in gestation, and animals in the postpartum period. A p value of <0.05 was considered significant.

Results

Binding curves of the displacement of $-[^{125}I]$cyanopindolol by *l*-isoproterenol were obtained for each animal studied. Fig. 1 shows binding curves only from nonpregnant and pregnant (≥0.9 of gestation) animals in the presence of magnesium chloride with or without guanosine triphosphate. Similar curves were obtained from all other groups. Each point on each curve represents the mean value of the percent $-[^{125}I]$cyanopindolol binding at that concentration of *l*-isoproterenol derived from individual binding curves from each animal. In the presence of magnesium chloride but in the absence of guanosine triphosphate, a statistically better fit ($p < 0.05$) of the experimental data points was obtained when a two-site model was hypothesized instead of one. We thus obtained estimates of the dissociation constants for the high-affinity (K_H) and low-affinity (K_L) states of β-adrenergic receptor, as well as an estimate of the relative percentage of the β-adrenergic receptor capable of forming the high-affinity state. The results from the calculations are shown in Tables I and II. There was a trend indicating that K_H was significantly different between pregnant animals at ≥0.9 of gestation and nonpregnant controls (Table I). However, there was no statistical difference in the values of K_L between groups. In contrast to the above, when guanosine triphosphate was added, the best fit for the experimental data points was obtained with a one-site model (low affinity). As expected, in the presence of magnesium chloride and guanosine triphosphate, the K_I obtained was very similar to the K_L.

The ratio of K_L to K_H was significantly higher in the myometria obtained from animals at ≥0.9 of gestation than in those from the nonpregnant (nulligravid, nulliparous or primigravid, animals) or pregnant animals at 0.3 and 0.7 of gestation (Table II). Finally, although there was a trend for the percentage of the β-

*Mean value of K_L/K_H for pregnant animals at 0.9 of gestation is significantly different from each of the other study groups by the Newman-Keuls test. There were no other significant differences.

adrenergic receptor capable of forming the high affinity of the receptor in the presence of magnesium chloride to be higher in the pregnant animals at 0.9 to 1.0 of gestation than in the nonpregnant or early pregnant groups, that difference did not achieve statistical significance.

Comment

This new series of experiments confirms our previously presented results[2] and describes new significant observations on the interaction between guinea pig myometrial β-adrenergic receptor and reproductive states and gestational age of the animals. In the absence of guanosine triphosphate but in the presence of magnesium chloride, guinea pig myometrial β-adrenergic receptor interacts with *l*-isoproterenol and is able to form two affinity states, "high" and "low" affinity, respectively. On the addition of guanosine triphosphate, β-adrenergic receptor is converted to the "low"-affinity state. These results were observed in all animals. However, the possibility of a significant effect of pregnancy on K_H of *l*-isoproterenol was seen only in the pregnant animals at ≥0.9 of gestation. Moreover, the ability to form a high-affinity state of β-adrenergic receptor, as reflected in the increase of the K_L/K_H ratio, is not observed until 0.9 to 1.0 of gestation since it is only in the latter group that this ratio is higher than that of the pregnant animals at 0.3 and 0.7 of gestation. Interestingly, this ratio returns to the nonpregnant level in the immediate postpartum period.

This is the first report where the ability of guinea pig myometrial β-adrenergic receptor to form a "high-affinity" state with a β-adrenergic receptor agonist has been reported at different times during pregnancy and the puerperium. These observations correlate well with our previous results concerning the up-regulation of β-adrenergic receptor–dependent adenylate cyclase activity in pregnant guinea pigs at ≥0.9 of gestation.[3]

The cause of this increase in the K_L/K_H ratio is not clear. However, several hypotheses can be advanced. First, an interaction between locally produced or systemic sex steroid hormones, such as estradiol or progesterone, could influence the interaction between β-adrenergic receptor agonists and myometrial β-adrenergic receptor. Preliminary observations in hormone-treated rabbits,[7] however, did not show a significant effect. Moreover, hormonal treatment of oophorectomized guinea pigs with local 17β-estradiol or progesterone did not result in any significant increase in the K_L/K_H ratio.[8] Thus the role of a sex steroid–induced β-adrenergic receptor modulation at the level of the guanosine nucleotide regulatory protein/*l*-isoproterenol interaction remains to be defined. Second, during pregnancy, the concentration of guinea pig myometrial norepinephrine decreases to an almost nondetectable level.[9] This prejunctional reduction of norepinephrine content can theoretically result ina postjunctional up-regulation of myometrial β-adrenergic receptor function. Finally, interaction of myometrial β-adrenergic receptor with other hormones specific to pregnancy (such as estriol) may be involved. Further work will be necessary to study these hypotheses.

Teleologically, a greater ability to form the high-affinity state of the myometrial β-adrenergic receptor and, consequently, an ability to stimulate adenylate cyclase activity to a greater extent may be extremely important in terms of achieving myometrial relaxation. This can be particularly relevant during the latter part of gestation when maximal uterine relaxation is necessary to accommodate the ever-enlarging fetal-placental volume. Why this change is detected only in animals who are about to go into labor is not understood. This process, however, is reversible in that in the postpartum period the K_L/K_H ratio returns to levels comparable to those seen in the nonpregnant animals or those of pregnant animals at 0.3 and 0.7 of gestation. Further experiments will be necessary to elucidate the factors controlling this reversible modulation of the interaction between the myometrial β-adrenergic receptor and β-adrenergic receptor agonists.

Vasopressin receptors in human pregnant myometrium and decidua: Interactions with oxytocin and vasopressin agonists and antagonists

Marina Ivanisevic, MD,* Oliver Behrens, MD, Hanns Helmer, MD, Keith Demarest, PhD, and Anna-Riitta Fuchs, DSc

New York, New York, and Raritan, New Jersey

Saturation analysis and competition experiments were performed to identify and characterize [^{3}H]arginine vasopressin binding to human myometrium and decidua in late pregnancy. [^{3}H]Arginine vasopressin bound with affinity similar to that of [^{3}H]oxytocin to both tissues (dissociation constant 1 to 2 nmol/L). The concentration of [^{3}H]arginine vasopressin binding sites was high, particularly in decidua, but in all instances was about 50% to 60% of [^{3}H]oxytocin binding. Analogs with selective oxytocic potency (4-threonine oxytocin, isotocin) had high affinity to both [^{3}H]arginine vasopressin and [^{3}H]oxytocin binding sites, as did analogs with both oxytocic and vasopressor activity (vasotocin). Analogs with selective antidiuretic activity (1-deamino-8-D-arginine vasopressin) showed drastically reduced affinity to [^{3}H]oxytocin binding sites and relatively low but significantly higher affinity to [^{3}H]arginine vasopressin binding sites. A new oxytocin antagonist (RW22164 or [1-deamino-2D-tyrosine-(O-ethyl)-4-threonine-8-ornithine]oxytocin) competitively bound to both binding sites. Its affinity to [^{3}H]oxytocin binding sites was greater than to [^{3}H]arginine vasopressin binding sites whereas the relative affinities of a predominantly vasopressor antagonist (Manning compound) were reversed, suggesting the presence of distinct receptors for oxytocin and arginine vasopressin in pregnant human myometrium and decidua. (Am J Obstet Gynecol 1989;161: 1637-43.)

Key words: Arginine vasopressin, oxytocin, receptor, human pregnant myometrium, decidua, oxytocin and vasopressin antagonists

Vasopressin is structurally closely related to oxytocin, but its physiologic actions are different and it is considered to have different target organs. In standard pharmacologic tests with rat uterus, arginine vasopressin has <5% of the oxytocic activity of oxytocin. However, in women, vasopressin is a powerful uterine stimulant; in nonpregnant women its potency surpasses that of oxytocin.[1, 2] The effects of vasopressin on the pregnant human uterus are not as well known. Embrey and Chassar Moir[3] reported in 1967 that in midpregnancy, vasopressin and oxytocin were about equipotent in stimulating human uterine contractions, but as pregnancy progressed, the uterus became increasingly sensitive to oxytocin whereas the responsiveness to vasopressin remained relatively unchanged. Theobald,[4] on the other hand, reported that the term pregnant human uterus was about equally responsive to oxytocin and vasopressin (antidiuretic hormone), and he successfully induced labor with antidiuretic hormone with infusion rates of 2 mU/min. Vasopressin is secreted in large amounts by the human fetus during labor[5]; therefore vasopressin may be of physiologic importance not only for fetal hemodynamics[6] but also for the stimulation of uterine contractions.

Vasopressin has been shown to bind to the nonpregnant human uterus,[7] and studies by Guillon et al.[8] suggested that distinct receptors for oxytocin and vasopressin were present in nonpregnant myometrium. While the importance of oxytocin receptors for the regulation of uterine contractility is well established,[9] little is known about vasopressin receptors in the pregnant human uterus. Since the presence of receptors is a prerequisite for hormone action, it is important to identify uterine arginine vasopressin receptors, as well as oxytocin receptors, to understand the role of neurohypophysial hormones in the physiology of the pregnant human uterus. In this study we have investigated the binding of arginine vasopressin to the pregnant uterus and studied the distribution of binding sites between myometrium and decidua, since we have previously shown that decidua is a target organ for oxytocin and has a high concentration of oxytocin receptors.[9] A fur-

ther purpose was to examine whether a newly developed oxytocin antagonist (RW22164 or [1-deamino-2D-tyrosine-(O-ethyl)-4-threonine-8-ornithine]oxytocin) (dTVT),[10] which competitively blocks the binding of oxytocin to the pregnant human uterus,[11] also blocks the binding of arginine vasopressin. For comparison, the pregnant rat uterus also was studied for the presence of arginine vasopressin receptors.

Material and methods

Subjects. Pregnant human uterine tissues were obtained from three patients in whom hysterectomy was performed in the thirty-sixth to thirty-eighth week of pregnancy for medical reasons (cervical cancer in one and total placenta previa causing intractable postpartum bleeding in the other two). Immediately after surgery the uteri were placed on ice and cut open longitudinally; the decidua parietalis was cut off with curved scissors. Pieces of myometrium were taken from the fundus and corpus. All tissues were wrapped in foil and frozen in dry ice and then kept at −70° C until prepared for receptor assay. The pregnant rats (Sprague-Dawley) were from the R. W. Johnson Pharmaceutical Research Institute at Ortho, Raritan, N.J. The rats were killed on the afternoon of day 22, the time that parturition begins in this strain of rats. The uteri were slit open, and the decidua was scraped off and frozen separately from the myometrium, which was cut free of mesometrium. The uteri and decidua from six to eight rats were pooled to obtain sufficient quantities of membranes.

Preparation of membranes. The preparation of crude plasma membrane fractions and the receptor assays were performed as described previously[7, 9] with minor modifications. Briefly, the frozen tissues were pulverized and then homogenized with five pulses of 5 seconds' duration with a Polytron homogenizer (Brinkmann Instruments, Westbury, N.Y.) followed by six up-and-down strokes with a glass tissue grinder (Kontes Co., Vineland, N.J.). The homogenization buffer consisted of 0.01 mol/L *tris*(hydroxymethyl)aminomethane hydrochloride buffer, pH 7.4, containing 0.5 mmol/L dithiothreitol and 1.5 mmol/L ethylenediaminetetraacetic acid (EDTA). Dissociation of endogenous oxytocin and vasopressin from their binding sites with EDTA permits measurement of the total number of binding sites, both unoccupied and occupied. The fraction sedimenting between 20,000 and 165,000 *g* was used for the binding studies. Further purification with sucrose gradient centrifugation did not significantly increase the binding so this was omitted. The fraction was washed twice in the same buffer and then suspended in Krebs-Ringer solution and stored frozen at −70° C in suitable aliquots. Protein concentration was measured by the method of Lowry et al. with bovine serum albumin used as standard.

Binding assays. Before assay aliquots of mem-

brane preparations were thawed and recentrifuged at 165,000 *g;* the pellets were suspended in the assay buffer with a Teflon pestle in a glass homogenizer. The assay buffer consisted of 0.05 mol/L mono (*tris*[hydroxymethyl]aminomethane) maleate buffer, pH 7.6, containing 5 mmol/L magnesium chloride and 0.1% gelatin. The total volume was 220 μl and the protein concentration was 0.225 to 0.45 mg/ml for human tissues and 0.9 to 1 mg/ml for rat tissues. The concentrations were chosen to be in the range where specific binding increases linearly with the protein concentration. Incubations were carried out at 22° C for 60 minutes and terminated by adding 5 ml of ice-cold buffer. Separation of bound from free protein was by rapid filtration through Whatman GF/F glass-fiber filters with a Millipore manifold (Millipore Corp., Bedford, Mass.). The filters were washed with 10 ml of buffer and dried. The amount of radioactivity retained on the filters was counted with 5 ml of Ecoscint (National Diagnostics, Manville, N.J.) in plastic minivials in a Beckman LS 350 apparatus (Beckman Instruments, Schiller Park, Ill.) with 40% efficiency.

Saturation analysis was performed with eight or nine different concentrations of labeled ligand (0.10 to 14 nmol/L); nonspecific binding was determined by adding 1.1 μmol/L unlabeled ligand. Displacement and competition analyses were carried out with 0.6 to 0.9 nmol/L labeled ligand in each tube and increasing amounts of either the unlabeled ligand or another analog or antagonist in the range of 0.9 to 200 nmol/L. All binding studies were carried out in parallel assays with [^{3}H]arginine vasopressin and [^{3}H]oxytocin and with the same membrane preparations.

Labeled and unlabeled ligands and analogs. [^{3}H]Arginine vasopressin and [^{3}H]oxytocin were obtained from New England Nuclear (Boston). Both were of high purity (97% to 99.5%); the specific activities were 67 Ci/mmol for [^{3}H]arginine vasopressin and 39 to 57 Ci/mmol for [^{3}H]oxytocin.

Unlabelled arginine vasopressin and oxytocin were obtained from Bachem Fine Chemicals, Torrance, Calif. The analogs used were 4-threonine-oxytocin (provided by Dr. Maurice Manning, Department of Biochemistry, Medical College of Ohio, Toledo), isotocin and vasotocin (Bachem Biosciences, Philadelphia) and (1-deamino-8-D-arginine) vasopressin (Sigma Chemical Co., St. Louis). The pharmacologic potencies of the agonists are shown in Table I. The antagonists were (1-β-mercapto-β,-β,-cyclopenta-methylene-propionic acid-2-Tyr(O-methyl)-8-Arg) vasopressin (Manning compound, Bachem Fine Chemicals, Torrance, Calif.) and dTVT (RW22164), provided by Ortho Pharmaceutical Corporation, Raritan, N.J. Manning compound is considered a highly specific blocker of vasopressin receptors of the VP_1 type, being more than

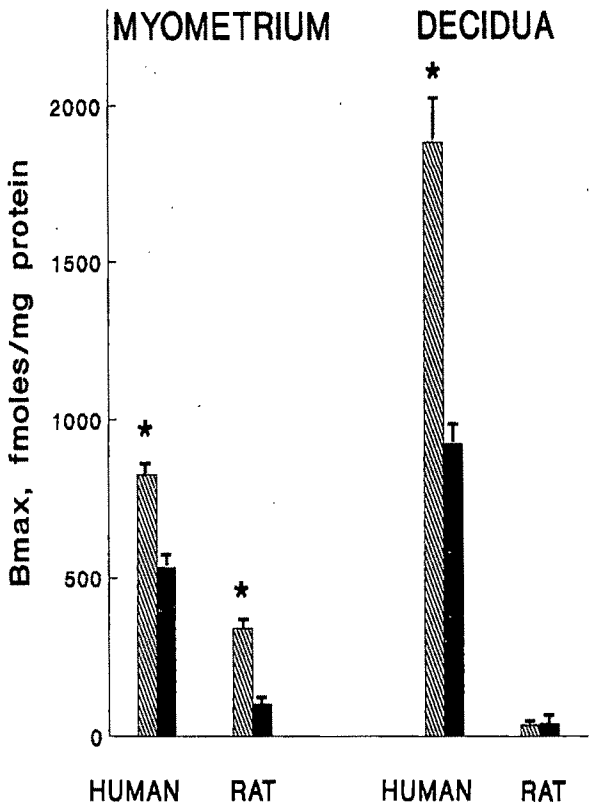

Fig. 1. Specific binding (B_{max}) of [^{3}H]oxytocin *(hatched columns)* and [^{3}H]arginine vasopressin *(solid columns)* to membrane preparations from three pregnant human uteri between 35 and 38 weeks of gestation and from pooled uteri of eight rats at term (day 22 of gestation). Saturation analyses were performed in duplicate with increasing concentrations of labeled ligands (0.1 to 14 nmol/L). Nonspecific binding was determined in the presence of 1.1 μmol/L unlabeled ligand. The concentration of protein was 0.25 to 0.45 mg/ml. The data were analyzed by an iterative nonlinear curve-fitting computer program to obtain the B_{max}, expressed as femtomoles bound per milligram of protein. *Asterisks* indicate significant differences between the two neuropeptides in each tissue. The B_{max} values for each neuropeptide were significantly higher in human than in rat uterine tissues. The B_{max} values were significantly higher in decidua than in myometrium for each neuropeptide in human uteri whereas the opposite was true in rats.

100 times more active in blocking vasopressor than oxytocic responses and having a weak antidiuretic activity.[12] dTVT is a highly specific oxytocin antagonist with a very weak diuretic activity and no vasopressor activity.[10] All peptides were stored as stock solutions in 0.25% acetic acid containing 0.1% gelatin and diluted with the assay buffer before each assay.

Data analysis and statistical analysis. Saturation analyses were performed in duplicate and the parameters presented (dissociation constant, K_d, and maximum binding, B_{max}) are means for two or three experiments. The binding data were analyzed by an iterative nonlinear curve-fitting program (Biosoft, Elsevier Sci-

entific Publishers), which is an adaptation of the LIGAND program developed at the National Institutes of Health by Munson and Rodbard. Statistical analysis of the goodness of fit for one or two affinity binding sites is performed by the program, with the F statistic used to compare residual variances. The binding data from displacement and competition experiments were also analyzed by the program. The parameters presented are K_I (the dissociation constant calculated according to Cheung and Prusoff, with the Hill constant near unity) and B_{max}. The significance of differences between means was determined by Student's t test, and $p < 0.05$ was considered significant.

Results

All decidual and myometrial membrane preparations of the three pregnant human uteri bound [^{3}H]arginine vasopressin specifically. Like [^{3}H]oxytocin binding, the specific binding of [^{3}H]arginine vasopressin was time and temperature dependent, reaching equilibrium in about 45 minutes at 22° C (data not shown). Addition of EDTA at equilibrium resulted in an immediate dissociation of the specific bound [^{3}H]arginine vasopressin, like [^{3}H]oxytocin.

Saturation experiments. Analysis of the data obtained in saturation experiments indicated that only one saturable site of high affinity and low capacity for [^{3}H]arginine vasopressin binding was present in both the myometrium and the decidua of women in late pregnancy. The K_d for both decidual and myometrial membrane preparations was 1 to 2 nmol/L and similar to the K_d for [^{3}H]oxytocin binding, with no significant differences (Table II). The saturation binding data for [^{3}H]oxytocin also indicated the presence of a single saturable site in both decidua and myometrium, confirming previous observations.[9] The concentration of [^{3}H]arginine vasopressin binding sites, like [^{3}H]oxytocin binding sites, was significantly higher in decidual than in myometrial membrane preparations (Fig. 1). The concentration (B_{max}) for [^{3}H]arginine vasopressin in the myometrium was 533 ± 27 fmol/mg protein and the decidual concentration was 924 ± 55 fmol/mg; for [^{3}H]oxytocin the corresponding values were 826 ± 37 and 1885 ± 130 fmol/mg (values are mean ± SE, n = 3).

Rat uterine membranes showed significantly lower affinity for [^{3}H]arginine vasopressin than for [^{3}H]oxytocin; this applied to both the myometrial and decidual membrane preparations (Table II). The concentration of [^{3}H]arginine vasopressin binding sites was much lower in rat uteri than in human uteri, both in myometrium and especially in decidua (Fig. 1). Myometrial receptor concentrations were significantly lower for arginine vasopressin than for oxytocin in rat uteri at term (arginine vasopressin, 100 ± 15 fmol/mg; oxytocin, 340 ± 27 fmol/mg) whereas decidual receptor concentrations were similar (oxytocin, 40 ± 5 fmol/mg; arginine vasopressin, 49 ± 9 fmol/mg). All values are mean ± SE, n = 3 (Fig. 1).

Displacement and competition experiments. In human uterine membrane preparations, displacement of [^{3}H]arginine vasopressin and [^{3}H]oxytocin by the unlabeled peptides arginine vasopressin and oxytocin also indicated interaction with a single population of binding sites for both peptides (Fig. 2). Although a curvilinear Scatchard plot was sometimes obtained at high unlabeled ligand concentrations, LIGAND analysis of the binding data resulted in the identification of only one saturable site of high affinity for both neuropeptides. The B_{max} values obtained from displacement experiments were similar to those obtained from saturation experiments, with no statistical differences (arginine vasopressin in myometrium: K_i = 3.8 ± 1.1

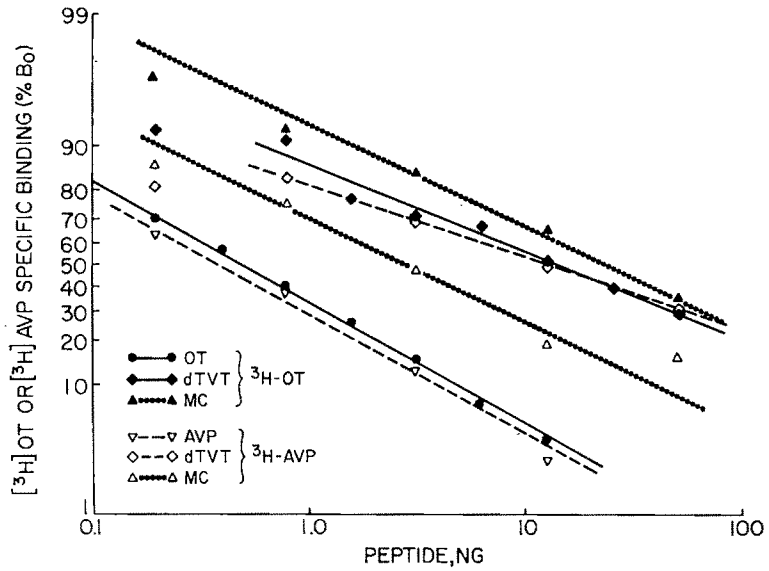

Fig. 2. Displacement and competition curves for [^{3}H]arginine vasopressin and [^{3}H]oxytocin by the oxytocin antagonist dTVT and the vasopressor antagonist Manning compound after logit-log transformation of the data. Experiments were performed in the presence of a constant amount of labeled ligand (0.6 to 0.8 nmol/L). The specific binding without added competitors is taken as 100% binding and the specific binding in the presence of increasing amounts of unlabeled ligand or analogs is expressed as a percent of this. Membranes were from myometrium of human pregnancy (0.45 μg per tube). Values are means of four to six experiments with each analog. For clarity the standard error bars are omitted; standard errors ranged from 1.2% to 14.3% (7.8% on the average).

nmol/L, B_{max} = 630 ± 55 fmol/mg; arginine vasopressin in decidua: K_i = 1.9 ± 0.4 nmol/L, B_{max} = 890 ± 75 fmol/mg; oxytocin in myometrium: K_i = 1.3 ± 0.2 nmol/L, B_{max} = 750 ± 50 fmol/mg; oxytocin in decidua: K_i = 2.0 ± 0.2 nmol/L, B_{max} = 1650 ± 180 fmol/mg).

Competition by oxytocin for [^{3}H]arginine vasopressin occurred with equal affinity as that for [^{3}H]oxytocin in both human myometrium (K_i = 0.6 nmol/L) and decidua (K_i = 0.7 nmol/L) while arginine vasopressin competed for [^{3}H]oxytocin with significantly lower affinity than that for [^{3}H]arginine vasopressin (K_i = 9.0 nmol/L for myometrium and K_i = 7.6 nmol/L for decidua, respectively) (Tables III and IV).

Competition for [^{3}H]arginine vasopressin and [^{3}H]oxytocin binding by selected analogs and antagonists with well-defined pharmacologic profiles showed many similarities between the two binding sites but also significant differences. The K_i values for the agonists are shown in Tables III and IV for human myometrium and decidua, respectively, and in Table V the corresponding values for the antagonists are shown. To facilitate comparison between the affinity profiles of oxytocin and arginine vasopressin binding sites in the two tissues, the relative affinities (K_i arginine vasopressin/K_i analog or K_i oxytocin/K_i analog) of all analogs are arranged in order of decreasing potency in Table VI, the analog with the greatest potency being listed as number 1.

Table V. Comparison of binding affinities of selected antagonists to oxytocin and arg-vasopressin receptors in pregnant human myometrium and decidua

Compound	*K_i (nmol/L)*	
	Oxytocin receptors	*Arg-vasopressin receptors*
Myometrium dTVT	37.0 ± 1.7[a] (n = 5)	18.7 ± 7.4[b] (n = 4)
Manning compound	68.4 ± 13.0[a] (n = 4)	9.9 ± 0.7[b] (n = 4)
Decidua dTVT	25.2 ± 6.1 (n = 4)	21.1 ± 8.6 (n = 3)
Manning compound	48.6 ± 12.1[a] (n = 2)	8.7 ± 4.6[b] (n = 4)

Values with different superscripts (*a* and *b*) for each analog differ significantly.

The affinity profiles of both binding sites were similar, but particularly striking was the great affinity of all analogs with high oxytocic potency to both binding sites; the affinity of isotocin and 4-threonine-oxytocin to myometrial [^{3}H]arginine vasopressin binding sites was even greater than to the [^{3}H]oxytocin binding sites. A difference between the two binding sites was noted in their affinities toward arginine vasopressin and (1-deamino-8-D-arginine) vasopressin, the analogs with the most selective antidiuretic activities; both had significantly greater affinity for the [^{3}H]arginine vaso-

IT, Isotocin; *AVT*, Arg-vasotocin; *OT*, oxytocin; *AVP*, Arg-vasopressin; *4-Thr-OT*, 4-threonine-oxytocin; *DDAVP*, 1-deamino-8-D-Arg-vasopressin; *MC*, Manning compound.

pressin than for the [^{3}H]oxytocin binding site (Tables III and IV). Another significant difference was observed between the relative affinities of the two antagonists, the oxytocin antagonist, dTVT, and the predominantly vasopressor antagonist, MC, for the [^{3}H]arginine vasopressin and [^{3}H]oxytocin binding sites (Tables V and VI), which were reversed for the two binding sites. This was observed in both decidua and myometrium (see also Fig. 2). Decidual binding sites for the two peptides showed generally qualitatively similar affinities when compared with the myometrial binding sites.

There was no significant correlation between the K_i values for the [^{3}H]arginine vasopressin binding sites and the relative antidiuretic or vasopressor potencies of the analogs, as reported in the literature. The high affinity of arginine vasotocin to both [^{3}H]arginine vasopressin and [^{3}H]oxytocin binding sites is noteworthy.

Comment

The results of this study demonstrate the presence of saturable high-affinity binding sites for both arginine vasopressin and oxytocin in human myometrium in late pregnancy. This is in agreement with Theobald's findings[4] that at term, vasopressin is as effective as oxytocin in eliciting uterine contractions. The analysis of the binding data with the iterative nonlinear curve-fitting program indicated in both instances the presence of a single class of homogeneous receptors. It is not possible on the basis of our results to prove definitely that the receptors for arginine vasopressin and oxytocin are distinct. However, the differences in binding capacity in the face of similar affinities and the differences in the relative affinities of the oxytocin and vasopressor antagonists and certain agonists for the [^{3}H]arginine vasopressin and [^{3}H]oxytocin binding sites suggest that a distinct receptor population is present in human myometrium and decidua for each neurohypophysial peptide. Guillon et al.[5] arrived at the same conclusion with respect to nonpregnant human myometrium. In contrast to our results, they found vasopressin to bind to two classes of binding sites, one with high affinity (K_d 2.2 nmol/L) and low capacity (B_{max} about 200 fmol/mg protein) and another with low affinity (K_d 655 ± 209 nmol/L) and high capacity (B_{max} about 6000 fmol/mg). This may be due to the use of the less potent [^{3}H]lysine vasopressin instead of [^{3}H]arginine vasopressin or to differences between the nonpregnant and pregnant tissues.

In contrast to our findings in human myometrium of pregnancy, the concentration of vasopressin binding sites in nonpregnant myometrium was considerably higher than that of oxytocin binding sites,[8] in harmony with the known effects of the two neuropeptides on uterine activity.[1-3] The arginine vasopressin binding sites in nonpregnant human myometrium differed from those in the pregnant human uterus also with respect to the relative affinities of various agonists. In nonpregnant myometrium the relative affinities of the analogs correlated well with their vasopressor activity,[8] whereas no significant correlation was found in pregnant myometrium or decidua. Thus the dynamic changes occurring during pregnancy in the human uterus in regard to neurohypophysial hormone binding are not only quantitative but also qualitative.

The much lower concentrations and lower affinity of arginine vasopressin binding sites in the pregnant rat myometrium in comparison to human myometrium is in keeping with the pharmacologic potency of arginine vasopressin measured in the uterus of this species.

The high concentration of both oxytocin and arginine vasopressin receptors in the human decidua is quite remarkable, and this tissue must therefore be considered a target organ for both neurohypophysial hormones. The function of oxytocin receptors in endometrium and decidua is believed to be stimulation of

arachidonic acid metabolism,[13, 14] probably by stimulating phosphoinositol turnover and phospholipase C.[15, 16] The cellular responses elicited by arginine vasopressin receptor occupancy in decidua are unknown at this time. Since one of the renal actions of arginine vasopressin is stimulation of prostaglandin E_2 synthesis, arginine vasopressin may have the same function in decidua, as also suggested by Schrey et al.[15]

The relative affinities of the various agonists to the arginine vasopressin binding sites and the lack of effect of arginine vasopressin on uterine cyclic adenosine monophosphate levels indicate that the uterine receptor is different from the adenyl cyclase–associated VP_2-subtype receptor that mediates the antidiuretic action of arginine vasopressin. On the basis of the order of potency of the oxytocic, vasopressor, and antidiuretic analogs in competing for the uterine [^{3}H]arginine vasopressin binding sites, they also differ from the VP_1-subtype receptor found in vascular smooth muscle and hepatocytes. The uterine vasopressin receptors may therefore represent a new subtype or perhaps a vasotocin receptor.

Of great clinical interest is the fact that the putative oxytocin antagonist competed with about equal affinity with both oxytocin and arginine vasopressin binding sites in myometrium and decidua. An oxytocin antagonist has pharmacologically minimal side effects and offers great promise as a new tocolytic agent, as suggested by preliminary clinical trials.[17]

The antagonistic effect of oxytocin and relaxin on rat uterine segment contractility

Laura T. Goldsmith, PhD, Joan H. Skurnick, PhD,[a] Andrea S. Wojtczuk, MS, Martin Linden, PhD,[b] Mary Jeanne Kuhar, MD, and Gerson Weiss, MD

Newark, New Jersey

To test the interaction of various hormones on the myometrium, the following experiments were done studying in vitro contractile activity of uterine segments from immature rats. The rats were divided into two groups: group 1 animals were treated with estrogen (n = 9) and group 2 animals were treated with both estrogen and progesterone (n = 11). Uteri from animals in each group were removed and segments were maintained in a temperature- and pH-controlled organ bath. After baseline contractions were established, uterine segments were treated with either oxytocin and then relaxin, or relaxin and then oxytocin. The dose of relaxin used, 20 ng/ml, was previously shown to be effective in inhibiting uterine contractions of animals treated with either estrogen or estrogen plus progesterone. The dose of oxytocin, 2.5 mIU/ml, was the maximal effective dose shown not to produce prolonged tetany. Estrogen plus progesterone treatment increased the frequency of contractions and resulted in contractions of greater duration of the maximal contractile force, as compared with treatment with estrogen alone. Oxytocin caused a stimulation of contractions in relaxin-inhibited uterine strips. Relaxin decreased the hypertonic contractions produced by oxytocin treatment, resulting in contractions similar to baseline. These data demonstrate that oxytocin and relaxin are directly antagonistic in their effects on uterine contractility. This suggests that labor may occur as a result of increased sensitivity to oxytocin or a decreased sensitivity to relaxin. (AM J OBSTET GYNECOL 1989;161:1644-9.)

Key words: Relaxin, oxytocin, myometrium, uterine contractions, labor

The inhibition of uterine activity during pregnancy and the initiation of labor depend, in part, on the interaction of various hormones on the myometrium.[1] Uterine activity is the sum of the dynamic balance between inhibitory and stimulatory factors. Labor occurs when the stimulatory factors become dominant.[2, 3]

The purpose of this study was to determine the interaction of an inhibitory agent (relaxin) and a stimulatory agent (oxytocin) on uterine contractions, and to determine whether progesterone modifies this interaction. The model system used was selected to avoid the interaction of other steroid or peptide factors that have uterine contractile activity.

Material and methods

The methods used in these studies were similar to those previously used to examine the effect of relaxin on rat uterine contractility in vitro.[4-7] Care and use of the experimental animals followed guidelines approved by the American Association for Accreditation of Laboratory Animal Care–accredited animal care facility at New Jersey Medical School. Immature female Long Evans rats, 33 to 36 days old, were given daily subcutaneous injections of 10.0 μg of estradiol benzoate (Sigma Chemical Co., St. Louis, Mo.) in sesame oil for 3 consecutive days. Exposure to estrogen, which increases the negativity of the cell resting potential and enhances the conduction of excitation throughout the muscle, is required for spontaneous uterine contractile activity. On the last 2 days of treatment with estradiol benzoate, one group of animals (n = 11) received 2 mg of progesterone (Sigma Chemical Co., St. Louis, Mo.) in sesame oil and another group of rats (n = 9) received only vehicle. On the fourth day, the animals were killed by cervical dislocation and the uteri were isolated, removed, and dissected free of extrauterine tissue. The cervical halves of the uterine horns were tied at each end with cotton threads, suspended in a double-jacketed organ bath, and immersed in 10 ml of Ringer-Locke solution (154 mM sodium chloride, 5.6 mM potassium chloride, 2.8 mM calcium chloride, 6.0 mM sodium bicarbonate, and 5.6 mM dextrose), pH 7.4, preheated to 37° C. One end of the uterine horn segment was attached to a hook at the bottom of the bath, and the other was attached to an isometric smooth muscle transducer of a Grass 7D polygraph (Grass Instrument Co., Quincy, Mass.). An initial tension of 1 gm was applied to the muscle.

was then continuously bubbled through the Ringer-Locke solution. After the uterine segments equilibrated, they were allowed to establish baseline contractions for 15 minutes. The chart speed was set at 50 mm/min. This rapid paper speed was used to allow observation and quantitation of alterations in waveform including duration of peak force, cycle length, and area under the contraction curve in addition to evaluation of amplitude. In the few cases in which segments did not contract at a frequency of once per minute, they were stimulated electrically with 5 V for 10 seconds every minute at 60 Hz, with the use of a direct-current stimulator. This was accomplished by placing one electrode in the bath with the other electrode touching the muscle at its fixed end. In those cases in which electrically stimulated cycles were preceded by intrinsic cycles, waveforms of the stimulated cycles closely resembled intrinsic waveforms.

Treatments were applied as described in Table I. To clearly delineate the interaction of relaxin and oxytocin, two sets of in vitro experiments were performed for both groups of animals: (1) those in which uterine segments were given relaxin first and then oxytocin, and (2) those in which uterine segments were given oxytocin and then relaxin. The dose of porcine relaxin (purified porcine relaxin CMa', 3000 guinea pig units/mg, kindly provided by Dr. Bernard G. Steinetz) used (20 ng/ml) was previously determined to inhibit contractions in uterine segments treated with estrogen and in those treated with estrogen plus progesterone.[5] The dose of oxytocin (Pitocin, synthetic oxytocin, 99.5% purity, Parke-Davis, Morris Plains, N.J.) used (2.5 mIU/ml) had been shown to be the maximal effective dose that did not produce prolonged tetany.

Several parameters of the initial baseline contraction pattern including cycle length, duration of peak force, amplitude, and frequency of contractions of uterine segments from animals treated with estrogen ($n = 9$) versus estrogen plus progesterone ($n = 11$) were evaluated and compared. The cycle length is defined as the time from the onset of one contraction to the onset of the next contraction. The duration of peak force is defined as the time from the onset of the contraction to the onset of the relaxation phase. The contractions recorded in a 15-minute period (generally eight contraction cycles) during baseline and hormone-treated contractions were analyzed. Statistical analysis of mean cycle length, frequency, and duration of peak force of these contractions was done with the use of the Student t test for a small sample size.[8]

Area under the curves of the initial baseline contractions and relaxin-treated and oxytocin-treated contractions were also assessed. These measurements were determined by the use of a MOP-3 morphometric image analyzer (Carl Zeiss Inc., Thornwood, N.Y.). Each contraction was traced with a magnetic optical pen;

Table II. Effect of progesterone on contractions of estrogen-treated uteri

	Estrogen only ($n = 9$)	*Estrogen and progesterone ($n = 11$)*
Mean cycle length (min/cycle)	1.68	1.26*
Frequency (cycles/min)	0.59	0.79*
Duration of peak force (min)	0.30	0.44*

*$p < 0.05$.

duplicate tracings were performed for each contraction to ensure reproducibility. Reproducibility in area under the curve measurements with this method was 99%. The contractions recorded in a 15-minute period (generally eight contraction cycles) during baseline and hormone-treated contractions were traced. The data were analyzed by paired Student t test and repeated measures analysis of variance.[8] For all statistical analyses used in these studies, 0.05 was taken as the criterion of statistical significance. Numbers of experiments performed were chosen to ensure an adequate statistical evaluation.

Results

Exposure to progesterone in vivo resulted in a decrease in the contraction cycle length, an increase in the frequency of contractions, and an increase in the duration of the peak force of contractions of rat uterine segments in vitro, as shown in Table II. The mean cycle length of the initial baseline contractions of uterine segments from rats treated with both estrogen and progesterone, 1.26 min/cycle ($n = 11$) was significantly shorter ($p < 0.05$) than the mean cycle length of the initial baseline contractions of uterine segments of rats treated with estrogen and vehicle, 1.68 min/cycle ($n = 9$). The frequency of contractions, the reciprocal of the mean cycle length, was significantly greater in uterine segments of animals treated with both estrogen and progesterone (0.79 cycles/min) than the frequency of contractions of uterine segments of animals treated with estrogen and vehicle (0.59 cycles/min).

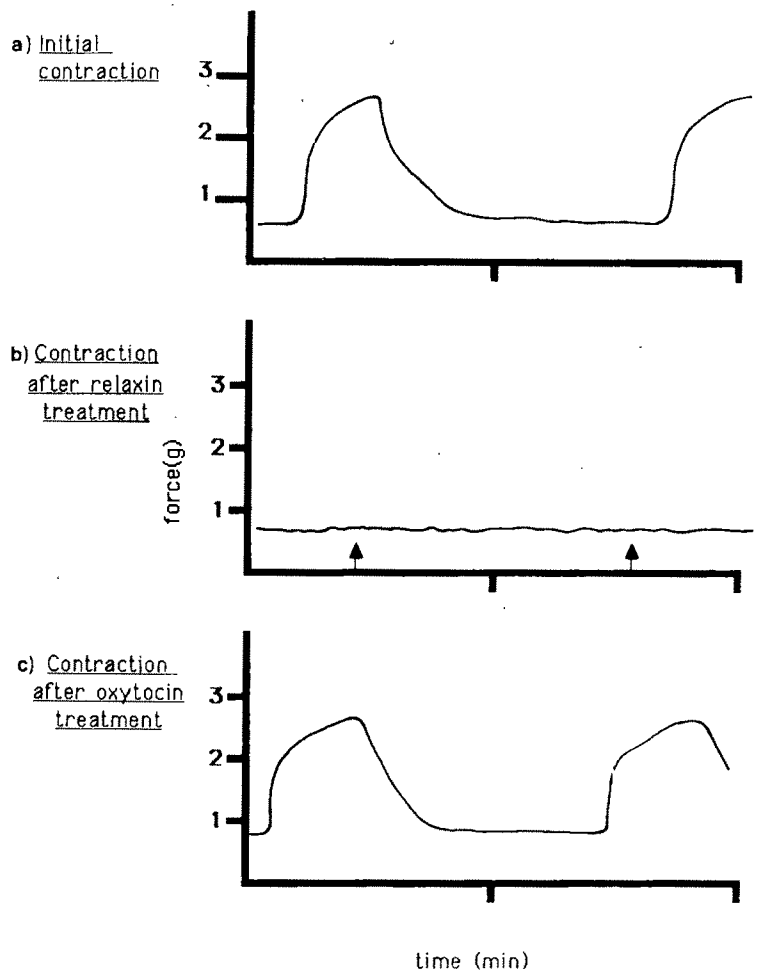

Fig. 1. Contractions of uterine segment from estrogen-treated rat. Panel **a** denotes initial baseline contraction; panel **b** denotes contraction pattern after addition of relaxin to baseline contraction; panel **c** denotes contraction pattern after addition of oxytocin to relaxin-treated tissue. *Vertical arrow* indicates electrical stimulation. Each subdivision on X axis (time) represents 1 minute.

Although contraction amplitude was similar in both groups, the duration of the peak force of the initial baseline contractions of uterine segments from rats treated with estrogen plus progesterone (0.44 min) was significantly longer ($p < 0.05$) than that of uterine segments of rats treated only with estrogen (0.30 min).

In addition, treatment with progesterone altered the shape of the contraction curve. A typical contraction curve of the estrogen-only group can be seen in Fig. 1, *a*. A typical curve of the group with estrogen plus progesterone can be seen in Fig. 2, *a*. Although differences in mean area under the curves were observed for baseline contractions of uterine segments from the two groups of rats, these differences did not achieve statistical significance (364 mm^2 for estrogen, $n = 7$; 541 mm^2 for estrogen plus progesterone, $n = 11, p = 0.16$).

In all uterine segments studied, those from both estrogen-treated and estrogen plus progesterone–treated rats, relaxin markedly decreased the amplitude or totally eliminated uterine contractions. As was expected from these results, a statistically significant decrease in mean area under the curves of contractions of relaxin-treated segments, as compared with baseline initial contractions, was shown (36 mm^2, $n = 4$, $p = 0.009$ for estrogen and 214 mm^2, $n = 4, p = 0.018$ for estrogen plus progesterone). In those cases in which relaxin totally eliminated contractions, electrical stimulation was employed but was unable to produce contractions in these relaxin-treated uterine segments (Fig. 1, *b*). Oxytocin restored contractions in relaxin-treated uterine segments, both in segments from rats treated with estrogen and rats treated with estrogen plus progesterone (Fig. 1, *c*). Oxytocin significantly increased mean area under the curve measurements of contractions of relaxin-treated segments to 394 mm^2, $n = 4$ ($p = 0.012$) for estrogen-treated

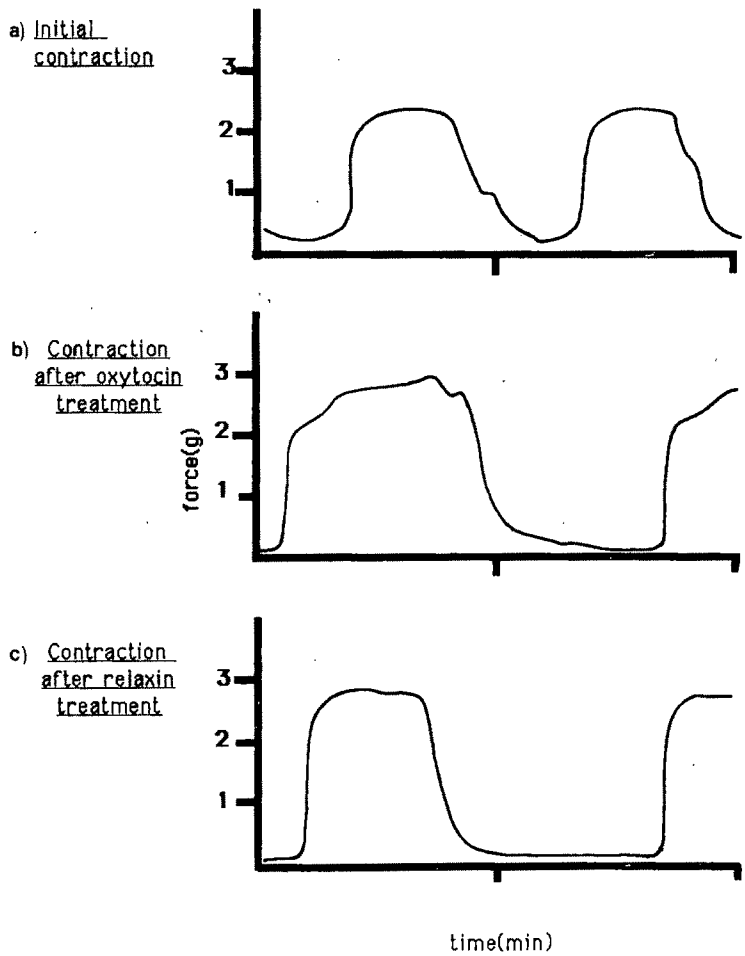

Fig. 2. Contractions of uterine segment from estrogen plus progesterone–treated rat. Panel **a** denotes initial baseline contraction; panel **b** denotes contraction pattern after addition of oxytocin to baseline contraction; panel **c** denotes contraction pattern after addition of relaxin to oxytocin-stimulated contraction. Each subdivision on X axis (time) represents 1 minute.

rats and to 474 mm², $n = 4$ ($p = 0.007$) for estrogen plus progesterone–treated rats. These areas were similar to that of baseline contractions.

In segments from estrogen-treated and estrogen plus progesterone–treated rats, oxytocin stimulated the force of contractions, as compared with initial baseline contractions. With prior exposure of the muscle segment to progesterone, oxytocin was more likely to produce a prolonged or tetanic contraction. Mean area under the curve measurements of contractions of uterine segments from estrogen-treated rats treated with oxytocin were increased above that of baseline to 495 mm², $n = 5$; yet this was not statistically significant ($p = 0.076$). Exposure to progesterone resulted in significantly increased mean area under the curve measurements of 1133 mm², $n = 7$ ($p = 0.015$). Whereas oxytocin stimulated all muscle segments, progesterone may have increased uterine sensitivity to oxytocin (Fig. 2, *b*). In segments from rats treated with estrogen and rats treated with estrogen plus progesterone, relaxin decreased the hypertonic contractions produced by oxytocin. Relaxin added to oxytocin-treated segments resulted in contractions similar to baseline (Fig. 2, *c*). Relaxin decreased mean area under the curve measurements in oxytocin-treated uterine segments from estrogen-treated animals to 299 mm², $n = 5$ ($p = 0.031$) and in those from animals treated with estrogen plus progesterone to 840 mm², $n = 7$ ($p = 0.056$).

Comment

The control of uterine activity is complex and involves a variety of hormonal and nonhormonal factors. The ultimate understanding of how the uterus acts during any physiologic state depends on an understanding of the effect of these various agents as individual substances and how uterine activity may be affected by these substances when they act together. A uterine tissue system that has not previously been exposed to any known or potential stimulatory or inhib-

itory hormones can be used to study the effects of various substances on uterine activity and generate clean and uncompromised results. The model used in this study is a simple and easily reproducible model to study the actions and interaction of various hormones on uterine activity without influence of unaccountable substances. It is not, however, a model of hormone action on human or pregnancy uterus, but rather a model of hormone action on a previously nonstimulated virgin uterus. The immature rat, not having been exposed to estrogen, has a nonreactive uterus. This is different from the uterus of mature ovariectomized animals, which is contractile and has been exposed to various hormonal and nonhormonal factors that can affect and bias results. The doses of hormones used in this study were chosen to give sensitive responses when used individually. Each dose was chosen separately on the basis of detailed experimental dose-response curves performed with this system before the experiments presented here. Electrical stimulation was used to dependably ensure contractions. The failure of this stimulus to cause contractions in the presence of relaxin demonstrates that relaxin suppresses conduction.

The use of rapid paper speed allows observation and evaluation of various parameters of the contraction patterns including alterations in waveform, cycle length, and duration of peak force of contractions not detected when a slower paper speed is used. A slower paper speed, which is most generally used in studies of uterine contractility, allows only observation of contraction amplitude. Thus this study is a more sensitive look at the alterations in contractions that occur under the influence of these hormones than that of looking at amplitude alone. We were able to demonstrate the effect of progesterone on these parameters, and can conclude that, in this system, progesterone increases the frequency and duration of peak force of uterine contractions. Studies of progesterone effects on contraction waveform and duration of peak force have not been previously done. Previous studies have demonstrated that progesterone synergizes with relaxin to decrease the amplitude of contractions.[4, 5] Further studies are needed to determine the interaction of relaxin and progesterone on the additional parameters studied here.

Our current observations demonstrate that a combination of progesterone and estrogen resulted in more prolonged contractions than those of estrogen alone in immature rat uterine segments, on the basis of duration of peak force. Progesterone also increased contraction frequency. In some experimental systems, progesterone has been shown to inhibit uterine activity.[9] However, progesterone is not a tocolytic agent[10]; it cannot be used to stop labor. The effect of progesterone in an experimental system may depend on conditions and dosage. This is also true of other steroid hormones; estrogen stimulates uterine contractions in immature rats but suppresses contractions in ovariectomized animals.[11] Use of the system described here was an attempt to eliminate nonspecific conditional and biologic effects and test the substances in question in as clean a system as possible. Progesterone has been shown to block estrogen stimulation of myometrial oxytocin receptors.[12] This effect may not have occurred in this system because the effect of oxytocin was not decreased by treatment of the rats with progesterone; rather, the stimulation of contractility by oxytocin appeared to be magnified by progesterone. Again, this difference may be due to conditions and dosage effects. Alternatively, it is possible that other mechanisms are responsible for the results presented here, mechanisms with workings that are not related to the concentration of the receptor. The results of the studies presented here clearly demonstrate that relaxin and oxytocin have antagonistic effects. These results should clarify some ambiguities in the literature regarding this issue. For example, Porter[10] has presented data that appear to demonstrate that relaxin inhibits the frequency of oxytocin-stimulated uterine contractions in the ovariectomized rat, yet the author states that relaxin had no effect. That relaxin and oxytocin have antagonistic effects suggests that labor can, in part, result from a probable increased sensitivity to oxytocin or a decreased sensitivity to relaxin. Additional studies with this model system can determine the effects of a combination of agents on uterine contractility with additional parameters of contractility able to be assessed. This information may provide insight beyond that provided for by studies of single agents on uterine contractility as is prevalent in the current literature.

Decreased β-carotene tissue levels in uterine leiomyomas and cancers of reproductive and nonreproductive organs

Prabhudas R. Palan, PhD, Magdy Mikhail, MD, and Seymour L. Romney, MD
Bronx, New York

The dietary importance of β-carotene as a factor in health maintenance has recently attracted considerable interest. Previously, total carotene content was estimated in a limited number of human tissues by means of spectrophotometric methods. In this study the levels of β-carotene were measured by high-pressure liquid chromatography in tissue samples of uterine leiomyomas and adjacent normal myometrium obtained at hysterectomy from uteri of 18 patients. β-Carotene concentration was significantly ($p = 0.0013$) lower in fibroid tissue than in normal myometrium. In addition, levels of β-carotene were assayed in tissue samples of cancers of the cervix, endometrium, ovary, breast, colon, lung, liver, and rectum and were compared with levels of respective adjacent normal sites. The concentrations of β-carotene were found to be lower in all cancer tissues. The decreased levels of β-carotene suggest that β-carotene deficiency may have a role in the cause and/or pathogenesis of leiomyomas and cancers of the organs that were investigated. The mechanism of action, however, remains unknown. (Am J Obstet Gynecol 1989;161:1649-52.)

Key words: β-Carotene, human tissue, leiomyoma, cancer

Increased attention is being focused on the role of essential micronutrients in the cause and possibly prevention of human cancer, as well as in the maintenance of health. The biologic functions of β-carotene (provitamin A) and vitamin A are currently of considerable interest.[1, 2] Numerous epidemiologic studies, linking diet and nutrition to cancer incidence and mortality, suggest a possible antitumor property of β-carotene, independent of its provitamin A activity.[3, 4] The antitumor implication is largely based on studies investigating the relationship between serum β-carotene levels and the incidence of specific cancers.[5-7]

A question of mechanistic interest is whether β-carotene exerts an independent influence through direct interactions at specific target tissues. In animal systems, dietary β-carotene supplementation exerts a preventive action on the spontaneous incidence of experimental tumors.[8, 9] Suda et al.[10] demonstrated that β-carotene, when applied topically, significantly inhibits oral carcinogenesis in an initiation-promotion hamster buccal pouch system. Tissue β-carotene levels in cancers of the uterine cervix, endometrium, ovary, and breast in humans have not been previously reported. We have investigated the tissue levels of β-carotene in coded tissue samples obtained from surgically excised specimens of each of these organ sites. In addition, the levels of tissue β-carotene in a spectrum of commonly encountered carcinomas of the colon, lung, liver, and rectum also were determined.

Material and methods

Collection of tissue samples. The study protocol was approved by the institutional review board. Staff pathologists of the Weiler Hospital of the Albert Einstein College of Medicine provided coded (a) normal, (b)

benign tumor, and (c) malignant tumor tissue samples within 2 hours of surgical excision of the involved organs and after removal of appropriate tissue specimens for pathologic assessment. Normal myometrium and fibroid tissues were obtained at hysterectomy from the same uteri of patients treated for benign gynecologic conditions. Tissue samples of various carcinomas, i.e., uterine cervix, endometrium, ovary, breast, lung, liver, colon, and rectum, were submitted with corresponding adjacent normal, noncancerous tissues obtained from the same patients. Before surgery, no special dietary restrictions were imposed on any of the patients.

Each tissue section of the surgical specimen, corresponding to the tissue samples released for biochemical analysis, was marked with india ink and processed for histologic-histopathologic interpretation by staff pathologists. Thus each subject served as her own control. All the β-carotene analyses were carried out without any knowledge of the source of the sample or the patient's clinical status.

Tissue extraction. Under the assigned code numbers, tumor and normal tissue specimens were collected immediately on surgical removal, transported to the laboratory in ice-cold 0.05 mol/L Tris buffer, pH 7.2, and stored in dark containers at −80° C until analyzed. Handling, processing, and assaying of all materials were done under subdued or gold light.

Samples of tissue (0.5 gm) were washed free of blood and homogenized with a Polytron PT homogenizer. An aliquot of the whole homogenate was saponified with 6% ethanolic potassium hydroxide for 20 minutes at 60° C in the dark and extracted with hexane (containing 0.025% butylated hydroxytoluene). Sample extracts were dried under nitrogen, redissolved in 300 μl of ethanol containing 0.025% butylated hydroxytoluene, and analyzed.

Analysis of β-carotene by high-pressure liquid chromotography. Briefly, 40 μl of the ethanolic extract was injected onto a C_{18} column (5 μm) and eluted with acetonitrile/methylene chloride/methanol (75:20:5) at a flow rate of 2 ml/min, with monitoring at 450 nm. Results were calculated by use of the peak area of the compound over the internal standard. The recovery after single extraction of β-carotene was about 95%. The coefficient of variation was <10% in all cases.

Statistical analysis. On completion of the β-carotene assays, the study code was broken and a comparative analysis was carried out for any association between β-carotene tissue levels and histologic or histopathologic diagnoses of the tissue specimens obtained from the same patients. The sign test of related samples (matched pairs of observations) was applied to determine whether the distribution of changes in the pathologic groups was significant. Because of the small sample size of tissues from various organ sites, the sign test was performed for all cancer sites combined.

Results

A total of 68 samples, consisting of 34 tumor samples and an equal number of normal tissue samples, were assayed. The surgical indications for removal of the various organs were: uterine leiomyoma, 18 patients; cancer of the uterine cervix, 5; cancer of the endometrium, ovary, breast, and colon, 2 each; and cancer of the lung, liver, and rectum, 1 each.

Leiomyomas and normal myometrium. A comparison of the β-carotene concentrations in extracts of normal myometrium with the levels in fibroid tissues of the 18 subjects is presented in Table I. The calculated mean β-carotene level of 18 normal myometrium samples was 64.0 ng/gm tissue whereas the mean level of β-carotene in eight fibroid tissue samples was 35.3 ng/gm tissue. β-Carotene was not detectable (<20 ng/gm) in the remaining 10 of the 18 fibroid tissue samples. When paired, in 16 of the 18 myometrium tissues, the fibroid specimens had lower β-carotene concentrations than normal specimens. When pair comparisons were analyzed by the sign test, the difference was significant ($p = 0.0013$).

Carcinomas versus adjacent normal tissues. Among the 16 patients with various carcinomas of the cervix, endometrium, ovary, breast, lung, liver, colon, and rectum, a wide range of β-carotene levels (i.e., 70 to 855 ng/gm wet tissue) was measured in the normal tissues

adjacent to cancer sites in the same excised surgical specimen. In contrast, β-carotene content was either reduced ($n = 6$) or nondetectable ($n = 10$) in cancer tissues of the various organs that were assayed compared with those of normal tissues (Table II). When pair comparisons were analyzed for all cancer sites combined by the sign test, the difference was highly significant ($p = 0.0004$).

Comment

This is the first study to report comparative β-carotene levels in normal and cancer tissue sites of uterine cervix, endometrium, myometrium, ovary, breast, colon, lung, liver, and rectum derived from surgically excised human specimens. The assays were measured by a specific and sensitive analytic high-pressure liquid chromatography method. Tumor tissue from these various organ sites and adjacent normal tissue were sampled and released for β-carotene analyses by staff pathologists under assigned code numbers. The analyses were carried out as unknowns without any knowledge of origin of the tissue or the patient's clinical status. The histologic or histopathologic nature of the tissue submitted was determined microscopically. β-Carotene was detected in all of the normal tissues in variable amounts. Tissue concentrations were significantly lower in the benign leiomyomas when compared with the amounts present in adjacent normal myometrium. The results of this pilot study revealed variable amounts of β-carotene in normal tissues, whereas lower or nondetectable β-carotene levels were measured in fibroid and different cancer tissues. In this study blood samples were not obtained from the patients. At present, simultaneous measurements of β-carotene levels in blood and tissues are being carried out to investigate the cause/effect relationship of our findings.

Human adipose tissue and the liver are important sites for storage and deposition of carotenoids. Most previous reports used nonsensitive spectrophotometric methods for the determination of total carotenoids or β-carotene in limited kinds of human tissues.[11, 12] The present findings are additionally important because the β-carotene levels in human female reproductive organs, as well as in the breast, colon, lung, liver, and rectum, were determined by a sensitive high-pressure liquid chromatography method. Our β-carotene values are comparatively lower than those reported for tissues of other human organs (10.8 μg carotene per gram adrenal, 4.7 μg carotene per gram testis, 150 μg per gram liver).[11-13] Spectrophotometric analyses of tissue extracts of the total carotene content are not as sensitive. The human uterus, ovary, breast, colon, lung, and rectum are not primary storage sites for β-carotene. Recently it was reported that the bovine ovarian corpus luteum can hydrolyze β-carotene suggesting that the ovary may store or use β-carotene as a source of retinol.[14]

The renewed interest in β-carotene, per se, in addition to its recognized provitamin A activity, is in its postulated role as a potential cancer protective agent.[1, 15] However, definitive evidence in support of this hypothesis in the pathogenesis of human neoplasms and possible mechanistic leads of a role for this micronutrient in cancer protection has thus far not been elucidated. β-Carotene has been reported to inhibit chemically induced tumor growth.[16, 17] More than

any other carotene, β-carotene is a free-radical trap and efficient quencher of singlet oxygen. Singlet oxygen is a known reactive form of oxygen that is both mutagenic and effective in causing lipid peroxidation.[18]

The human diet contains many natural mutagens and carcinogens that may act through the generation of oxygen radicals.[19] The dietary consumption of natural antioxidants, such as vitamins C and E, as well as β-carotene, may enhance the host's ability to detoxify such carcinogens. Exposure to other potential carcinogens, including human papillomavirus, may induce increased essential micronutrient requirements of tissues and an altered epithelial metabolism. While tissue availability of β-carotene may not be related directly to dietary intake, the decreased levels of β-carotene in leiomyomas and cancer tissues investigated suggest that a deficiency of tissue β-carotene may be a confounding variable in the multifactorial etiology of both benign and malignant neoplasms.

These findings focus attention on the possible metabolic interactions of β-carotene in commonly encountered gynecologic neoplasms, as well as malignant tumors of the breast, colon, lung, liver, and rectum. Basic studies are needed to elucidate the potential importance of β-carotene, possibly other carotenoids, and the synergistic interaction of other essential micronutrients in the etiology of human cancer and the role of nutrition in its prevention.

We thank Dr. Boyce Bennett of the Weiler Hospital of the Albert Einstein College of Medicine and his staff for providing surgical specimens and histopathologic diagnoses.

Compensatory ovarian hypertrophy occurs by a mechanism distinct from compensatory growth in the regenerating liver

Ronald D. Alvarez, MD, William E. Grizzle, MD, PhD, Lori J. Smith, and Donald M. Miller, MD, PhD

Birmingham, Alabama

The mechanism by which compensatory ovarian growth occurs is complex and not completely understood. To compare the molecular events in compensatory ovarian growth with those known to occur in other compensatory growth processes such as the regenerating liver, the temporal pattern of proto-oncogene expression and dexoyribonucleic acid synthesis was investigated in rat ovarian tissue after unilateral castration. One hundred fifty female rats were subjected to either a left hemioophorectomy or a sham oophorectomy. Twenty-four rats from each group were put to death at 3 and 14 days after the initial procedure and the ovaries were weighed. There was a mean compensatory weight increase in the right ovaries of the hemioophorectomy group of 7.9% at 3 days and 22.5% at 14 days. The temporal pattern of proto-oncogene expression was determined by removing the right ovary from six rats in each group at 4, 8, 12, 24, 36, and 48 hours after the initial procedure. The ovaries were paired into three samples in each group for each time point and the ribonucleic acid was extracted. Dot blot hybridization was performed on each ribonucleic acid sample with radiolabeled complementary dexoyribonucleic acid probes for the proto-oncogenes c-*myc*, c-HA-*ras*, and c-*fos*. There was no significant increase in proto-oncogene expression in the right ovaries of the hemioophorectomy group when compared with the right ovaries of the sham oophorectomy group. The temporal pattern of dexoyribonucleic acid synthesis was determined by removing the right ovary from three rats in each group at 8, 12, 24, 36, and 48 hours after the initial procedure. Each rat had been injected intraperitoneally with [^{3}H]thymidine 2 hours before the right oophorectomy. The specific activity of dexoyribonucleic acid extracted from each ovarian sample did not demonstrate a significant increase in ovarian dexoyribonucleic acid synthesis after hemioophorectomy or any significant difference in dexoyribonucleic acid synthesis between the hemioophorectomy and the sham oophorectomy groups. This report concludes that compensatory ovarian growth occurs by a mechanism distinct from compensatory growth in the regenerating liver. (Am J Obstet Gynecol 1989;161:1653-7.)

Key words: Compensatory ovarian growth

Compensatory ovarian growth has been demonstrated to occur in the rat and other animal models after unilateral castration.[1, 2] It has been hypothesized by some investigators that compensatory ovarian growth occurs as a result of an increase in gonadotropin secretion stimulated by declining levels of ovarian steroids or by declining levels of an "inhibin-like" factor.[3-7] Others have postulated a functional role of the peripheral autonomic nervous system in compensatory ovarian growth.[8-10]

In other compensatory growth processes, cellular proliferation is preceded by an increase in proto-oncogene expression. For example, increased expression of the proto-oncogenes c-*myc*, c-Ha-*ras*, and c-*fos* precedes an increase in dexoyribonucleic acid (DNA) synthesis and cell proliferation in the regenerating liver after partial hepatectomy.[11-16] No study to date has reported the molecular events in compensatory ovarian growth or compared these events with the molecular events in regenerating liver. It is the purpose of this study to do so by investigating the temporal pattern of proto-oncogene expression and DNA synthesis in rat ovarian tissue after unilateral castration.

Material and methods

Animals. Fischer rats (weight range 106 to 177 gm) were housed under controlled conditions of temperature, humidity, and light (lights on 12 hours and lights off 12 hours). All animals were fed water and standard rat chow as desired. Institutional guidelines for the care and experimental use of animals were strictly adhered to.

Determination of compensatory growth. Twelve female rats were subjected to a left hemioophorectomy and 12 female rats were subjected to a sham oophorectomy both through a ventral midline abdominal in-

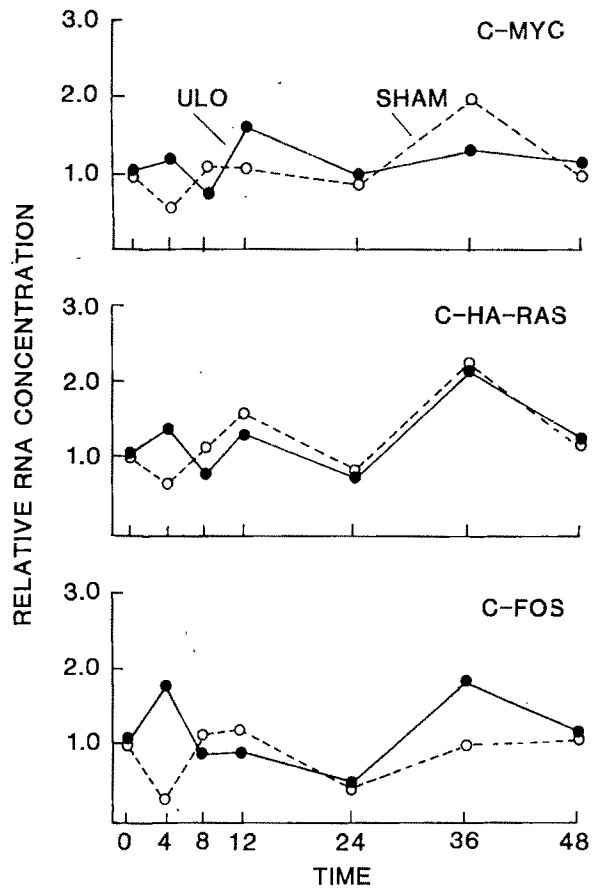

Fig. 1. Mean fold increases in proto-oncogene expression in the hemioophorectomy *(ULO)* and sham oophorectomy *(SHAM)* groups. The right ovaries were excised from each group at various intervals between 4 and 48 hours after the initial procedure. RNA extracted from ovarian samples was analyzed by dot hybridization to radiolabeled cDNA probes for the proto-oncogenes c-*myc*, c-HA-*ras*, and c-*fos*.

cision with the animals under ketamine anesthesia. Encapsulating fibroadipose tissue was trimmed from the excised ovaries and the ovaries were weighed individually. At 3 and 14 days after the initial procedure, the remaining ovaries were excised from six rats in each group, trimmed of fibroadipose tissue, and individually weighed.

The amount of compensatory ovarian growth was calculated by the formula:

$$\text{Compensatory growth (\%)} = \frac{R_o - R_s}{R_s} \times 100$$

where R_o is the mean weight of the right ovaries in the hemioophorectomy group and R_s is the mean weight of the right ovaries in the sham oophorectomy group.

The experiment was repeated in 24 additional female rats, and the mean compensatory ovarian growth was determined from the results of the two experiments.

Determination of proto-oncogene expression. Thirty-six female rats were subjected to a left hemioophorectomy and 36 were subjected to a sham oophorectomy. At 4, 8, 12, 24, 36, and 48 hours after the initial surgery, six rats from each group were put to death. The right ovaries were excised and paired into three samples in both study groups for each time point and immediately frozen in liquid nitrogen.

Total cellular ribonucleic acid (RNA) was isolated from each sample by the method described by Chomczynski and Sacchi.[17] RNA was extracted from pulverized frozen tissue homogenized in a guanidium thiocyanate solution. After phenol-chloroform extraction the RNA was precipitated with isopropanol and quantitated by absorption spectrophotometry. RNA samples from each time point in both the hemioophorectomy group and the sham oophorectomy group were analyzed by dot hybridization.[18] Each RNA sample was assayed by hybridization to complementary DNA (cDNA) probes for the c-*myc*, c-Ha-*ras*, and c-*fos* proto-oncogenes. The cDNA insert for each probe was purified by preparative gel electrophoresis and radiolabeled by nick translation.[19] Autoradiograms of each filter were analyzed by laser densitometry, and the mean increase in proto-oncogene expression was plotted for both the hemioophorectomy and the sham oophorectomy group.

Determination of DNA synthesis. Fifteen female rats were subjected to a left oophorectomy and 15 underwent a sham oophorectomy. At 6, 10, 22, 34, and 46 hours after the initial procedure, three rats from each group were injected intraperitoneally with 200 mCi of [^{3}H]thymidine diluted in 1 ml of saline solution. Two hours later the right ovaries were excised from each rat and immediately frozen in liquid nitrogen.

Cellular DNA was isolated from each frozen ovary specimen by proteinase K digestion and phenol extraction.[20] The rate of DNA synthesis in the hemioophorectomy group and in the sham oophorectomy group was determined by measuring the specific activity of each DNA sample and by calculating the mean specific activity for each time point.

Results

The mean compensatory weight increase in the right ovaries of the rats who had undergone left hemioophorectomy was 7.9% at 3 days and 22.5% at 14 days. This degree of compensatory ovarian growth is in agreement with that seen by previous investigators.[1, 2, 5, 7] This compensatory growth is less dramatic than that seen in the regenerating liver, which has a 300% to 500% increase in mass within 7 to 14 days after partial hepatectomy.[11]

As demonstrated in Fig. 1, there is no significant difference in the level of expression of the proto-oncogenes c-*myc*, c-HA-*ras*, and c-*fos* between the right

ovaries of the hemioophorectomized rats and the right ovaries of the sham oophorectomized group. This is in clear contradistinction to the observations in regenerating liver. Previous studies conducted in our laboratory have demonstrated a sevenfold to eightfold increase in c-*myc* expression within 3 hours after partial hepatectomy (Campbell VW, Rousell J, Rigsby D, et al. Selective inhibition of c-myc expression by mithramycin prevents hepatocyte proliferation in regenerating liver. Unpublished data). Others have reported as much as a fifteenfold increase in c-*myc* expression during the same time period.[12-14] The c-*myc* expression returns to baseline, only to rise again to a less pronounced level of expression between 8 and 24 hours after partial hepatectomy (Campbell VW, Rousell J, Rigsby D, et al. Selective inhibition of c-myc expression by mithramycin prevents hepatocyte proliferation in regenerating liver. Unpublished data). The c-Ha-*ras* expression has been demonstrated by our previous studies[1] and by others[12, 15, 16] to increase 200% to 300% within 48 hours after partial hepatectomy. Fig. 2 graphically compares our observations of the pattern of c-*myc* and c-Ha-*ras* expression in compensatory ovarian growth and in regenerating liver. In similar studies, c-*fos* levels have been shown to be at least fourfold above normal 30 minutes after partial hepatectomy, only to decline by 2 hours.[13] A second twofold increase in c-*fos* expression occurs at 8 hours after partial hepatectomy.

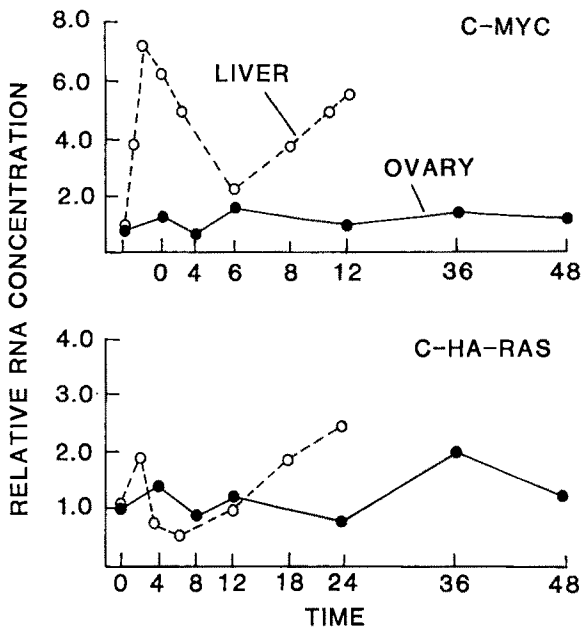

Fig. 2. Mean fold increase in proto-oncogene expression in regenerating liver and compensatory ovarian growth. In previous studies (Campbell VW, Rousell J, Rigsby D, et al. Selective inhibition of c-myc expression by mithramycin prevents hepatocyte proliferation in regenerating liver. Unpublished data) RNA extracted from regenerating liver within 24 hours after partial hepatectomy was analyzed by dot hybridization to radiolabeled cDNA probes for the proto-oncogenes c-*myc* and c-HA-*ras*.

As shown in Fig. 3, there is no significant increase in ovarian DNA synthesis after hemioophorectomy. The level of DNA synthesis in the hemioophorectomy and the sham oophorectomy groups is not significantly different at any time during the first 48 postoperative hours. In contrast, there is a dramatic burst of DNA synthesis in the regenerating liver that occurs 20 to 24 hours after partial hepatectomy.[21] Our previous studies (Campbell VW, Rousell J, Rigsby D, et al. Selective inhibition of c-myc expression by mithramycin prevents hepatocyte proliferation in regenerating liver. Unpublished data) have demonstrated peak [^{3}H]thymidine incorporation into regenerating hepatocytes approximately 20 hours after partial hepatectomy. The pattern of DNA synthesis in the regenerating liver is compared with that in compensatory ovarian growth in Fig. 4.

Comment

In this investigation the molecular events surrounding compensatory ovarian growth have been compared with those that occur during liver regeneration. The results of these experiments indicate that the early events of compensatory ovarian growth are quite different from those of liver regeneration. The distinction between these types of compensatory growth may reflect two basic mechanisms by which different organs respond to injury. In spite of an increase in mass of the remaining ovary, there appears to be no increase in the expression of the c-*myc*, c-Ha-*ras*, or c-*fos* proto-oncogenes and no increase in DNA synthesis during compensatory ovarian growth.

The apparent dissimilarities in compensatory growth between these two organ systems raise several key issues. First, does the magnitude of compensatory growth explain the differences in the molecular events during compensatory growth in these two systems? The regenerating liver approaches its original weight by 7 days after partial hepatectomy.[11] However, by 14 days after hemioophorectomy, compensatory growth in the contralateral ovary is only slightly >20%. Increased proto-oncogene expression may have evolved as a mechanism to initiate more rapid growth in more vital organ systems. The magnitude of compensatory ovarian growth may explain the differences in this process when compared with that in regenerating liver, although the complete absence of even a proportional increase in proto-oncogene expression and in DNA synthesis in compensatory ovarian growth argues against this.

Second, although there appears to be no increase in expression of the proto-oncogenes c-*myc*, c-Ha-*ras*, and c-*fos*, our results do not exclude the possibility that other

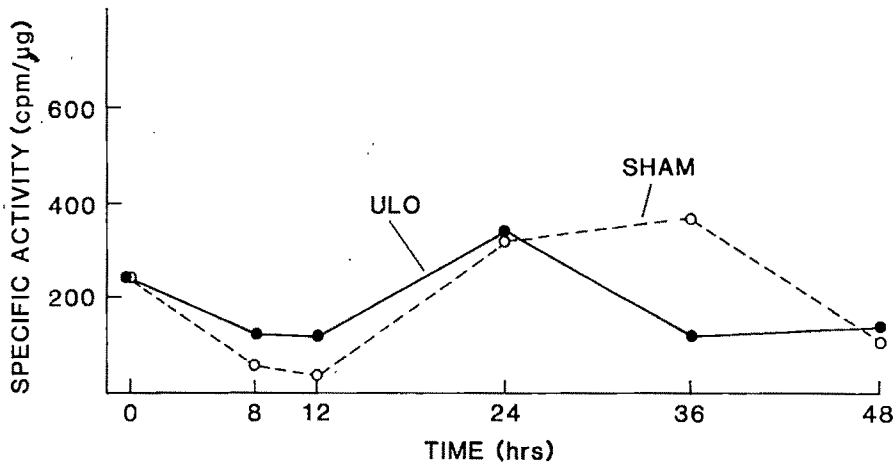

Fig. 3. DNA synthesis in the hemioophorectomy *(ULO)* and sham ovariectomy *(SHAM)* groups. Each rat was injected intraperitoneally with 200 mCi of [^{3}H]thymidine at various intervals between 6 and 46 hours after the initial procedure. The right ovaries were excised 2 hours after [^{3}H]thymidine injection and DNA was extracted. The level of DNA synthesis was determined by calculating the mean specific activity for each time point.

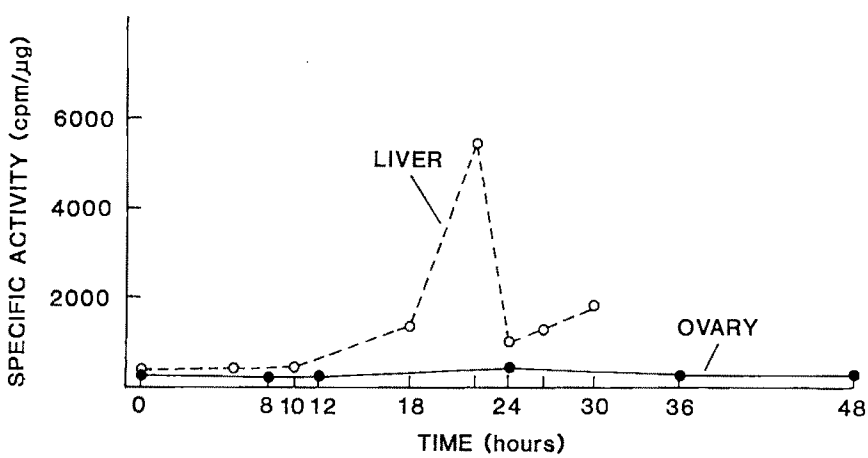

Fig. 4. DNA synthesis in regenerating liver and compensatory ovarian growth. In previous studies (Campbell VW, Rousell J, Rigsby D, et al. Selective inhibition of c-myc expression by mithramycin prevents hepatocyte proliferation in regenerating liver. Unpublished data) DNA was extracted from regenerating liver 1 hour after intraperitoneal injection of [^{3}H]thymidine at various intervals between 6 and 30 hours after partial hepatectomy. The level of DNA synthesis was determined by measuring the specific activity of each sample at each time point.

proto-oncogenes may be involved in the compensatory ovarian growth process. Many of the known proto-oncogenes have been documented to have increased expression in both normal and abnormal (neoplastic) cell transformation processes.[22-25] Although increased c-*myc* expression has provided an accurate marker for cellular proliferation in other growth processes, the results of this experiment do not exclude the possibility of a more ovary-specific proto-oncogene that may initiate a slower growth mechanism in the compensatory ovarian growth process.

Last, are hypertrophic, rather than hyperplastic, cell processes involved in the early events of compensatory ovarian growth? If hyperplasia plays a major role in compensatory growth, cell divison and DNA synthesis should occur. Contrary to the events in the regenerating liver, there appears to be no measureable increase in DNA synthesis in the remaining ovary within the

first 48 hours after hemioophorectomy according to the results of this study. The molecular distinction between hypertrophic and hyperplastic changes is unclear, but it would appear from our data that should hypertrophic changes occur in compensatory ovarian growth, they do so by a pathway different from the hyperplastic changes in regenerating liver.

Assessment of epidermal growth factor in the healing process of clean full-thickness skin wounds

Alfredo J. Jijon, MD, Donald G. Gallup, MD, M. Ali Behzadian, PhD, and William P. Metheny, PhD

Augusta, Georgia

Epidermal growth factor is a potent stimulant of epithelialization. However, the usefulness of topical applications of epidermal growth factor in accelerating wound healing in full-thickness skin wounds with a large panniculus adiposus has not been clear. Four full-thickness skin incisions were made in the back of 10 female pigs that treated twice a day for 14 days with 2 ml of epidermal growth factor (300 ng/ml) or 2 ml of Ringer's lactate solution in a single-blind, randomized fashion. Two pigs received only epidermal growth factor, two pigs received only Ringer's lactate solution, and six pigs were treated with both solutions. The original skin plug was weighed to ensure similarity of groups. Photographs and measurements of each incision were taken every 7 days. The mean surface areas of the incisions treated with epidermal growth factor were 8.45, 7.50, and 2.30 cm^2; in the incisions treated with Ringer's lactate solution the measurements were 8.42, 8.16, and 2.37 cm^2 on observation days 1, 7, and 14, respectively. Although a trend toward a faster healing rate was noted in the incisions treated with epidermal growth factor, this difference was not statistically significant. With the doses and the time interval used between treatments, minimal benefit was obtained with epidermal growth factor when compared with Ringer's lactate solution. (Am J Obstet Gynecol 1989;161:1658-62.)

Key words: Epidermal growth factor, wound healing

The different properties of epidermal growth factor have been established. It is a potent stimulant of epithelialization both in vivo and in vitro. It has been noted to increase the thickness of the epidermis, increase the epithelial cell proliferation and keratinization,[1] and accelerate wound contraction.[2] Thus its use generally results in decreased wound contracture and scarring.[3] Epidermal growth factor also decreases the thickness of the skin by decreasing the amount of fat,[4] and stimulates protein synthesis.[5] Most studies on the wound-healing properties of epidermal growth factor have been done in split- or partial-thickness skin wounds in animals that have a small panniculus adiposus.[3, 5, 6-8]

Our study was designed to evaluate the in vivo effectiveness of epidermal growth factor in accelerating epithelial regeneration in full-thickness skin wounds in an experimental animal model with a large panniculus adiposus to determine the potential application of epidermal growth factor in superficial abdominal wound breakdown. If wound healing is accelerated, the use of epidermal growth factor could potentially decrease hospitalization time, costs, and discomfort for affected patients. Its application could be useful in patients with infection, hypoproteinemia, and diabetes, not uncommon conditions occurring in some patients in our specialty.

Material and methods

Ten female pigs of approximately 2 to 3 months of age served as animal models. Pigs were chosen because of their large panniculus adiposus. Four full-thickness skin incisions, including the panniculus carnosus, were made with a sterile knife in the back of each animal, two on the right side and two on the left side. Each incision was 5 cm long and 1.5 cm wide. The cuts were made with a sterile technique and with the animals under general anesthesia. Permission for this study was obtained from the Committee on Animal Use for Research and Education at the Medical College of Georgia; all guidelines for the care and use of animals at our institution were followed. The tissue removed was weighed. Each wound was assigned a number, measured, and photographed from a standard distance of 50 cm.

Two solutions were prepared; one contained 300 ng of epidermal growth factor per milliliter of Ringer's lactate solution, and the other contained only Ringer's lactate solution. A laboratory assistant, blinded to the intent of the study, marked the two solutions as red or green.

The ten pigs were divided into three groups: group 1, two pigs with eight incisions that were treated only with green solution; group 2, two pigs with eight incisions treated only with red solution; group 3, six pigs in which the incisions on the left received the green solution and the incisions on the right received the red solution. Thus a total number of 40 incisions were studied; 20 were treated with the green solution and 20 with the red solution. Treatments of the incisions were done twice a day after the pigs were sedated. Wet-to-dry dressing changes with 2 ml of either the green or the red solution were applied. Each pig was caged separately and supplied with regular food and water. The duration of the project was 14 days.

Measurements of the incisions were done every 7 days with the pigs under heavy sedation, for a total of three measurements of each incision. The maximum and minimum length, depth, and width were obtained, and from these values a maximum, minimum, and mean area and volume were calculated.

Each incision was photographed every 7 days with a ruler placed on its side to more accurately measure the surface of the wound. Color slides were obtained. Each individual slide was projected onto sheets of standardized batches of paper from exactly the same distance so that the length of the ruler was always kept constant. The margins of each wound picture were traced, cut, and weighed.

As a sideline to this experiment, we compared the correlations among the three different measurements used to assess wound healing. We examined these correlations to determine whether all three measurements are necessary for future studies in this line of investigation. A strong correlation (>0.80) would suggest that only one assessment method is necessary.

Before the analysis the code was broken, and it was established that the green solution contained the epidermal growth factor and the red solution contained the placebo.

The results were analyzed with an independent *t* test and a repeated-measures analysis of variance test with a single covariate, and the Pearson Product-Moment correlation coefficient. The α-value was set at 0.05 with a one-tailed test. We considered that the sample size of 20 incisions per condition would provide sufficient power to detect significant differences, judging from the large effect size (>0.08) yet low power (<0.30) as a result of small samples observed in previous studies.[2, 3, 6-9]

Results

During each observation means and standard deviations were calculated for each of the three variables: surface area, wound volume, and weight of the tracing paper. To ensure that the individual values did not make a difference, we used the weight of the skin plug as covariate in our analysis.

Table I. Initial values (mean ± SD) of wounds per treatment condition

Assessment measurements	*Ringer's lactate solution and epidermal growth factor*	*Ringer's lactate solution and placebo*
Skin plug (gm)	3.43 ± 0.86	3.64 ± 0.68
Surface area (cm^2)	8.45 ± 0.41	8.41 ± 0.48
Wound area (cm^3)	3.67 ± 0.98	4.06 ± 0.93
Weight of paper tracing (gm)	0.82 ± 0.07	0.84 ± 0.08

The weight of the skin plug removed at the beginning of the experiment was nearly equivalent for both groups, and the values were not statistically different according to an independent *t* test. The values of the two groups with regard to surface area, wound volume, and the weight of paper tracing were roughly equivalent, and no statistically significant differences were found between them (Table I).

We subsequently performed three separate analyses and used the weight of the skin plug removed from each pig at the beginning of the experiment as a control for each. In the first analyses we compared the mean surface area for the 3 days of observation. On observation day 1 (initiation of the study) the mean surface area was 8.45 cm^2 in the epidermal growth factor group and 8.41 cm^2 in the placebo group. On observation day 7 the area was 7.50 cm^2 (±2.1) and 8.16 cm^2 (±2.16) in the epidermal growth factor and placebo groups, respectively. On observation day 14 the area was 2.30 cm^2 (±1.15) and 2.37 cm^2 (±1.18) in the epidermal growth factor and placebo groups respectively (Fig. 1).

An identical analysis was conducted for the weight of the paper tracing. On observation day 1 the weight of the paper tracing of the projected slides of the incisions was 0.82 gm, and 0.84 mg in the epidermal growth factor and placebo groups, respectively. On observation day 7 the weight was 0.75 gm (±0.26) and 0.80 gm (±0.23) in the epidermal growth factor and placebo groups, respectively. On observation day 14 the weight was 0.24 gm (±0.11) and 0.25 gm (±0.12) in the epidermal growth factor and placebo groups, respectively (Fig. 2).

In the third analysis the mean wound volume only was compared during the first two observations because it was thought that at the end of the experiment all incisions could have a depth of zero. On observation day 1 the wound volume was 3.67 cm^3 and 4.06 cm^3 in the epidermal growth factor and placebo groups, respectively. On observation day 7 the volume was

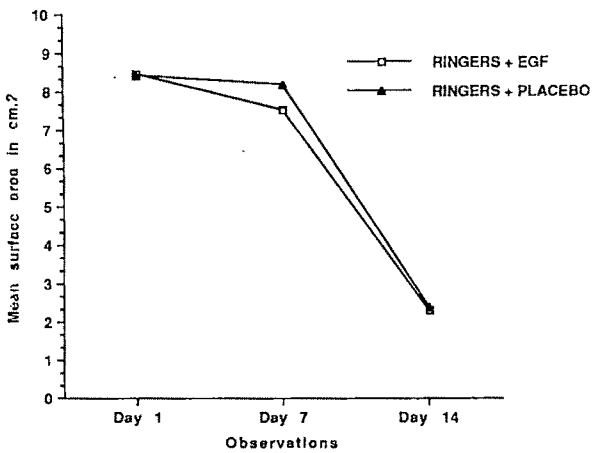

Fig. 1. Plotted comparison of two treatments for wound healing measured by mean surface area in square centimeters at three observation points.

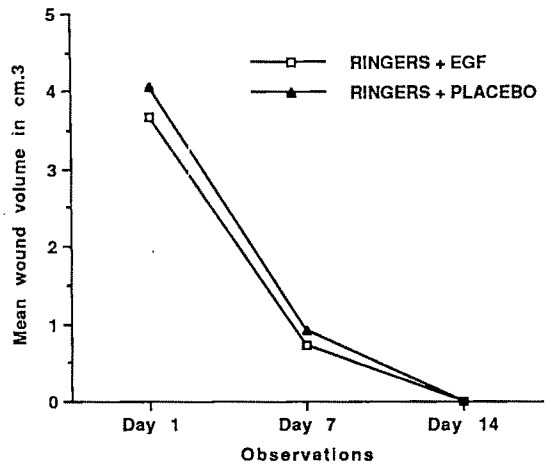

Fig. 3. Plotted comparison of two treatments for wound healing measured by mean volume in cubic centimeters at three observation points.

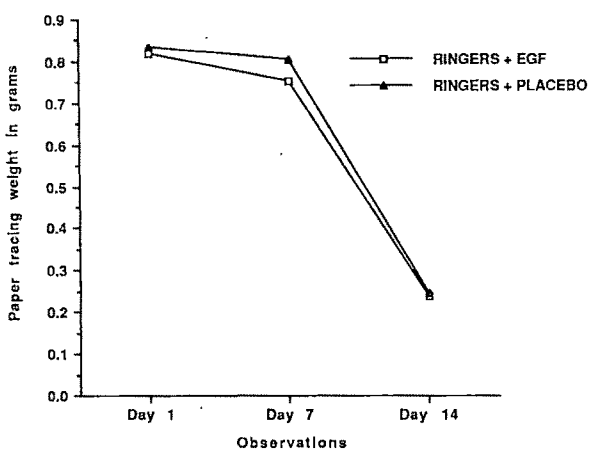

Fig. 2. Plotted comparison of two treatments for wound healing measured by mean weight in grams from paper tracings of surface area photographs at three observation points.

0.72 cm^3 (± 1.28) and 0.92 cm^3 (± 1.33) in the epidermal growth factor and placebo groups, respectively. On observation day 14 both groups of incisions had a volume of 0 (Fig. 3).

Although a faster healing rate was noted in incisions treated with epidermal growth factor compared with those treated with placebo, in none of the three analyses was this difference found to be statistically significant. Nevertheless, all three analyses demonstrated a time effect in the healing rate, independent of group. Most healing occurred during the first week.

The incisions were then analyzed according to the initial three groups of treatment: group 1, those incisions made in the two pigs that only received epidermal growth factor; group 2, those incisions made in the two pigs that only received placebo; and group 3, those incisions made in the six pigs that received both epidermal growth factor and placebo. This group was divided for the purpose of the analysis into two groups: group 3.1, incisions on the left side of the pigs that received only epidermal growth factor; group 3.2, incisions on the right side of the pigs that received only placebo.

In the study of the incisions by treatment groupings, we noted that the groups were statistically equivalent (see Figs. 4 and 5) at the onset of the experiment. However, by observation day 7 the incisions in both groups 1 and 2 had healed faster than those in both groups 3.1 and 3.2. The groups were roughly equivalent by observation day 14, since no statistically significant differences appeared. These results indicate that incisions on animals treated with only one solution, either epidermal growth factor or placebo, healed faster than incisions on animals that received epidermal growth factor on the left side and placebo on the right side.

As a third component of this study, we examined the correlations among the three different methods used to assess wound healing. The correlation of 0.92 between surface area and mean wound volume indicates that these two methods are equivalent. Surface area also correlated significantly with the weight of the paper tracing measure ($r = 0.75$). The paper tracing measure showed a weaker relationship with mean wound volume ($r = 0.65$).

Comment

Controversy still exists concerning the actual benefit of epidermal growth factor in accelerating wound healing. Some have found epidermal growth factor to be useful,[2, 3, 5, 6, 9] whereas others have found no significant effect.[7, 8] Because of this controversy we used three different assessment methods of wound healing to eval-

uate epidermal growth factor in the pig model. Thus confirmation of our values was attained. Analyses of the correlation of the different assessment methods showed that surface area provides the optimal method for assessing wound healing.

Many animals tend to lick their open wounds. This observation and the documented presence of epidermal growth factor in the saliva led Niall et al.[6] to evaluate its use in open granulating wounds. They noted that topical applications of epidermal growth factor enhanced wound closure and demonstrated that the healing rate was faster in both intact or castrated male rats than in female rats. They postulated an androgen-dependent cell sensitivity to epidermal growth factor but noted that such sensitivity does not require the continuous presence of androgens for its expression. Hutson et al.[2] demonstrated that mice caged in groups healed faster than those caged separately; however, sialoadenectomized mice caged in groups did not. To avoid the potential androgenic influence on the activity of epidermal growth factor, we used only female pigs. Each pig was caged separately to avoid licking of the incisions.

Franklin and Lynch[3] performed full-thickness incisions in rabbits' ears and demonstrated that the wound defects treated with epidermal growth factor filled sooner with more cellular elements, thus leaving less space for collapse by wound contracture. Brown et al.[9] also found that epidermal growth factor significantly accelerates epidermal regeneration in partial-thickness skin burns of miniature pigs. Greaves et al.[7] were unable to see any effect in otherwise healthy skin wounds of five human volunteers. Thornton et al.[8] used once-a-day treatments in partial-thickness skin wounds and obtained similar results. We chose twice-a-day treatments, a regimen frequently used in wound breakdowns in our patients.

Epidermal growth factor has two types of cellular receptors. The high-affinity receptors seem to play the major role for epidermal growth factor stimulation of cell division, and these receptors are stimulated at low concentrations of epidermal growth factor. Low-affinity receptors are stimulated with higher concentrations of epidermal growth factor, a process of down-regulation of the receptors is produced, and an inhibitory effect of cell division is seen.[10, 11] Behzadian et al.[11] demonstrated that blocking low-affinity receptors by a specific monoclonal antibody does not decrease the cellular response to epidermal growth factor and the subsequent stimulation of deoxyribonucleic acid synthesis. They concluded that low concentrations of epidermal growth factor (100 to 200 ng/ml), which mainly stimulate high-affinity receptors, are ideal for cellular proliferation. Our choice of 300 ng/ml was based on this information. However, we recognize that the topical

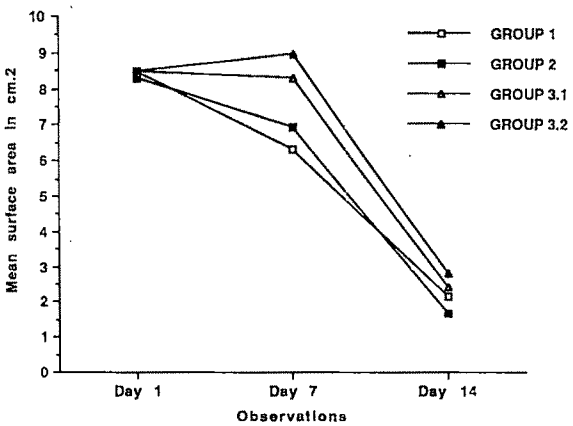

Fig. 4. Plotted comparison of two treatments, grouped by condition within subject, for wound healing measured by mean surface area in centimeters at three observation points: group 1, incisions treated with epidermal growth factor only; group 2, incisions treated with placebo only; group 3.1, incisions on left side treated with epidermal growth factor; group 3.2, incisions on right side treated with placebo.

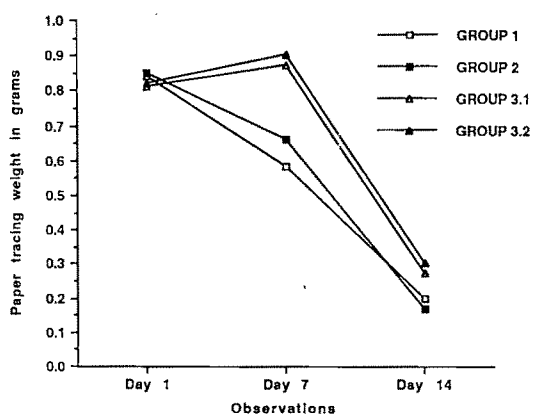

Fig. 5. Plotted comparison of two treatments, grouped by condition within subject, for wound healing measured by mean weight in grams from paper tracing of surface area photographs at three observation points: Group 1, incisions treated with epidermal growth factor only; group 2, incisions treated with placebo only; group 3.1, incisions on left side treated with epidermal growth factor; group 3.2, incisions on right side treated with placebo.

application of the ligand on a live animal could never be as precise and uniform as noted in in vitro studies. We applied 2.0 ml of the solution to each wound, since this amount completely moistened the gauze.

When the analysis was done by groups of treatment, pigs with half of their incisions treated with either epidermal growth factor or placebo were statistically different from those pigs with all four of their incisions treated with either epidermal growth factor or placebo. The healing rate was faster when only one solution was used on the same animal. However, no significant dif-

ference was noted between the incisions on the animals that received either only one solution or both solutions. These results suggest that a systemic regulation of epidermal growth factor may be present.

In summary, a trend toward faster healing in the incisions treated with epidermal growth factor was noted. The benefit of using epidermal growth factor to accelerate the healing of full-thickness skin wounds in the pig model was not demonstrated in this study. Further research is needed to assess the potential of epidermal growth factor in wound healing.

Immunocytochemical study of *ras* and *myc* proto-oncogene polypeptide expression in the human menstrual cycle

Lawrence D. Odom, MD,[a] J. Michael Barrett, PhD,[b] Cooley G. Pantazis, MD,[c] Leland D. Stoddard, MD,[c] and Paul G. McDonough, MD[a]

Augusta, Georgia

The human endometrium is a unique and dynamic tissue model system characterized by cyclic processes of cellular proliferation, differentiation, and menstrual desquamation. Both the glandular epithelial and stromal mesenchymal components work in synchronous response to the mitogenetic effect of estradiol and the antimitogenetic effect of progesterone. Mechanisms whereby estradiol and progesterone exert their effects are not completely understood. This study was undertaken to evaluate the expression and localization of the polypeptide products of the *ras* and *myc* proto-oncogenes sequentially during the menstrual cycle. Sixteen endometrial biopsy specimens were evaluated. Immunocytochemical quantitation of *ras* and *myc* expression was done by use of color image analysis (CoreScan). There was no cyclic variation in the *ras* polypeptide product, but the expression of *myc* polypeptide was low in the secretory phase and high in the proliferative phase. (AM J OBSTET GYNECOL 1989;161:1663-8.)

Key words: Proto-oncogene, *ras*, *myc*, endometrium, menstrual cycle

It is well established that the glandular and stromal endometrial components contain target cell responders to steroid hormones produced sequentially by the dominant ovarian follicle and the corpus luteum. Endometrial proliferation occurs in response to estradiol production, a factor of granulosa cell activity. Estradiol, while remaining in the nuclei of target cells, stimulates the synthesis of deoxyribonucleic acid (DNA) resulting in a wave of mitosis. With the secretion of progesterone, there is a cessation of mitotic activity and the glandular cells differentiate.

Despite continued progress in the understanding of the physiologic mechanisms involved in proliferation of the endometrium and control of such proliferation, additional questions have been raised. It has been demonstrated that murine uterine epithelium is dependent on the presence of homologous stroma for proper response to estrogen stimulation.[1] Additionally, the presence of immunoreactive epidermal growth factor (EGF) in the uterus,[2] the rapid increase in EGF messenger ribonucleic acid (mRNA)[3] and EGF receptor[4] after estrogen, and the growth-promoting effect of EGF in uterine cell culture[5] support the hypothesis that autocrine or paracrine growth factors may be important in the uterine response to estrogen.

The mRNA levels of genes known to be regulated by sex steroids are not altered until ≥1 hour after steroid administration, although the steroid receptor complex has attained an intranuclear location within minutes. A possibility considered by Fink et al.[6] is that steroid-induced gene regulation might involve early regulatory genes whose transcription would be rapidly modulated by steroid receptor binding and whose protein products would in turn regulate the transcription of the structural genes.

To further investigate endometrial physiologic characteristics, a study was undertaken to evaluate the expression of two proto-oncogene (*ras* and *myc*) polypeptide products in the proliferative and secretory phases of the human menstrual cycle.

Material and methods

Fifteen endometrial biopsy specimens were chosen on the basis of a normal menstrual and conception history, as well as absence of pathologic changes at the time of laparoscopic sterilization. One biopsy specimen was obtained before total vaginal hysterectomy for procidentia. No associated abnormalities could be determined at the time of surgery. There was no history of recent exogenous hormonal exposure in any of the study subjects. Dates of the formalin-fixed, paraffin-embedded biopsy specimens were assigned by one author (L. D. S.) without prior knowledge of the clinical history. Histomorphologic criteria used to establish dates of the 4 μm thick sections were based fundamentally on the study by Noyes et al.[7] The menstrual

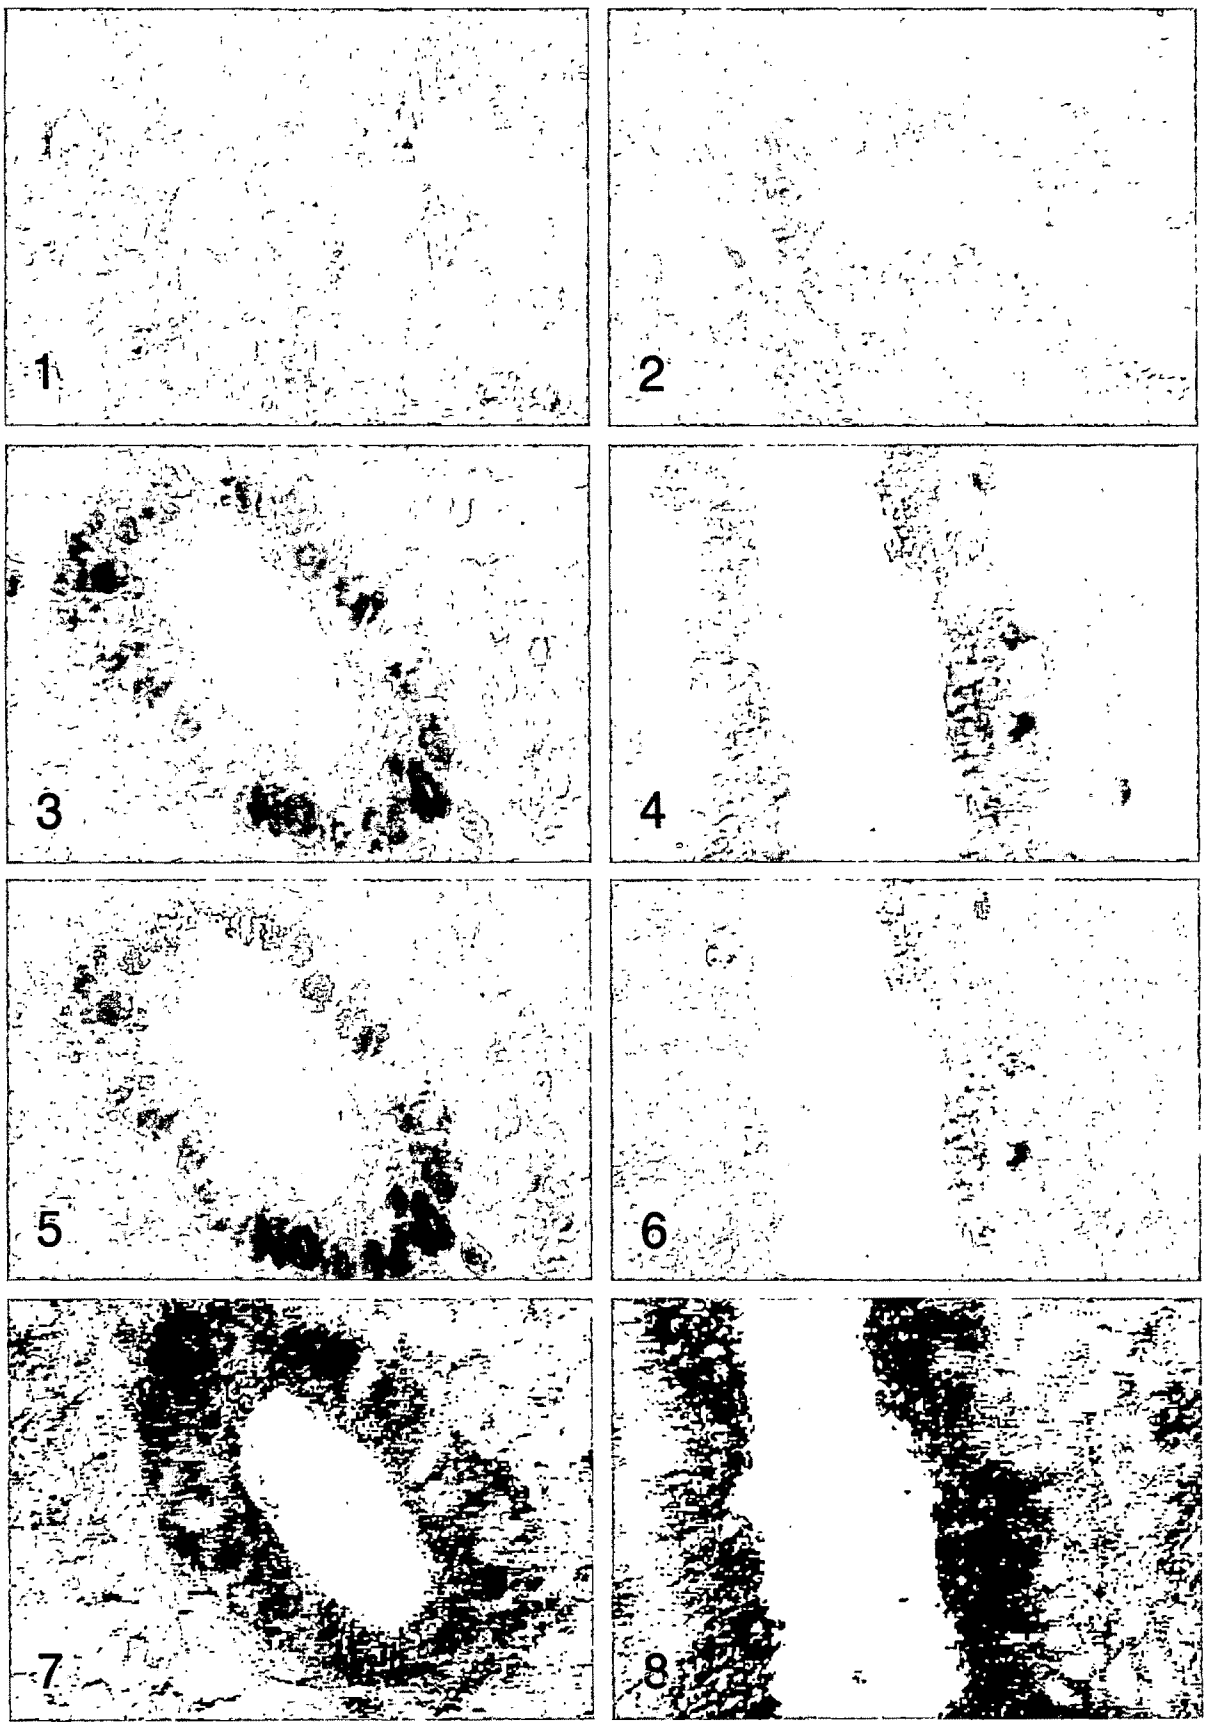
Stages 1 to 3 are proliferative; stages 4 to 6 are secretory.



cycle was divided into six stages. These were early, mid, and late proliferative and secretory designations. These stages were categorized 1 through 6. There was one patient in category 1, one patient in category 2, seven patients in category 3, three patients in category 4, three patients in category 5, and one patient in category 6. For statistical evaluation, these categories were grouped 1 to 3 ($n = 9$) and 4 to 6 ($n = 7$).

For this study an indirect peroxidase-antiperoxidase method described previously[8] was modified. In situ hybridization was performed with the use of the CRL Universal immunoperoxidase staining kit. Sections were deparaffinized in xylene (two changes, 5 minutes each). Rehydration was performed with a graded series of ethanols (100% alcohol, two changes, 3 minutes each; 95% alcohol, two changes, 3 minutes each; 70% alcohol, 3 minutes). The slides were then placed in a final bath of 0.05 mol/L Tris buffer plus 1.5% sodium chloride, pH 7.6. Steps in the method are as follows: step 1, blocking agent—3% hydrogen peroxide (10 minutes); step 2, blocking agent—normal serum (40 minutes); step 3, primary antibody—dilution RAP-5 1:1000 and OP-10 1:10 (18 hours)[9]; step 4, linking reagent (20 minutes); step 5, labeling reagent (peroxidase-antiperoxidase immunoenzyme complex). The complex was visualized by the addition of a chromogenic substrate, amino-ethylcarbazole. All sections were counterstained with hematoxylin and mounted with Permount.

To evaluate the presence of *ras* proto-oncogene (c-*ras*) polypeptide product, the monoclonal antibody RAP-5 was chosen. This monoclonal antibody was supplied by the Tissue Type Culture at the National Institutes of Health (by Dr. Jean Simpson). It was developed against a synthetic peptide immunogen reflecting positions 10 to 17 of the human *ras* protein product from the T-24 bladder carcinoma cell line. RAP-5 has demonstrated reactivity with cellular and point-mutated forms of the polypeptide product (p21) from all three members of the *ras* oncogene family.[10-12] The presence of *myc* proto-oncogene (c-*myc*) polypeptide product was demonstrated with the assistance of the monoclonal antibody OP-10 purchased from Oncogene Science. This monoclonal antibody was developed by using a synthetic peptide corresponding to residues 405 to 432 of the human c-*myc* polypeptide (p62) and was characterized by Evan et al.[13] Positive controls consisted of a T-24 bladder carcinoma cell line for the RAP-5 monoclonal antibody and a Burkitt lymphoma specimen for the OP-10 monoclonal antibody. Negative controls in both instances were provided by omitting the primary antibody application.

The immunoreactive product was quantitated with CoreScan Color Image System software (Delta Tech-

nologies, Inc., Augusta, Ga.). The system includes a color video camera mounted on a Zeiss Axiophot microscope. The video is cabled to an AT & T True Vision Image Capture Board (ICB) installed in an IBM-PC computer. The output from the ICB monitor is directed to a Sony color monitor. A software program called CoreScan was used to perform color video analysis.[14] Three representative glandular structures and stromal areas were chosen from each slide by two investigators (C. G. P. and L. D. O.) for digitized analysis.

Since the categories were grouped 1 to 3 (n = 9) and 4 to 6 (n = 7), statistical analysis was carried out with hypothesis testing, the difference between population means and Student's t test. To assume equality of population variances, the sample variance ratios were evaluated on the basis of the F distribution.

This study was presented before the Human Assurance Committee of the Medical College of Georgia and met with its approval.

Results

The values obtained in Table I represent reaction product expressed as a percentage of the total area scanned averaged over the three fields (×40). The polypeptide products, c-*ras* p21 and c-*myc* p62, were found to be expressed in both the proliferative and secretory phases of the normal menstrual cycle (Figs. 1, 2, 3, and 4, respectively). Reaction product was identified in both the glandular epithelial and stromal compartments of the endometrium. The *ras* monoclonal antibody identified reaction product was localized exclusively to the cytoplasm (plasma membrane) as expected (Figs. 1 and 2). The *myc* monoclonal antibody–identified reaction product was in both the nucleus and the cytoplasm. In this study a nuclear distribution for c-*myc* was visually apparent in the actively dividing cells (proliferative phase) (Fig. 3). In differentiated cells (secretory phase) the c-*myc* distribution was primarily cytoplasmic in location (Fig. 4). Figs. 5 (c-*myc* late proliferative phase) and 6 (c-*myc* postovulation day 5) represent computerized banding with a reduction to 64 colors. Figs. 7 and 8 are representative of the same two biopsy specimens with computerized localization of the immunocytochemical reaction product.

Statistical analysis (α = 0.05) of the sample data indicated no statistically significant difference between proliferative and secretory expression of the c-*ras* peptide product in either the glandular epithelium (significance level p = 0.14) or stromal compartments (significance level p = 0.06) (Fig. 9). However, there was evidence that the c-*myc* peptide product was expressed to a lesser degree in both the glandular (significance level p = 0.00003) and stromal compartments (significance level p = 0.005) of the secretory phase when compared with the proliferative phase (Fig. 10). The progressive loss of c-*myc* expression was seen through-

out the secretory cycle and followed a temporal relationship with the postovulation day status.

Comment

Cellular oncogenes are present in all normal cells. Current evidence suggests that most oncogenes code for proteins that are involved in the regulation of cell division and/or differentiation.[15] The *ras* genes were first isolated as the transforming genes of Harvey and Kirsten sarcoma viruses. At least three different *ras* genes (Harvey-*ras*, Kirsten-*ras*, and N-*ras*) exist in mammals. All three genes have a similar genetic structure and code for a protein product of 188 or 189 amino acids with a molecular weight of 21,000 d. The cellular location of the p21 polypeptide is the inner surface of the plasma membrane. The specific cellular function of *ras* p21 is unclear; however, it has been shown to bind guanosine 5′-diphosphate and triphosphate, to have guanosine triphosphatase activity, and to exhibit autokinase activity. Its properties suggest that *ras* p21 may function as a signal transducer, similar to the G proteins.[10, 12] The human c-*myc* proto-oncogene is a cellular gene homologous with the 3′ sequence of the transforming gene of avian myelocytomatosis virus MC29. The protein product of the c-*myc* gene has a molecular weight of 62,000 d and is believed to be composed of 439 amino acids. Like the c-*ras* p21, the action of c-*myc* p62 in normal cells is not entirely known. However, unlike p21, active c-*myc* p62 is localized in the nucleus.[13] Studzinski et al.[16] have shown that the addition of polyclonal or monoclonal antibodies against human c-*myc* protein to nuclei isolated from several types of human cells reversibly inhibited DNA synthesis and DNA polymerase activity but not the transcription of RNA. This suggests that c-*myc* encodes a polypeptide product that participates in DNA replication.

With the rat uterus as a model, Murphy et al.[17] confirmed that mitogenetic stimulation resulted in a rapid accumulation of *myc* proto-oncogene mRNA. In this case the mitogen was estradiol. The administration of estrogen had no significant effect on the abundance of c-*myc* transcripts in the kidney, liver, or lung. The avian oviduct study performed by Fink et al.[6] revealed a tissue-specific and rapid down-regulation of c-*myc* mRNA by progesterone. They concluded that the reduction of c-*myc* gene expression in target cells might represent one mechanism whereby progesterone inhibits estrogen-induced mitogenetic events.

As stated previously, active c-*myc* p62 polypeptide seems to be localized in the nucleus. However, additional data suggest that c-*myc* transcripts are exported from the nucleus in quiescent cells.[18] In a study by Jack et al.,[19] a nuclear distribution of c-*myc* p62 was seen in the actively dividing cells of the bone marrow and in some tumors. However, in most normal cells the localization was cytoplasmic. It was suggested that localization of the polypeptide in vivo may differ in cells that are dividing compared with those that are arrested or terminally differentiated.

To our knowledge this report represents the first to evaluate the expression of the *ras* and *myc* proto-oncogenes serially in the human menstrual cycle. With the use of monoclonal antibodies, there has been confirmation of *ras* and *myc* polypeptide products in normal endometrial tissue. On the basis of our data, the expression of the *ras* polypeptide product during the menstrual cycle is not cyclic. Since it is not certainly known that the *ras* p21 polypeptide is involved in signal transduction, these findings do not rule out an autocrine or paracrine effect in the endometrium. On the other hand, the lack of change in p21 expression may be due simply to the sensitivity of the testing procedure or the fact that guanosine triphosphate binding is an on-again/off-again phenomenon leaving a constant amount of p21 polypeptide at the plasma membrane's inner surface.

Our data add to the growing evidence that *myc* p62 polypeptide expression is influenced by steroidal mitogenetic effect (estradiol), as well as steroidal antimitogenesis (progesterone). Furthermore, we have made observations suggesting the transportation of the c-*myc* p62 polypeptide from the nucleus to the cytoplasm in differentiated cells.

We extend our appreciation to Mr. William Wansley for his technical expertise in slide preparation and to Mr. Rollie Harp of the Research Computing and Statistical Department of the Medical College of Georgia for his contributions to statistical analysis.

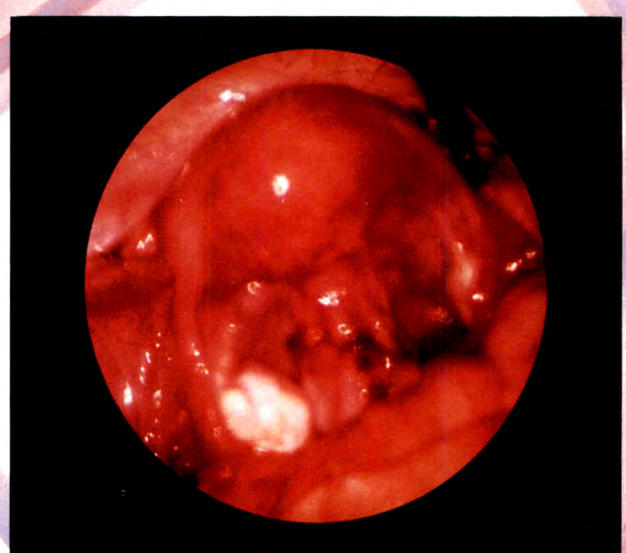
Surgical breakthrough

To reduce adhesions later...

Intercede now

Introducing the first proven adhesio

Sidewall adhesion prior to lysis.



Without INTERCEED Barrier, adhesions were prevented in only 24% of the pelvic sidewalls (N = 32) treated with state-of-the-art surgery alone (134 patients).

The first surgical adjuvant specifically indicated to reduce postoperative adhesions.

- **Effective adhesion control** may help preserve fertility[1-4]
- **Twice as effective** as state-of-the-art surgery alone, when used in conjunction with meticulous surgical techniques
- **Minimal tissue reaction**–significantly less than other absorbable products
- **No complications**–the INTERCEED Barrier was completely absorbed within 28 days . . . no adverse reactions were reported

rrier for gynecologic pelvic surgery

With INTERCEED Barrier, 51% of the pelvic sidewalls (N = 68) treated with state-of-the-art surgery were completely free of adhesions (134 patients).

Evaluation at second-look laparoscopy.

Landmark study demonstrates:

INTERCEED*(TC7) Absorbable Adhesion Barrier helps reduce adhesion formation

Twice as effective in preventing adhesion formation

Study design

INTERCEED Barrier was evaluated in a controlled multicenter study[5] of 134 women undergoing elective surgery to correct bilateral pelvic-sidewall adhesions. After microsurgery via laparotomy (with hemostasis consistent with microsurgical principles), application of INTERCEED Barrier was randomized to the left or ri side, with the contralateral side serving as a control site. *Thus, patient was, in effect, her own control.* Results established the utility of INTERCEED Barrier as adjuvant to gynecologic surger

INTERCEED Barrier prevented th formation of adhesions in twice many sites as surgery alone.

NEW

INTERCEED* (TC7)

Absorbable Adhesion Barrier

(OXIDIZED REGENERATED CELLULOSE)

Brief Summary for INTERCEED* (TC7) Absorbable Adhesion Barrier (Oxidized Regenerated Cellulose). Before prescribing, please see full prescribing information.

INDICATIONS: INTERCEED* (TC7) Absorbable Adhesion Barrier is indicated as an adjuvant in gynecologic pelvic surgery for reducing the incidence of postoperative pelvic adhesions after hemostasis is achieved consistent with microsurgical principles.

CONTRAINDICATIONS: The use of INTERCEED Barrier is contraindicated in the presence of frank infection. INTERCEED Barrier is not indicated as a hemostatic agent. Appropriate means of achieving hemostasis must be employed.

WARNINGS: INTERCEED Barrier must not be used in cases in which complete hemostasis has not been established. The effectiveness of INTERCEED Barrier is reduced when saturated with blood.

INTERCEED Barrier is supplied sterile. As the material is not compatible with autoclaving or ethylene oxide sterilization, INTERCEED Barrier must not be resterilized.

Although none have been reported, foreign body reactions may occur in some patients.

PRECAUTIONS: The safety and effectiveness of using INTERCEED Barrier in combination with other adhesion prevention treatment have not been clinically established.

Ectopic pregnancies have been associated with fertility surgery of the female reproductive tract. No adequate and well controlled studies have been conducted in women who become pregnant within the first month after exposure to INTERCEED Barrier. No data exist to establish the effect, if any, of INTERCEED Barrier on the occurrence of ectopic pregnancies. No teratogenic studies have been performed. Therefore, an avoida conception should be considered during the first complete menstrual cycle after use of INTERCEED E Care should be exercised in applying INTERCEED Barrier to a pelvic organ not to constrict or restric

ADVERSE REACTIONS: To date, no adverse reactions have been reported attributable to the INTERCEED Barrier.

CAUTION: Federal law restricts this device to sale, distribution, or use by or on the order of a phy

Comparison of Cytobrush and cervicovaginal lavage sampling methods for the detection of genital human papillomavirus

Gary L. Goldberg, MD,[a] Sten H. Vermund, MD,[b, c] Mark H. Schiffman, MD,[c] Diane B. Ritter, MD,[a] Carol Spitzer, BS, MS,[d] and Robert D. Burk, MD[c, d]

Bronx, New York, and Bethesda, Maryland

The development of an accurate method for the detection and typing of genital human papillomavirus is of substantial clinical importance. This virus has been implicated as an etiologic agent in the development of cervical neoplasia. To detect human papillomavirus infection with maximum sensitivity, cells must be collected and assayed for human papillomavirus deoxyribonucleic acid. We compared two noninvasive methods of sampling exfoliated cervical cells—cervicovaginal lavage and scrape–Cytobrush. Seventy-four patients newly referred to the colposcopy clinic were divided randomly for cell sampling by either cervicovaginal lavage followed by scrape-Cytobrush or, conversely, scrape-Cytobrush followed by cervicovaginal lavage. Restriction analysis and Southern blot hybridization were used to test all the samples thus obtained for human papillomavirus. Overall, test results from 42 patients (56.8%) were positive for human papillomavirus deoxyribonucleic acid. Twenty-six (31.1%) tested positive for human papillomavirus by both sampling methods, and 32 (43.2%) tested negative for human papillomavirus by both methods. One (1.4%) tested positive with scrape-Cytobrush sampling but negative with cervicovaginal lavage, while 15 (20.3%) tested negative with scrape-Cytobrush but positive with cervicovaginal lavage ($p < 0.001$, McNemar's test). These data, combined with previous work from our group, suggest that, of the available methods, cervicovaginal lavage, coupled with human papillomavirus deoxyribonucleic acid hybridization, is the most sensitive noninvasive method for harvesting cells for molecular identification of human papillomavirus in the female lower genital tract. (Am J Obstet Gynecol 1989;161:1669-72.)

Key words: Papillomavirus, cervix diseases, epidemiology

The development of an accurate method for the detection and typing of genital human papillomavirus (HPV) is of substantial clinical importance. Increasing research and mounting evidence have suggested that HPV infection of the cervix is associated with the development of cervical neoplasia.[1, 2] A variety of HPV types is commonly found in cervical cancer tissues, premalignant cervical lesions, and, less commonly, in normal cervical epithelium.[3-8]

At present, HPV cannot be propagated in cell culture or reliably identified by immunologic methods. According to Schneider,[9] only the detection of HPV deoxyribonucleic acid (DNA) gives direct confirmation of the presence or absence of the virus. Various methods of HPV DNA identification have previously been described: dot blot, filter in situ hybridization, Southern blot hybridization, and, recently, polymerase chain reaction.[9-11] Restriction enzyme analysis, coupled with Southern blot hybridization, appears to be the currently preferred method for the detection of HPV DNA.[9]

The clinical sampling technique used to collect the material for DNA analysis is important. A noninvasive test offers the potential to screen a large number of patients. Routine Papanicolaou smear techniques do not always yield enough exfoliated epithelial cells for HPV assessment by DNA hybridization. We have previously compared the scrape-swab technique with cervicovaginal lavage for the collection of exfoliated cells from the female lower genital tract.[12] The cervicovaginal lavage cell collection technique is significantly more sensitive than the scrape-swab technique for assessing HPV infection. The Cytobrush cell collection instrument (Zelsmer) also have recently been shown to be more effective than a cotton-tip swab for obtaining endocervical cells for routine Papanicolaou screening.[13-15] We compared the Cytobrush with the cervicovaginal lavage for sampling and collection of exfoliated cervicovaginal cells.

Methods

Seventy-four patients referred to a City Hospital colposcopy clinic in the Bronx, New York, were enrolled

From the Departments of Obstetrics and Gynecology,[a] Epidemiology and Social Medicine,[b] Pediatrics,[c] and Microbiology and Immunology,[d] Albert Einstein College of Medicine/Montefiore Medical Center, Bronx, and the Environmental Epidemiology Branch,[e] National Cancer Institute, Bethesda.[e]

Supported in part by National Institutes of Health Contract No. 263-MD-706528-2. Dr. Ritter is supported by National Institutes of Health, National Cancer Institute Training Grant No. CA-09173.

Presented at the Thirty-sixth Annual Meeting of the Society for Gynecologic Investigation, San Diego, California, March 15-18, 1989.

in this study, which was approved by the hospital's institutional review board. All patients were examined by a single gynecologist (G. L. G.). Standard Papanicolaou smears, obtained by use of a cotton-tip swab and then a spatula, were obtained for cytologic study, after which both study methods (scrape-Cytobrush and cervicovaginal lavage) were used to collect cells for HPV testing. Patients were randomly divided into two groups, according to the last digit of their medical record numbers. Thirty-six of the 74 patients had scrape-Cytobrush sampling followed by cervicovaginal lavage, while 38 had cervicovaginal lavage followed by scrape-Cytobrush. Under this method, each woman served as her own control, and ordering effects could be assessed by comparison of the two groups. For the scrape-Cytobrush technique, a Cytobrush was inserted and rotated 360 degrees twice inside the endocervical canal. A wooden cervical spatula was then rotated 360 degrees twice around the external cervical os and squamocolumnar junction. The Cytobrush and the spatula tip were then vigorously shaken to dislodge cells into 10 ml of a 0.9% sodium chloride–50 mmol/L ethylenediaminetetraacetic acid (EDTA) solution in a 50 ml polypropylene tube. A 10 ml syringe with a 2-inch, 18-gauge Teflon extension catheter was used to spray 10 ml of sterile saline solution against the external cervical os and the ectocervix. The fluid that pooled in the posterior vaginal fornix was aspirated into the syringe and transferred to a 50 ml polypropylene tube containing 1.0 ml of 0.5 mol/L EDTA. Specimens collected by both methods were refrigerated at 4° C until processing. Cellular material was quantitated by determining the packed volume of cells after centrifugation at 13,000 rpm for 5 minutes. DNA was then extracted as previously described and resuspended in 30 μl of TE (10 mmol/L Tris buffer, pH 8.;0, and 0.1 mmol/L EDTA).[7]

For the detection of HPV DNA, 10 μl of the unknown sample DNA solution was digested with the *Pst* I restriction enzyme according to conditions specified by the supplier, New England Biolabs. DNA fragments were separated by electrophoresis in 0.8% Agarose slab gels. DNA was visible after staining with ethidium bromide and was photographed under ultraviolet light. Southern blot hybridization was then performed with a mixed probe of HPV-11, HPV-16, and HPV-18 DNA inserts labeled with phosphorus 32.[7] After exposures ranging from 2 to 14 days, the autoradiographs were interpreted by researchers who did not know the origin of the specimens.

To assess the statistical significance of the differences in HPV diagnosis between scrape-Cytobrush and cervicovaginal lavage techniques, we used McNemar's test for correlated proportions.[16] A χ^2 analysis, with the Yates continuity correction where appropriate, was used for testing the significance of differences between cell volumes in samples obtained by cervicovaginal lavage after scrape-Cytobrush, as compared with those obtained by scrape-Cytobrush after cervicovaginal lavage.[16]

Results

More cellular material was obtained with cervicovaginal lavage than with the scrape-Cytobrush method. The median cell volume for scrape-Cytobrush was 5 μl, the mean volume was 11.2 ± 10.4 μl (±SD), and the range was 2 to 50 μl. The median cell volume for cervicovaginal lavage was 62.5 μl, the mean volume was 96.0 ± 96.5 μl (±SD), and the range was 5 to 500 μl. The cervicovaginal lavage method yielded a twelvefold greater median cell volume of recovered sample and provided more cellular material in 66 of the 74 patients (89.2%). The same yield in microliters was noted in 8 of the 74 patients (10.8%). All specimens, irrespective of collection method, contained visible cell pellets.

We were concerned that repeated collection of cervicovaginal cells during a single examination would in-

fluence the cell yield and the possibility of the HPV DNA detection, so we compared the order of testing and the cell sample size. The ordering effects on cell sample recovery by the two collection methods can be seen in Tables IA and IB. There was no statistically significant correlation between test order and amount of cellular material collected by cervicovaginal lavage or scrape-Cytobrush ($p = 0.3$ and 0.5, respectively). A lower overall recovery was obtained with scrape-Cytobrush regardless of the order of the tests.

Twenty-six of the 74 patients' (35.1%) samples collected by both the scrape-Cytobrush and the cervicovaginal lavage techniques revealed HPV DNA (Table II). Thirty-two of the 74 (43.2%) samples collected by both techniques tested negative for HPV DNA. In 15 of the 74 cases (20.2%) the virus was detected in the cervicovaginal lavage sample, but not in the scrape-Cytobrush sample. In one case HPV was detected in the scrape-Cytobrush sample alone. The discordant findings are unlikely to have occurred by chance alone ($p < 0.001$ by McNemar's test).

Southern blot analysis was used to determine the presence and type of HPV DNA, as illustrated in Fig. 1. The virus types detected in the 42 women whose sample tested positive for HPV DNA were consistent between the two techniques. Twenty-four of the 26 patients (92.3%) who tested positive for HPV with both sampling techniques had the same HPV DNA types in the cervicovaginal lavage and scrape-Cytobrush samples. In the 15 samples that were positive with cervicovaginal lavage only, the virus type identified was consistent for cervical infection and for the population being studied (Burk RD, et al., unpublished data). Overall, in this study type 16 was the most prevalent HPV type, a finding consistent with our previous results.[12]

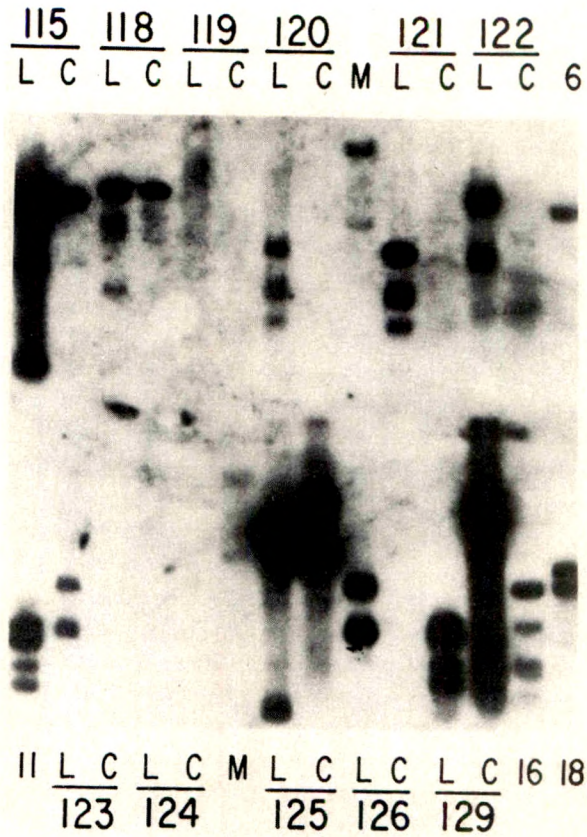

Fig. 1. Detection of HPV DNA by *Pst* I restriction analysis and Southern blot hybridization. DNA samples were isolated from cells collected by either lavage *(L)* or Cytobrush *(C)*, digested with *Pst* I, separated by gel electrophoresis, and transferred to a Nytran filter (Schleicher and Schuell). The filter was hybridized with a mixed probe of HPV-11, HPV-16, and HPV-18 DNA labeled with ^{32}P and washed under stringent conditions (TM-10 C). Patient number is shown above the *solid line*. A total of 10 to 20 pg of gel-isolated linear HPV DNA was mixed with 5 μg of genomic DNA, digested with *Pst* I, and run as hybridization sensitivity control (equivalent to approximately two viral genomes per cell). The lanes containing HPV-6, HPV-11, HPV-16, or HPV-18 DNA are indicated. The *L* and *C* samples from patients *115* and *118* contained the same type of HPV DNA, whereas the *L* sample was positive and the *C* negative in No. *120*, No. *121*, No. *122*, and No. *123*. The DNA samples from the *C* specimen of No. *125* and No. *129* were incompletely digested and the HPV type could not be determined from this blot. Interpretation of HPV types from this blot indicate: patient *115*, HPV-18 and HPV-14; patient *118*, related HPV; patient *120*, HPV-16; patient *121*, HPV-16; patient *122*, HPV-45; patient *123*, HPV-31; patient *125*, HPV-18 and related HPV; patient *126*, HPV-31; patient *129*, HPV-11.

Comment

The definitive role of HPV in cervical neoplasia remains unresolved. Mounting evidence links or associates HPV infection with premalignant and malignant lesions of the cervix.[3-8] Specific HPV DNA types are commonly found in biopsy specimens of cervical carcinoma and cervical intraepithelial neoplasia. Certain HPV types contain genetic information capable of transforming cells in culture, although this oncogenic potential has not been unequivocally demonstrated in vivo.[6] Accurate documentation of the HPV status is of epidemiologic and potential clinical importance.

The Cytobrush is a device specifically designed for sampling the endocervical canal. It has been used to collect clinical samples for testing for chlamydia and other sexually transmitted diseases. Various authors have reported improved endocervical cell collection when they used the Cytobrush instead of a cotton-tip swab for Papanicolaou smears.[13-15] No samples collected by the scrape-Cytobrush technique were labeled "quantity not sufficient for DNA evaluation." Recent data suggest that standard techniques obtain a greater proportion of insufficient cell yields from patients with cervical lesions, compared with samples collected by the

same methods from patients who do not have lesions.[22] This bias is partially mitigated by the use of scrape-Cytobrush and further minimized with the cervicovaginal lavage technique. We were aware that obtaining a Papanicolaou smear before the HPV sampling method might affect the cell collection. Moreover, it could have had more effect on the cell count in samples collected by the scrape-Cytobrush method, in comparison with the cervicovaginal lavage method, because cervicovaginal lavage could have been collecting cells that had already exfoliated into the vaginal fornix. Alternatively, cervicovaginal lavage might have been picking up HPV in vaginal cells, the same types that were infecting the cervix. In practice, many clinicians are not willing to collect cells for HPV determination before the Papanicolaou smear because doing so might compromise the cytologic result. Since HPV tresting is being promoted primarily as an adjunct to the Papanicolaou smear and is usually performed at the same examination, we therefore included a standard Papanicolaou smear before scrape-Cytobrush and cervicovaginal lavage.

The multifocal potential of the squamous epithelium of the lower genital tract for intraepithelial neoplasia and carcinoma is of clinical and epidemiologic significance. Sampling that includes the cervix, endocervix, and vaginal fornices increases the yield of exfoliated cells and the sensitivity of HPV DNA detection while reducing the number of false-negative tests.

We conclude that substitution of the scrape-Cytobrush method for the scrape-swab method improved the cell yield for HPV DNA detection. However, our study reaffirmed that cervicovaginal lavage is the most sensitive collection method for exfoliated cervicovaginal cells for the detection of HPV and should replace the standard or routine scrape techniques currently in use, including the Cytobrush.

We thank Mrs. Audrey Mack for the preparation of the manuscript.

Spontaneously resorbing ectopic pregnancy: Preservation of human chorionic gonadotropin bioactivity despite declining steroid hormone levels

Mark V. Sauer, MD,[a] Robert E. Anderson, MD,[b] Michael Vermesh, MD,[a] Bronte A. Stone, PhD,[c] and Richard J. Paulson, MD[a]

Los Angeles, California

We compared serum hormone profiles of patients with normal intrauterine pregnancies (n = 14), spontaneously resorbing ectopic pregnancies (n = 10), and viable ectopic pregnancies (n = 26). Hormone profiles were evaluated at 5 to 8 weeks' gestational age. Ectopic pregnancies were diagnosed by laparoscopy; intrauterine gestations were confirmed by ultrasonography. Immunoreactive β–human chorionic gonadotropin, progesterone, estradiol, and 17-hydroxyprogesterone were measured by radioimmunoassay. Bioactive human chorionic gonadotropin was measured by a modified mouse Leydig cell bioassay. Diminished steroid production was noted in ectopic pregnancies; levels in serum of patients with resorbing ectopic pregnancies were lower than values expressed in viable ectopic pregnancies ($p < 0.01$). Serum levels of human chorionic gonadotropin bioactivity correlated closely with immunoreactive human chorionic gonadotropin in all three groups ($r = 0.81$, $p < 0.01$). Ratios of bioactive human chorionic gonadotropin to immunoreactive β–human chorionic gonadotropin were similar (0.93 ± 0.26 in resorbing ectopic pregnancies, 1.11 ± 0.16 in viable ectopic pregnancies, and 0.90 ± 0.10 in intrauterine pregnancies). We conclude that although reduced serum levels of steroids noted in ectopic pregnancy suggest an impairment in corpus luteum activity, diminished steroid production was not attributable to lower human chorionic gonadotropin bioactivity. (Am J Obstet Gynecol 1989;161:1673-6.)

Key words: Ectopic pregnancy, progesterone, bioactive human chorionic gonadotropin

Whereas serum levels of human chorionic gonadotropin (hCG) are generally lower in women with ectopic pregnancies than in normal intrauterine gestations, levels of sex steroids are proportionately lower, which facilitates rapid discrimination of normal or abnormal gestations.[1,2] Suggested reasons for diminished serum steroid content include altered hCG bioactivity, perturbed steroidogenesis by the corpus luteum, absence of a still-uncharacterized ovarian stimulator of steroid biosynthesis, and alterations in hCG glycosylation.[3] We previously described the clinical course of women with ectopic pregnancies destined to resolve spontaneously without intervention.[4] In this population, ovarian steroid production was noted to be depressed; progesterone and 17-hydroxyprogesterone levels in serum were <0.8 ng/ml. Because the half-life of steroid hormones in serum is shorter than that of hCG, it is possible that low peripheral levels of steroids that originate from the corpus luteum reflect diminished luteotropic support of hCG (bioactive/immunoreactive ratio) before its clearance from the circulation. This study investigates this latter possibility by examination of the relationship between bioactive hCG and immunoreactive hCG, and the markers of corpus luteum function in women with differing pregnancy outcomes.

Material and methods

Patients. A total of 36 women with laparoscopically visualized ectopic pregnancies were studied. All pregnancies were between 30 and 56 days' gestation (mean ± SE, 42 ± 4 days) at the time of diagnosis, based on recollection of the last menstrual period. Within this population, 10 women were enrolled in a study of nonsurgical treatment as previously described,[5] based on the following criteria: (1) tubal pregnancy <3 cm diameter; (2) tubal serosa intact; (3) no active bleeding present at time of diagnosis; and (4) declining serum β-hCG levels as measured by radioimmunoassay (RIA). All patients in this group went on to resolve their ectopic pregnancies without medical or surgical intervention. The remaining 26 cases were termed *viable ectopic pregnancies* and were treated surgically in standard fashion. A control group comprised 14 women with normal intrauterine pregnancies of similar gestational age. All patients were followed up until

Table I. Hormonal characteristics of all patients

*$p < 0.01$ versus resorbing ectopic pregnancy.

†$p < 0.01$ versus ongoing ectopic pregnancy.

intrauterine cardiac activity was noted by transvaginal ultrasonographic examination. Aliquots taken from sera obtained from patients at the time of pregnancy diagnosis were stored at −20° C until assayed. Blood samples from ectopic gestations were drawn preoperatively.

Radioimmunoassays. Serum β-hCG, estradiol, progesterone, and 17-hydroxyprogesterone were measured in duplicate with commercial RIAs (ICN Biomedical Inc., Carson, Calif.). Validation of these assays has been detailed elsewhere.[6, 7] Intra-assay coefficients of variation were <12% for all hormones studied. Values of immunoreactive β-hCG are reported in terms of the World Health Organization First International Reference Preparation (75/537).

Bioassay of hCG. Serum hCG bioactivity was measured by the modified mouse Leydig cell assay.[8] Briefly, adult mice (strain B6BFL) were killed and the testes were removed. After mechanical dispersion, aliquots (100 μl) of cell suspension that contained approximately 200,000 viable Leydig cells were combined in triplicate with 100 μl of diluted sample or standard hCG (iodination grade, 15,000 IU/mg; Sigma Chemical Company, St. Louis) diluted in culture medium (Dulbecco's Modified Eagle's, GIBCO, New York, N.Y.). After incubation for 3 hours at 34° C, 50 μl aliquots of supernatant were assayed for testosterone content by a direct RIA (Pantex, Santa Monica, Calif.), sensitive to 5 pg testosterone per tube. Average coefficients of variation for testosterone assayed were <10%. Levels of bioactive hCG in individual samples were derived from curves fitted to hCG concentrations in the standards (calculations performed on an IBM-XT based 3001 Quality Control System, Iso-Data Inc., Rolling Meadows, Ill.). Average intra-assay coefficients of variation for the hCG bioassay were <10% and interassay coefficients of variation were <16%.

Statistics. Means of distributions of immunoreactive β-hCG, bioactive hCG, progesterone, estradiol, and 17-hydroxyprogesterone were compared with the nonparametric method of Mann-Whitney. Least squares linear regression correlation coefficients were calculated on log transformed data. Statistical significance was defined as the 5% level for two-tailed data.

Results

Table I lists hormonal values obtained in the three groups of women. Despite similar gestational age, levels of immunoreactive β-hCG and all steroid hormones were significantly lower in ectopic pregnancies than in normal intrauterine gestations. Levels of all hormones in serum of patients whose gestations were destined to resorb spontaneously were significantly lower than corresponding levels of hormone in patients with viable ectopic pregnancies, although some overlap did exist between value ranges.

Overall, measurements of bioactive hCG and immunoreactive β-hCG correlated closely ($r = 0.81$, $p < 0.01$; Fig. 1). As noted in Table I, ratios of bioactive hCG/immunoreactive β-hCG were not dissimilar among groups, and ratios were near unity.

Comment

Heterogeneity has been appreciated in the clinical presentation and course of ectopic pregnancy since Lund first reported on spontaneous resolution in the 1950s.[9] More recently, several authors have reported successful expectant management of selected cases of laparoscopically confirmed ectopic gestations.[10, 11] The concepti are characteristically small in size (<3 cm), ampullary in location, and produce low levels of immunoreactive β-hCG (<1000 mIU/ml). It remains uncertain why some ectopic implantations of trophoblast continue to proliferate, invade the tubal epithelium, and progress to tubal rupture, whereas others remain confined, relatively dormant, and are destined to abort or resorb. Physician intervention may occur any time along this continuum, and there appears to be no easy way to anatomically discriminate between ectopic pregnancies that require treatment and those that would spontaneously resolve.

During the initial course of normal pregnancy the

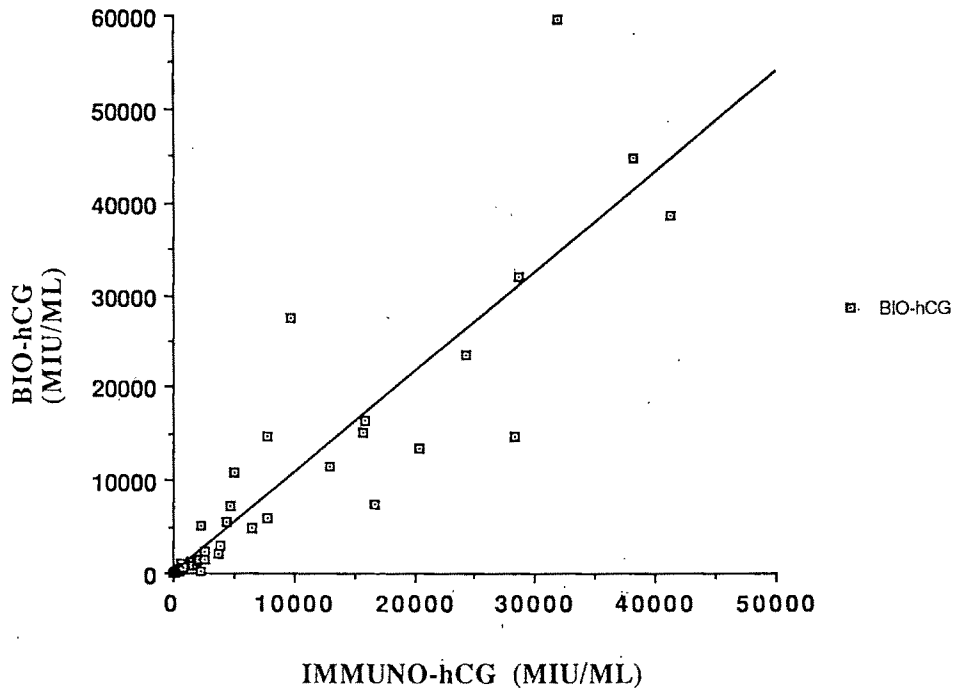

Fig. 1. Correlation of bioactive hCG to immunoreactive β-hCG for all values ascertained ($r = 0.81$, $p < 0.01$).

corpus luteum releases large amounts of sex steroid in response to hCG secreted by the developing trophoblast. However, by 8 weeks' gestation the placenta begins to contribute the majority of steroid hormone, which diminishes further need for corpus luteum support to the developing pregnancy. Although both the placenta and ovary secrete estradiol and progesterone, it is believed that the low levels of steroid hormone seen in abnormal gestations result from aberrant corpus luteum secretion because most ectopic pregnancies are detected before the time of the luteoplacental shift.

Our previous data[1] support suggestions that a persistent downward trend of immunoreactive β-hCG is characteristic of small unruptured ectopic pregnancies destined to resorb. In cases in which the ectopic pregnancy could be visualized, we did not observe tubal rupture during the time that preceded clearance of immunoreactive hormone. Furthermore, as confirmed in this report, we noted a relative dissociation between the clinical course of pregnancy and luteal function. In medically managed patients, a decline in the functional activity of the corpus luteum always preceded the decline in hCG, usually several days in advance of the eventual resolution of the ectopic pregnancy.[2] We attributed this to the diminished synthesis of the steroid hormones, and thought it probable that a reduction in hCG bioactivity could account for this phenomenon. However, as indicated by this report, hCG bioactivity did not differ between the outcome groups.

The ratio of bioactive hCG/immunoreactive hCG has previously been shown to remain constant (near 1:1) throughout normal pregnancy.[12] This also has been demonstrated in an unselected group of ectopic gestations matched to subjects with similar concentrations of immunoreactive hCG.[3] Such findings imply the lower serum steroid levels noted in ectopic gestations are a consequence of abnormal ovarian response to luteotropin (i.e., hCG) rather than diminished hCG activity. We chose not to match subjects by hCG levels because these are very low in resorbing ectopic pregnancy and require controls to be of gestational ages different from the ectopic group. We were more interested in the determination of whether degeneration of the resorbing ectopic pregnancy was associated with reduced bioactivity of its secreted hCG, which could differentiate it endocrinologically from viable proliferating ectopic pregnancies. Our data imply that other factors that modulate luteal function may be altered in or absent from ectopic gestations. Accordingly, peptides such as oxytocin and relaxin have been found in the corpus luteum and may function as paracrine or autocrine modulators of luteal cell steroidogenesis.[13] Alternatively, an improper amount or rate of increase of bioactive hCG may desensitize the corpus luteum to hCG with a subsequent decline in steroid production.

In conclusion, it appears that during the course of spontaneous resorption of ectopic pregnancies immunoreactive hCG levels decline, probably as a result of trophoblastic cell death. Bioactivity of hCG persists during this decline, and even at very low levels parallels

hCG immunoreactivity. This suggests that hCG remains bioactive while being cleared from the circulation during the final stages of secretion by degenerating trophoblast. Despite continuous production of hCG, steroid secretion by the corpus luteum is characteristically low or absent, which indicates prior dissociation from the trophoblastic hCG signal. However, the mechanism of this dissociation remains to be elucidated.

Decreased in vitro production of 6-keto-prostaglandin $F_{1\alpha}$ by uterine arteries from postmenopausal women

Alex Steinleitner, MD,[a] Frank Z. Stanczyk, PhD,[a] Jay H. Levin, MD,[a] Gerritt d'Ablaing III, MD,[b] Marcela A. Vijod, BS,[a] Violette L. Shahbazian, BS,[a] and Rogerio A. Lobo, MD[a]

Los Angeles, California

Cessation of ovarian function is associated with a marked increase in morbidity and mortality secondary to ischemic heart disease. Estrogen replacement has been shown to impart protection against ischemic heart disease. We hypothesized that estrogen may influence vascular production of vasodilators such as prostacyclin. To investigate this relationship we have measured the production of 6-keto-prostaglandin $F_{1\alpha}$ and thromboxane B_2 by superfused uterine arteries from pre- and postmenopausal women. Arterial specimens from healthy normotensive premenopausal ($n = 5$) and postmenopausal women ($n = 5$) were superfused for 5 hours. Production of 6-keto-prostaglandin $F_{1\alpha}$ reached steady state levels by 120 minutes and remained linear for the length of the experiment. Indomethacin (4×10^{-5} mol/L) added at 120 minutes significantly decreased prostanoid production. In subsequent experiments, 17β-estradiol in concentrations of 10, 100, 1000 ng/ml was added to the superfusion media at 120 minutes. Total production of 6-keto-prostaglandin $F_{1\alpha}$ by premenopausal arteries superfused with neat media during the steady state interval (3 hours) was significantly greater than that of postmenopausal specimens (1.25 versus 0.27 ng/mg dry tissue, $p < 0.05$). Thromboxane B_2 levels were undetectable in spent media. However, the addition of 17β-estradiol did not alter production of 6-keto-prostaglandin $F_{1\alpha}$. These data suggest that arterial production of prostacyclin is significantly decreased in uterine arteries from postmenopausal women, but in this in vitro model system estrogens did not affect vascular prostanoid production. (Am J Obstet Gynecol 1989;161:1677-81.)

Key words: Estrogen replacement therapy, prostacyclin, ischemic heart disease, menopause

Loss of ovarian function is known to be associated with a dramatic increase in the incidence of ischemic heart disease,[1] which is the leading cause of death in postmenopausal women.[2] Estrogen replacement therapy is known to ameliorate the risk of ischemic heart disease in these patients, reducing the mortality of myocardial infarction by as much as 50%.[3, 4] Given these data, it has been suggested that protection of postmenopausal women against the development of ischemic heart disease should be the primary indication for the administration of estrogen replacement therapy.[5]

Although beneficial changes in lipids and lipoproteins have been offered as an explanation for the cardioprotection associated with estrogen replacement therapy, emerging evidence suggests that other factors may play an important role in this phenomenon.[6] Estrogens are known to enhance blood flow in many tissues.[7, 8] This may be a result of alterations in the relationship between vasodilatory and vasoconstrictive mediators, resulting in enhanced coronary perfusion and decreased systemic vascular resistance. Prostacyclin (PGI_2) is a potent vasodilator known to play a central role in the regulation of vascular tone. Additionally, the local balance between PGI_2 and thromboxane A_2 (TxA_2) is thought to impact on platelet aggregation and thrombus formation.

We postulated that one consequence of menopause may be reduced vascular production of PGI_2. It is conceivable that alterations in the regulation of PGI_2 metabolism by gonadal steroids might impact significantly on the development and progression of ischemic heart disease. To test this hypothesis we used an in vitro system to measure the production of PGI_2 and TxA_2 metabolites by uterine arteries obtained from pre- and postmenopausal women.

Material and methods

Subjects. Uterine arteries were obtained from pre- and postmenopausal women ($n = 5$ per group) undergoing elective hysterectomy because of benign gy-

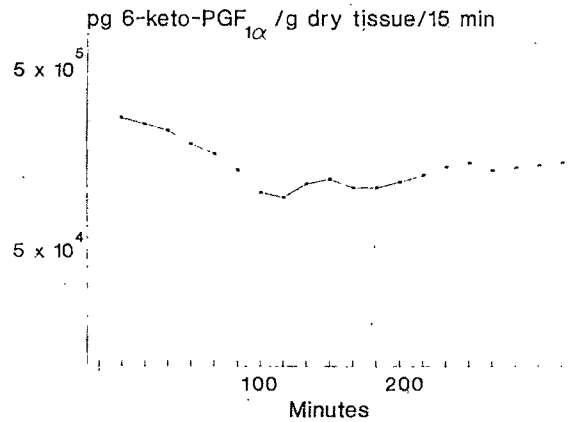

Fig. 1. Typical production curve for in vitro production of 6-keto-$PGF_{1\alpha}$ by uterine artery obtained from premenopausa. woman.

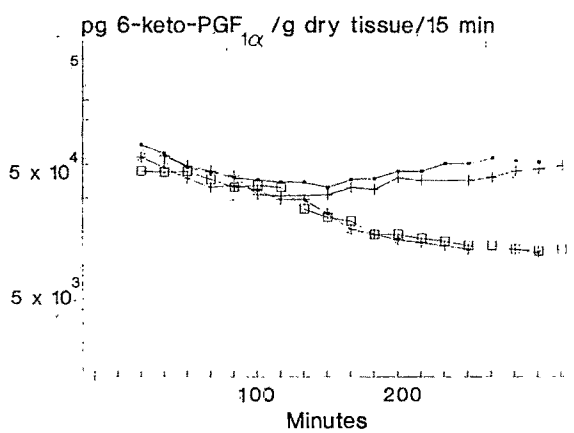

Fig. 2. Inhibition of 6-keto-$PGF_{1\alpha}$ production by uterine arteries from two premenopausal patients after addition of indomethacin (4×10^{-5} mol/L) to superfusate (control, *crosses, dots;* indomethacin, *stars, boxes*).

necologic indications. Mean age of premenopausal women was 36.5 ± 2.2 (±SEM) years, and of postmenopausal women was 62.4 ± 3 years. All subjects were known to be healthy and without evidence of significant medical disorders. Specifically absent were diabetes, hypertension, or ischemic heart disease. Patients had not been exposed to exogenous steroids for at least 6 weeks before surgery.

Superfusion procedure. Specimens of uterine artery were carefully dissected from the surrounding connective tissue immediately on removal of the hysterectomy specimen. All specimens were processed within 45 minutes of uterine artery clamping. Specimens of 20 to 40 mg (wet weight) were opened longitudinally with a scalpel blade. Extreme care was taken to ensure that the intima was not separated from the underlying vessel wall.

An in vitro superfusion system, based on the procedure of Mitchell and Flint,[9] was used to maintain the tissue under near physiologic conditions during these short-term evaluations. Uterine artery specimens were placed between 8.0 μm nylon Millipore filters (type C) in individual polypropylene Swinnex chambers (Millipore Corporation, Bedford, Mass.). Specimens were perfused at a flow rate of 0.2 ml/min with minimal essential medium (Gibco Laboratories, Santa Clara, Calif.) gassed with a mixture of 95% oxygen and 5% carbon dioxide. Temperature was maintained at 37° C with a circulating water bath. An automated fraction collector was used to collect spent media at 15-minute intervals over the course of a 5-hour experiment. Samples were stored at −20° C until assayed.

In the course of preliminary experiments, a steady state of prostanoid production was attained after 2 hours. A typical curve for the production of 6-keto-prostaglandin $F_{1\alpha}$ by a uterine artery taken from a premenopausal woman is depicted in Fig. 1. Substances used to perturb the system were added to the superfusate at 2 hours.

Validation. To determine whether the presence of prostanoids in spent media was a result of de novo synthesis by arterial tissue, two preliminary experiments were performed in which the effect of indomethacin on 6-keto-$PGF_{1\alpha}$ production was assessed. In each experiment indomethacin was added to the media of two specimens at a final concentration of 4×10^{-5} mol/L after 120 minutes. Production of 6-keto-$PGF_{1\alpha}$ in the presence of indomethacin was compared with that of untreated controls.

Effect of 17β-estradiol (E_2) on prostanoid production. Specimens from pre- and postmenopausal arteries ($n = 5$ per group) were subjected to four different conditions for 3 hours beginning at 120 minutes, as follows:

1. Control, superfusion with neat media
2. Superfusion with media + E_2 10 ng/ml
3. Superfusion with media + E_2 100 ng/ml
4. Superfusion with media + E_2 1000 ng/ml.

Radioimmunoassay. The stable metabolites of PGI_2 and TxA_2 (6-keto-$PGF_{1\alpha}$ and TxB_2, respectively) were measured in superfusate by means of direct radioimmunoassays developed in our laboratory. Highly specific antibodies for 6-keto-$PGF_{1\alpha}$ and TxB_2 were provided by Dr. Carlo Patrono, Universita Cattolica del Sacro Cuore, Rome, Italy. Relative cross-reaction to the anti-6-keto-$PGF_{1\alpha}$ serum was <1% for $PGF_{2\alpha}$, 2,3-dinor-6-keto-$PGF_{1\alpha}$, PGE_2, PGD_2, TxB_2, and arachidonic acid; cross-reaction to the anti-TxB_2 serum was 10.5% for 2,3-dinor-TxB_2, and <1% for 11-dehydro-TxB_2, $PGF_{2\alpha}$, PGD_2 PGE_2, 6-keto-$PGF_{1\alpha}$, and arachidonic acid. ^{3}H-labeled 6-keto-$PGF_{1\alpha}$ (specific activity, 157 Ci/mmol) and TxB_2 (specific activity, 180 Ci/mmol) were purchased from Amersham (Arlington Heights, Ill.). Assay sensitivity was 20 pg/ml for both the 6-keto-$PGF_{1\alpha}$ and

TxB_2 radioimmunoassays. Interassay coefficients of variation were 17.4% and 17.5%, respectively. Intraassay coefficients of variation were 7.1% and 7.9%, respectively.

Histologic evaluation. Hematoxylin and eosin sections of vessels used in the superfusion experiments were taken whenever sample mass permitted. Histologic evaluation confirmed in all cases that specimens were, in fact, arteries.

Protein determination. Protein content of pre- and postmenopausal arteries was determined by the bicinchoninic acid method (Pierce Chemicals, Rockford, Ill.). Pre- and postmenopausal arteries were found to be essentially equivalent in their protein content (0.35 to 0.45 mg protein/mg dry weight). Therefore dry weight of desiccated samples was subsequently used as a denominator to calculate prostanoid production by superfused uterine arteries. Results are expressed in terms of total 6-keto-$PGF_{1\alpha}$ production over the steady state portion of the experiment (3 hours) per milligram of dry weight.

Production kinetics. Production kinetics for 6-keto-$PGF_{1\alpha}$ were estimated by the use of linear regression analysis to estimate the slope of the production curve during the steady state portion of the experiment. Results are expressed in picograms of 6-keto-$PGF_{1\alpha}$ per milligram of desiccated tissue per minute.

Statistical analysis. Analysis of variance and nonparametric statistics (Mann-Whitney test) were used as appropriate to evaluate the data. Data are presented as the mean ± SEM.

Results

Validation experiment. Addition of indomethacin to the superfusate of premenopausal specimens resulted in a prompt and significant decline in 6-keto-$PGF_{1\alpha}$ production (Fig. 2).

Basal prostanoid production by pre- and postmenopausal uterine arteries. In vitro 6-keto-$PGF_{1\alpha}$ production by uterine arteries was observed to vary significantly with menopausal status. Integrated steady state 6-keto-$PGF_{1\alpha}$ production by specimens from premenopausal women was nearly fivefold that of postmenopausal specimens (1.25 ± 0.5 versus 0.27 ± 0.2 ng of 6-keto-$PGF_{1\alpha}$/mg of desiccated tissue per 3 hours, respectively; $p < 0.05$, Mann Whitney test, Fig. 3). Production kinetics for 6-keto-$PGF_{1\alpha}$ were also found to differ significantly with menopausal status ($K_{premenopausal} = +0.002$ versus $K_{postmenopausal} = -0.0011$ pg 6-keto-$PGF_{1\alpha}$/mg desiccated tissue per minute).

Steady state concentrations of TxB_2 in spent media were found to be at or below the detectable limits of the assay (<20 pg/ml).

Effect of E_2 on short-term prostanoid production. Addition of E_2 in concentrations that ranged from 10 to 1000 ng/ml to superfusate, beginning 120 minutes into the experiment, did not significantly affect integrated 6-keto-$PGF_{1\alpha}$ production (p = NS, analysis of variance, Fig. 4) or 6-keto-$PGF_{1\alpha}$ production kinetics in pre- or postmenopausal uterine arteries.

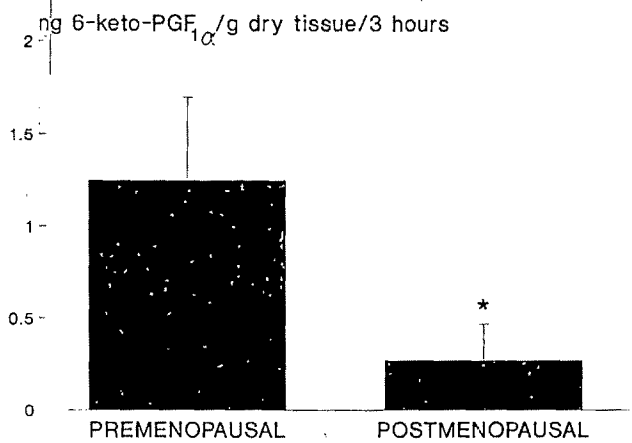

Fig. 3. Total steady state production (3 hours) of 6-keto-$PGF_{1\alpha}$ by uterine arteries from pre- and postmenopausal women. *$p < 0.05$, Mann-Whitney test.

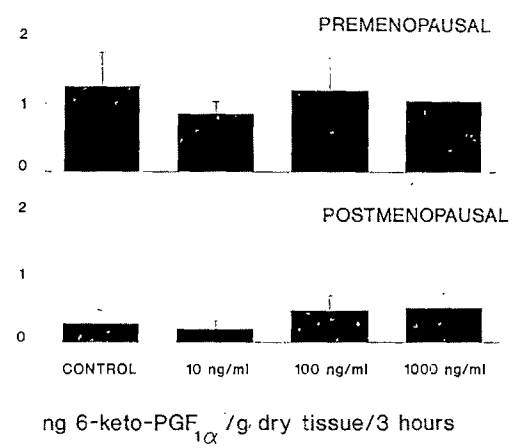

Fig. 4. Effect of 17β-estradiol on total steady state in vitro 6-keto-$PGF_{1\alpha}$ production by uterine arteries from pre- and postmenopausal women.

Comment

The physiologic mechanisms that underly the increased incidence of ischemic heart disease that occurs with menopause and its amelioration by estrogen replacement therapy remain incompletely understood. Alterations in lipoprotein metabolism induced by hypoestrogenism are thought to be the principal effectors of this phenomenon. However, epidemiologic data suggest that additional factors must be sought to explain the observed increase in morbidity.[6] An understanding of the ancillary mechanisms through which changes in estrogen status alter the risk of ischemic heart disease

is essential for the rational design of estrogen replacement strategies.

An important observation in this regard is that estrogens are known to increase blood flow in a variety of vascular beds.[7, 8] The means through which estrogens exert this effect are unknown. Possible mechanisms include a direct vasodilatory effect of estrogen or modulated production of endogenous mediators of vascular tone.

The purpose of this investigation was to determine whether vascular production of PGI_2 differs in pre- and postmenopausal women. PGI_2 is a potent vasodilator and inhibitor of platelet activation and is known to play a central role in vascular homeostasis. The possibility that estrogens modulate vascular PGI_2 metabolism in women is supported by data from a variety of models. Makila and colleagues[10] have shown that perfusion of umbilical vessels by pharmacologic amounts of estrogens increased vascular production of PGI_2. This effect was completely reversed by addition of progesterone to the perfusion media. PGI_2 production by piglet aortic endothelial cells obtained from female (but not male) animals was markedly augmented by incubation with estradiol.[11] Similar results have been obtained with cultured rat aortic smooth muscle cells.[12, 13] In the sheep, vascular PGI_2 production in response to angiotensin II varies dramatically with pregnancy.[14]

The model used in these experiments provides a means to assess the effect of menopausal status and short-term estradiol exposure on prostanoid production. Uterine arteries were used in this model because of their availability in our center. However, we are cognizant that in the selection of uterine arteries as a model we may not be able to extrapolate these findings to PGI_2 production in the heart and central circulation. Nevertheless, studies in the sheep suggest that regulation of PGI_2 production in uterine arteries is similar to that of systemic (omental) vessels in the nonpregnant state.[14] Although differences may exist in the regulation of PGI_2 production in the heart and great vessels (as compared with peripheral vessels), this model provides preliminary data concerning the production of prostanoids by human vessels in vitro.

In these experiments 6-keto-$PGF_{1\alpha}$, the stable metabolite of PGI_2, was actively synthesized by uterine artery specimens from all patients studied. Inhibition of 6-keto-$PGF_{1\alpha}$ production by indomethacin showed the presence of prostanoids in spent media to be a result of de novo synthesis by superfused tissue, as opposed to leaching of adsorbed prostanoid from vascular endothelium or release from disrupted cells. In vitro TxB_2 production during steady state was observed to be at or below the limits of detection in both pre- and postmenopausal patients. These data are consistent with previous observations in sheep[14] and cattle.[15, 16]

Production of 6-keto-$PGF_{1\alpha}$ was found to be significantly depressed in vessels obtained from postmenopausal women. Additionally, production kinetics for 6-keto-$PGF_{1\alpha}$ were found to differ significantly between the two groups. These data suggest that menopausal status has a significant effect on vascular PGI_2 production. This finding may be consistent with a direct effect of long-term estrogen deprivation on the regulation of the vascular PGI_2 biosynthetic pathway. Alternatively, decreased PGI_2 synthesis may be a result of progressive atherosclerotic injury arising as a consequence of prolonged hypoestrogenicity and aging. However, data from Fitzgerald[17] suggest that atherosclerosis may induce a compensatory increase in PGI_2 production, rather than the decrease in production noted in these studies. In addition, the similarities in protein content of uterine arteries from pre- and postmenopausal patients observed in this investigation appear to negate the latter possibility. A third possibility is an indirect effect of altered menopausal lipoprotein profiles on PGI_2 production. In vitro studies[18] suggest that lipoproteins may modulate vascular PGI_2 synthesis. Low-density lipoproteins have generally been shown to exert an inhibitory effect and high-density lipoproteins a stimulatory influence on PGI_2 production. Regardless of the specific mechanism involved, given the importance of PGI_2 as a vasodilator and inhibitor of platelet activation and thrombosis, these data imply that estrogen-related alterations of PGI_2 production may contribute to the increased ischemic heart disease observed in menopausal women. However, we believe that modulation of vascular prostanoid production may account for only a portion of the interaction between estrogens and ischemic heart disease.

Although basal PGI_2 production was found to be significantly decreased in specimens obtained from hypoestrogenic (menopausal) patients, short-term estrogen exposure did not affect vascular PGI_2 production. Uterine vessels are known to possess the ability to respond to appropriate stimuli (e.g., angiotensin II) with increases in PGI_2 production.[14] This response is most consistent with a mediator-receptor-second messenger interaction resulting in an acute allosteric stimulation of prostaglandin synthetase and enzymes contributing to prostaglandin substrate mobilization. The failure of short-term incubation with pharmacologic amounts of estradiol to elicit an increase in vascular production of PGI_2 in these experiments suggests an alternative means of regulation in these patients. Chang and coworkers[13] have shown that estrogen-induced enhancement of PGI_2 synthesis by cultured aortic smooth muscle cells occurred over the course of 3 to 5 days and was a result of an induction of cyclooxygenase and PGI_2 synthetase rather than an acute allosteric phenomenon. Extrapolation of these data to the human

might explain both the disparity in basal PGI_2 production between pre- and postmenopausal women and the failure of short-term estrogen treatment to modulate PGI_2 synthesis.

Although the results of these experiments suggest that menopausal status (and perhaps estrogenicity) modulates vascular PGI_2 tone, it is evident that further studies are required to examine this association. The treatment of a group of postmenopausal women with an extended course of estrogens before hysterectomy would provide a means to examine this question further. Studies designed to specifically assess these factors are in progress.

Depressive episodes in premenstrual syndrome

Joseph F. Mortola, MD,* Lyda Girton, PhD, and Samuel S. C. Yen, MD, DSc**
La Jolla, California

Episodic depression, a prominent but poorly defined symptom of premenstrual syndrome, was quantitated in 24-hour cortisol secretory episodes (determined by sampling at 20-minute intervals) as biochemical markers, as well as the Beck Depression Inventory and Profile of Mood States as psychometric measures. Results of 16 patients with premenstrual syndrome were compared with six age-matched women with endogenous depression and 16 control women. On both the Profile of Mood States and Beck Depression Inventory, women with premenstrual syndrome showed a marked worsening of scores ($p < 0.01$) during the luteal phase compared with either their own follicular phase scores or the scores of controls in either cycle phase. However, Beck Depression Inventory scores were threefold higher ($p < 0.005$) in women with depression than in those with luteal phase premenstrual syndrome (33.7 ± 3.6 vs. 11.9 ± 2.5). The Profile of Mood States depression scale was also higher ($p < 0.05$) in women with depression than in those with premenstrual syndrome, while scores on other Profile of Mood States scales were similar. The numbers of cortisol secretory pulses identified by the cluster algorithm were similar (5 to 6 per 24 hours) in all groups, and the times of circadian nadirs as determined by cosinor rhythmometry were comparable. While the mean amplitude and duration of the cortisol pulses were also similar in women with premenstrual syndrome and controls, both were significantly higher ($p < 0.05$) in women with depression. This resulted in markedly enhanced ($p < 0.005$) cortisol secretion during a given secretory episode in women with depression and in higher 24-hour transverse mean cortisol values in women with depression (87.8 ± 5.8 ng/ml) than in either those with premenstrual syndrome (66.7 ± 3.3 ng/ml) or controls (58.9 ± 3.3 ng/ml). These data affirm the clinical impression that depressive episodes occurring selectively in the luteal phase of the cycle in women with premenstrual syndrome are not present in controls and demonstrate, for the first time, that these episodes are distinct from endogenous depression as measured by both cortisol secretory parameters and psychological indices. (Am J Obstet Gynecol 1989;161:1682-7.)

Key words: Premenstrual syndrome, cortisol, depression

Among the most debilitating and commonly reported symptoms premenstrual syndrome (PMS) are depressive episodes.[1-4] As a result of this clinical observation, a possible association between PMS and major affective disorder has been sought with both positive[5-8] and negative[9-11] results. More recently, depressed subtypes of PMS have been described.[12] To date, however, prospective delineation of the similarities and differences between the depressive episodes in endogenous depression and PMS has not been achieved. Moreover, the expanded serum cortisol pulsatile episodes that have been demonstrated to be a sensitive index of endogenous depression[13-15] have not been evaluated in patients with PMS. In the present study well-characterized patients diagnosed as having PMS without major depressive episodes are compared with age-matched women with unipolar endogenous depression and with normally cycling controls by means of well-validated and relaible psychometric instruments. In addition, analysis of pulsatile activities of serum cortisol levels measured at 20-minute intervals around the clock is used as a neuroendocrine marker.

Methods

Subjects. Sixteen women with premenstrual syndrome, 16 controls, and six women with endogenous depression were studied. All women were between 21 and 36 years old and had recorded regular menstrual cycles for the preceding 6 months, which ranged from 26 to 34 days. They had no history of previous medical or psychiatric illness (with the exception of major depression in those included in the endogenous depres-

sion group) and had normal results of physical examination before admission into the study. Women with prior substance abuse or those taking any medications including oral contraceptives and vitamin tablets were excluded. Control subjects who denied any physical or behavioral symptoms associated with the premenstrual phase of the cycle were compensated for their participation in the study. The presence of normal ovarian cyclicity, including normal luteal lengths (≥12 days) was confirmed by daily urine pregnanediol glucuronide levels measured by an immunoassay with monoclonal antibody[16] and normalized by correction for urinary creatinine values.

Women in the endogenous depression group met DSM III criteria[17] for major depression and research diagnostic criteria for major depressive episode, endogenous subtype.[18, 19] None received any medication during the study. However, for ethical reasons their participation was limited to 1 month to allow for appropriate psychopharmacologic intervention. Women included in the PMS group met a set of inclusion criteria that was developed in our research unit. The inclusion criteria for PMS (Table I) was the predictable occurrence of both behavioral and somatic symptoms reproducibly in the late luteal phase of the cycle, as well as the identifiable disruption of interpersonal or socioeconomic functioning during this time. Subjects with any historical evidence of affective disorder were excluded. Thus no women with both endogenous depression and PMS were included in the study. After satisfaction of the initial inclusion criteria for the study all women in the PMS group and controls were prospectively evaluated for a 2-month period before enrollment with the Calendar of Premenstrual Experiences (COPE). This inventory, a four-point Likert scale self-report instrument, further ensured the cyclic occurrence of physical and behavioral symptoms in women with PMS and the absence, by self-report, of these symptoms in controls. All women in the PMS groups showed a twofold increase ($p < 0.001$) in luteal phase scores (defined as the sum of scores on days 20 to 26) over follicular phase scores (defined as the sum of scores on days 3 to 9), while the follicular and luteal phase scores of controls were not statistically different. This study was approved by the Committee on Investigations Involving Human Subjects of the University of California, San Diego (UCSD).

Psychometric measures. On completion of the 2-month screening interval, PMS and control subjects were given the Beck Depression Inventory (BDI)[20] and the Profile of Mood States (POMS)[21] once on day 5 to day 9 and again on day 24 to day 27 of two consecutive menstrual cycles. Depressed women were administered the inventory on one occasion between days 5 and 9 of the menstrual cycle. All subjects were instructed to answer questions on both inventories according to their experience on the particular week the inventory was taken. Raw scores on the BDI were obtained. Scores on the six scales of the POMS, including tension, depression, anger, vigor, fatigue, and confusion, were converted to T scores by the method described in the manual of the POMS.[21]

Table I. Diagnostic criteria for PMS

1. The presence by self-report of at least one of the following somatic *and* affective symptoms during the 5 days before menses in each of the three prior menstrual cycles:

Affective	*Somatic*
Depression	Breast tenderness
Angry outbursts	Abdominal bloating
Irritability	Headache
Anxiety	Swelling of extremities
Confusion	
Social withdrawal	

2. These symptoms are relieved within 4 days of the onset of menses, without recurrence until at least cycle day 13
3. The symptoms are present in the absence of any pharmacologic therapy, hormone ingestion, or drug or alcohol use
4. The symptoms occur reproducibly during two cycles of prospective recording
5. Identifiable dysfunction in social or economic performance by one of the following criteria:
   - Marital or relationship discord confirmed by partner
   - Difficulties in parenting
   - Poor work or school performance, poor attendance, or tardiness
   - Increased social isolation
   - Legal difficulties
   - Suicidal ideation
   - Seeking medical attention for a somatic symptom

Cortisol measurements. Six of the women with PMS had serum cortisol measurements in the midluteal phase of the menstrual cycle (days 6 to 8 after the midcycle luteinizing hormone surge) as determined by rapid urinary assay (Monoclonal Antibodies, Inc.). All six depressed women were studied in the early follicular phase (days 3 to 5 after the onset of menses) so as not to confound results in this group with possible superimposed PMS. Eight controls were also studied in the early follicular phase to avoid potential contamination of the results by subtle PMS manifestations that may occur in normal women during the luteal phase, although evidence indicates that the hypothalamic-pituitary-adrenal axis does not change throughout the course of the normal menstrual cycle.[22] All subjects were admitted to the Clinical Research Center at UCSD for an accommodation night, during which an indwelling catheter was placed into a vein in the nondominant forearm. Light-dark schedules and mealtimes were standardized. Ambulation and daytime napping were

avoided. Lights were off from 11 PM to 7 AM and sleep was monitored by trained observers. Meals were at 8 AM, 12 noon, and 6 PM. Meals contained approximately 50% of calories as carbohydrate, 35% as fat, and 15% as protein. Blood samples (2 ml) were obtained at 20-minute intervals for 24 hours through the indwelling catheter, which extended into an adjacent room so as not to disturb the subject during sleep hours.

Serum cortisol was measured by radioimmunoassay in each of the unextracted samples by techniques previously described.[23] The interassay coefficient of variation was 6.5% and the sensitivity of the assay was 10 ng/ml. All samples from a given subject were included in the same assay run.

Pulse detection. Cortisol pulses were characterized by using the computerized cluster analysis algorithm.[24] This program searches for significant increases and decreases in a series of hormone values. This analysis affords assessment of attributes of pulse amplitude, duration, and area, as well as frequency. A significant pulse was defined by a cluster configuration of 2 × 2 (two values for the upstroke and downstroke) and a t statistic of 3.34 for both significant increases and decreases and limits the likelihood of false-positive determinations to <5%.[24] A method described by Merriam et al.[25] was used in estimating the within-sample variance at various hormone concentrations. To establish a relationship between the coefficient of variation and its corresponding hormone level, 10 replicates were measured at 10 different doses between 40.3 and 394 ng/ml and a second-degree polynomial regression for standard deviation as a function of hormone concentration was constructed. The resulting coefficients were 0.00014, 0, and 2.12 for the second-degree coefficient, first-degree coefficient, and intercept, respectively. These calculated standard deviations were used in the cluster algorithm. The coefficient of variation at any given hormone concentration was then obtained by division of the calculated standard deviation by the dose. The resulting intraassay coefficients of variation ranged from 2.8% to 6.2% at doses between 40 and 400 ng/ml.

Circadian rhythm. The nadir of the circadian rhythm of cortisol for each subject was determined by single cosinor computation by means of the rhythmometry algorithm described by Nelson et al.[26]

Statistical analysis. The 24-hour transverse mean levels were defined as the arithmetic mean of the 73 determinations obtained for each subject. Differences between groups in 24-hour transverse mean cortisol levels, cortisol pulse parameters, and cortisol circadian rhythm, as well as in psychometric scores (BDI scores and T scores on each of the scales of POMS), were analyzed by one-way analysis of variance followed by Newman-Keuls multiple range tests. The data are presented as mean ± SE.

Results

Psychometric measures. Results of the BDI scores (Fig. 1) were similar in control subjects during both follicular and luteal phases and in subjects with PMS during the follicular phase. In contrast, in the luteal phase, subjects with PMS showed a twofold increase ($p < 0.05$) in the BDI score. Mean luteal phase scores in PMS, however, remained threefold lower ($p < 0.005$) than the scores obtained in women with depression in the follicular phase (11.7 ± 2.5 vs. 33.7 ± 3.6).

Control subjects did not show any differences on any of the Profile of Mood States scales between the follicular and luteal phases (Table II). As with the BDI, follicular phase POMS scores in women with PMS were similar to those of controls on all scales. However, a marked worsening of all mean scores ($p < 0.01$) occurred in women with PMS during the luteal phase to a degree similar to that obtained in depression on tension, anger, confusion, and fatigue, and there was also a decrease in vigor. The greater ($p < 0.05$) depression scale was the only parameter that exhibited departure of PMS from depression in the luteal phase (Table II).

Cortisol 24-hour rhythms. Representative samples of the 24-hour circadian profiles of women with PMS, women with depression, and controls are shown in Fig. 2. In all subjects the circadian variation was maintained. The mean nadir times of the circadian rhythm of cor-

tisol were similar in all groups and occurred at approximately 9 PM. As illustrated, a loss of the evening quiescent period of cortisol (6 PM to 12 midnight) was noted in women with depression and was accompanied by continued secretory episodes only in this group. Analysis of the 73 sampling times throughout the 24-hour biologic clock revealed that subjects with depression had higher mean cortisol levels ($p < 0.001$) than those of controls at all times, with the exception of a brief period during the early morning hours when values overlapped (Fig. 3), whereas women with PMS showed mean cortisol values that overlapped those of controls throughout the 24-hour circadian clock. This resulted in significantly ($p < 0.05$) higher 24-hour transverse mean levels in depression (87.8 ± 10.0 ng/ml) than in PMS (66.7 ± 3.3 ng/ml) or controls (58.9 ± 3.3 ng/ml), which were similar (Table III).

Analysis of the cortisol pulsatile activity (Table III) among the three groups revealed that the mean number of pulses (pulse frequency) during the 24-hour sampling period were similar (PMS, 6.3 ± 0.6; depression, 5.2 ± 0.4; controls, 5.6 ± 0.5). Compared with controls, subjects with PMS did not differ significantly with respect to either pulse amplitude (PMS, 90.2 ± 11.0 ng/ml; controls, 102.5 ± 6.9 ng/ml) or pulse duration (PMS, 156.7 ± 15.0 minutes; controls, 169.6 ± 16.6 minutes) and these values were lower ($p < 0.05$) than those of women with depression for both amplitude (132.8 ± 10.5 ng/ml) and duration (215.0 ± 24.5 minutes). Thus the combination of increased amplitude and duration led to markedly expanded ($p < 0.005$) cortisol secretory episodes in depressed women (103.8 ± 8.7 × 10^2 ng · min/ml) as compared with those of controls (56.3 ± 6.0 × 10^2 ng · min/ml), which was not evident in PMS (49.6 ± 6.2 × 10^2 ng · min/ml).

Comment

Our subjects with PMS demonstrated depressive episodes that occurred selectively in the luteal phase of the cycle. Characteristics of these episodes included both elevated scores on the BDI and a worsening of all scores on the POMS during the luteal phase. The follicular phase BDI scores in our subjects with PMS were far lower than those found in a previous study using this instrument in PMS.[27] This was due primarily to the

(*Asterisk* denotes pulses.)

specific exclusion of depressed subjects in our study. On the basis of the POMS, the degree of tension, anger, confusion, or fatigue experienced in our subjects with PMS did not differ from the degree of these symptoms seen in major depression, and the loss of vigor was also comparable. These scores in women with PMS, however, returned to control values during the follicular phase of the cycle and reproducibly recurred during the luteal phases of consecutive menstrual cycles. These

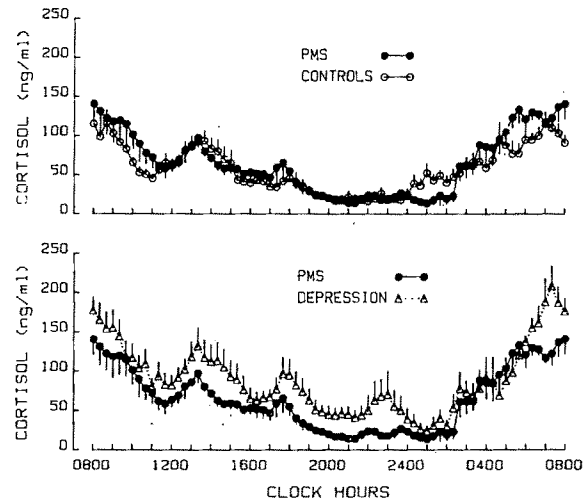

Fig. 3. Comparison of 24-hour mean (±SE) serum cortisol levels in subjects with PMS and controls *(top panel)* and in subjects with PMS and those with endogenous depression *(bottom panel)*.

results are consistent with a previous report using this measure.[3] Several studies have found a high incidence of PMS in women with major affective disorder.[3-8] To date the nature and severity of luteal phase depressive symptoms has not been adequately assessed in women who have PMS with a specifically excluded history of major depression. Our study is the first to compare these scores with those of a population of women with endogenous depression that was simultaneously evaluated. Within the limitations of our psychometric measures, the degree of the symptom of depression itself showed marked differences in the luteal phase between women with PMS and those with major depression. Such differences are explained on the basis of the degrees of self-reproach, loss of interest in life, and sense of helplessness and hopelessness, which are more pronounced in major depression than in our subjects whose lives were significantly disrupted by symptoms of PMS.

In addition to the greater severity of the symptom of depression itself, the cortisol changes that have previously been noted to occur in endogenous depression[13-15] were absent in our subjects with PMS in whom overt depression was specifically excluded. This may be due to differences in the pathophysiology of these disorders or the fact that the hypothalamic-pituitary-adrenal axis changes that occur in depression require longer time to manifest than the relatively brief episodes of affective symptoms in PMS. In either case this study expands on previous findings that abnormalities in the dexamethasone suppression test and elevations of 24-hour urinary cortisol level were not found in PMS.[11] It confirms the results of a small study in which circadian cortisol rhythms in two subjects with PMS

were found to be similar to those of controls.[10] To our knowledge, however, the present study represents the first demonstration that PMS is distinct from endogenous depression on the basis of the differences in both amplitude and duration of serum cortisol pulses, which were used as a biochemical marker, as well as prospective psychometric evaluation.

We are grateful to Gail Laughlin for her assistance in use of the computerized cluster detection algorithm and to Del Alsobrook for her assistance in preparation of the manuscript. We are also indebted to the nurses in the UCSD Clinical Research Center for their invaluable assistance in sample collection.

Peri-implantation phase endometrial estrogen and progesterone receptors: Effect of ovulation induction with clomiphene citrate

Bryan R. Hecht, MD, Firyal S. Khan-Dawood, PhD, and M. Yusoff Dawood, MD
Chicago, Illinois

The effects of clomiphene citrate on endometrial nuclear estradiol receptors and progesterone receptors were examined in 10 normal women during an untreated cycle (control) and during treatment with 50 mg clomiphene citrate and 150 mg clomiphene citrate daily on days 5 through 9. Concentrations and binding constants of the receptors were determined in endometrium obtained 8 to 12 days after midcycle luteinizing hormone surge. Scatchard plots for both estrogen receptors and progesterone receptors were linear, indicating only one type of high-affinity binding sites. In control cycles, estrogen receptor levels (mean ± SEM) were 199.6 ± 23.1 fmol/mg deoxyribonucleic acid, (n = 8) and were not significantly different from either 50 mg clomiphene citrate (180.5 ± 19.1 fmol/mg deoxyribonucleic acid, n = 6) or 150 mg clomiphene citrate (194.3 ± 35.2 fmol/mg deoxyribonucleic acid, n = 4). Similarly, the dissociation constants were unaffected by clomiphene citrate treatment. The concentrations of progesterone receptors in the control cycles (613 ± 31 fmol/mg deoxyribonucleic acid, n = 5) and treatment cycles (50 mg clomiphene citrate – 652.8 ± 121 fmol/mg deoxyribonucleic acid, n = 6; 150 mg clomiphene citrate – 592.6 ± 31 fmol/mg deoxyribonucleic acid, n = 7) were also not significantly different. Clomiphene citrate also did not affect dissociation constants for progesterone receptors. Therefore, ovulation induction with clomiphene citrate apparently did not affect peri-implantation phase endometrial estrogen receptors and progesterone receptors or their respective binding constants. (Am J Obstet Gynecol 1989;161:1688-93.)

Key words: Clomiphene citrate, estrogen receptors, progesterone receptors, implantation, endometrium

In the human uterus, estrogen, followed by progesterone, stimulates endometrial maturation and preparation for blastocyst implantation. These two ovarian hormones exert their effects on the endometrium through their specific hormone receptors, concentrations of which may determine the sensitivity of the endometrium to circulating estrogen or progesterone. Estrogen induces its own receptors and progesterone receptors. Delayed, inadequate, or asynchronous development of the endometrium may arise from inadequate levels of estrogen, progesterone, or their receptors and abnormal receptor activity. Studies of steroid hormone receptors in endometrial tissues of infertile women with luteal phase defect have yielded conflicting results.[1-7] These discrepancies may result from the diverse mechanisms responsible for this disorder and differences in methods and analysis used for steroid hormone receptor populations.

Clomiphene citrate, a nonsteroidal synthetic compound with both estrogenic and antiestrogenic activity,[8] is widely used for ovulation induction. Inasmuch as clomiphene citrate is concentrated in the endometrium, inhibits tissue uptake of estrogen,[8] and has been implicated in delayed endometrial development,[9] a direct adverse effect on the endometrium has been suggested. This effect may contribute to the discrepancy observed between successful ovulation and pregnancy rates when clomiphene citrate is used for ovulation induction and points to possible impaired implantation as a factor. Because clomiphene citrate is known to bind to estrogen receptors and alter their intracellular kinetics[8, 10, 11] it could alter endometrial maturation directly through estrogen receptors or indirectly through progesterone receptors, which are normally induced by estrogen. Previous studies[12-14] on the effect of clomiphene citrate on human endometrial steroid receptors were not designed to address the relationship between the receptors and luteal phase abnormalities or the biochemical

basis of implantation. In a study of infertile women treated with clomiphene citrate, only the cytosolic receptor population from secretory endometrium could be studied because of limitations on the quantity of tissue obtained.[15] Because these studies were performed in infertile women, it is not possible to exclude other potential infertility effects on the endometrium. This study was carried out to examine the effect of clomiphene citrate on the concentrations and binding activities of endometrial estrogen and progesterone receptors at the peri-implantation phase. We conducted the present investigation on normal ovulatory women to eliminate other confounding infertility factors on the endometrium. In addition, we determined the effect of high-dose (150 mg) and low-dose (50 mg) clomiphene citrate administration on endometrial steroid hormone receptors in the same subjects.

Material and methods

Subjects. Ten normal fertile female volunteers with regular menstrual cycles were recruited and gave informed consent for the study, which was approved by our Institutional Review Board. All subjects had previously undergone tubal sterilization or were using barrier contraception. The clinical characteristics are summarized in Table I.

Medication and biopsy protocol. Eight subjects were studied for three consecutive menstrual cycles, whereas two were studied for three nonconsecutive cycles. The first cycle was a control cycle during which the subjects did not receive medication. In the second cycle, clomiphene citrate 50 mg was given daily on days 5 through 9 of the cycle; in the third cycle, 150 mg clomiphene citrate was given daily on days 5 through 9.

Basal body temperature (BBT) was recorded by each subject for all cycles studied. First-voided urine samples were collected daily, beginning on cycle day 11 and continuing until a luteinizing hormone (LH) surge was identified or a sustained BBT rise was demonstrated. The urinary LH surge was determined by the Q test ovulation test kit (Clay Adams, Division of Becton Dickinson, Parsippany, N.J.) with a monoclonal LH antibody in an enzyme immunoassay for LH. The day of the LH surge was subsequently confirmed by the measurement of LH in the plasma.

Daily peripheral heparinized venous blood samples were obtained from cycle day 11 until the day of the endometrial tissue biopsy. The plasma was separated and stored at −20° C until assayed. Plasma LH was measured by a specific double antibody radioimmunoassay. Plasma progesterone was measured by a specific radioimmunoassay as previously described,[16] with the use of an antibody raised against progesterone-11-oxime bovine serum albumin conjugate. To reduce interassay variability, all blood samples from the same patient were performed in the same assay for each hormone.

Table I. Clinical characteristics of the 10 subjects studied

Characteristics	*Mean ± SEM*
Age (yr)	30.3 ± 1.1
Weight (kg)	77.3 ± 5.4
Parity	2.4 ± 0.4
Menstrual cycle length (days)	28.5 ± 1.1

Endometrial biopsies were performed 8 to 12 days after the LH surge with a mean of 10.4 to 10.8 days (Table II). The subjects were given ibuprofen 800 mg orally 1 hour before the endometrial biopsy, which was performed with a paracervical block. The uterine cavity was systematically and thoroughly curetted to obtain as much endometrial tissue as possible. Endometrial curettings were immediately rinsed in ice-cold normal saline solution to remove blood and debris, and a small piece was taken for histologic studies. The remaining tissue was snap frozen by immersion in liquid nitrogen and after removal was stored at −70° C until ready for receptor studies (within 2 weeks of collection for most of the samples but in a few cases between 2 and 4 weeks of collection). Preparation of tissue nuclear fraction and determination of endometrial nuclear estradiol and progesterone receptors were as previously described and validated in this laboratory by Khan-Dawood and Dawood.[17, 18]

Preparation of endometrial cell nuclei. The frozen tissue was homogenized at 4° C in eight volumes of Tris-glycerol buffer (10 mmol of Tris-base, 1.5 mmol dithiothreitol, and 30% vol/vol of glycerol at a pH of 7.4) with a Tissumizer homogenizer (Tekmar, Cincinnati, Ohio) at a setting of 50. Three 10-second bursts with 30-second cooling intervals were used for homogenization. The homogenate was centrifuged at 800 *g* for 10 minutes at 4° C. The 800 *g* pellet was washed three times with 20 volumes of Tris-glycerol buffer and resuspended in the same volume of buffer for measurement of nuclear receptors. The nuclear deoxyribonucleic acid (DNA) concentration was determined by the method of Burton.[19] Approximately 400 μg of tissue was needed for a seven-point saturation assay to enable satisfactory Scatchard analysis of hormone receptor binding.

Measurement of nuclear receptors. Concentrations of nuclear progesterone and estradiol receptors were determined by exchange assays with the use of [^{3}H] promegestone (R5020) and [^{3}H] moxestrol (R2858), respectively (New England Nuclear Research Products, Boston, Mass.). Aliquots of 500 μl nuclear suspension were incubated with 100 μl of tritiated moxestrol (specific activity, 87 Ci/mmol) or promegestone

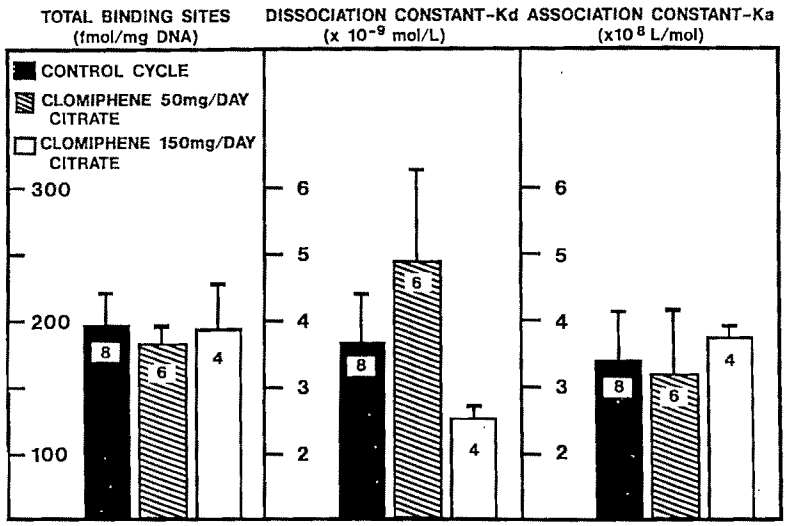

Fig. 1. Mean ± SEM nuclear estrogen receptors, K_d and K_a in peri-implantation phase (luteal phase) endometrium. Treatment with clomiphene citrate in doses of 50 mg/day and 150 mg/day from days 5 through 9 of the cycle had no effect on nuclear estrogen receptor concentrations or binding affinities. Numbers within the *bar graphs* represent number of subjects whose endometrial tissues were studied.

Table II. Characteristics of cycles before and during treatment with clomiphene citrate (mean ± SEM)

	Cycles		
		Clomiphene citrate

*$p < 0.05$.

(specific activity, 87 Ci/mmol) in concentrations that ranged from 2.5 to 20 nmol. A parallel set of tubes were incubated with 100-fold excess of nontritiated ligand (moxestrol or promegestone) to measure nonspecific binding. For the estradiol receptor assay, the mixtures were incubated at 37° C for 30 minutes, and for the progesterone receptor determination the incubation was carried out at 4° C for 16 hours. The binding reaction was terminated by the addition of 1 ml of ice-cold Tris-glycerol buffer and centrifuged at 800 *g*. The pellet was washed three times in the same buffer. One ml of 100% ethanol was used to elute the bound nuclear receptors from the washed pellet. The ethanolic supernatant was added to 10 ml of high-efficiency scintillation fluid (Biocount, Research Products International Corp, Mount Prospect, Ill.) and radioactivity was counted in a liquid scintillation counter with an efficiency of 58% for tritium.

Data analysis. A Scatchard plot was constructed for analysis of the total number of binding sites and the dissociation constant (K_d) and association constant (K_a). Specific binding is expressed as femtomoles of hormone bound per milligram of DNA. Data are expressed as mean ± SEM. Means between different treatment cycles were compared by one-way analysis of variance before the paired or nonpaired Student *t* test between two different treatment regimens. A *p* value >0.05 was not considered significant.

Results

Clinical findings. All menstrual cycles in control and treatment cycles were ovulatory as determined by identification of an LH surge, biphasic BBT, elevated progesterone concentrations, or the presence of secretory endometrium on biopsy. The cycle length, day of the LH surge, and plasma progesterone concentrations are indicated in Table II. Only the plasma progesterone levels on the day of the biopsy during the 150 mg clomiphene cycles were significantly different from control values.

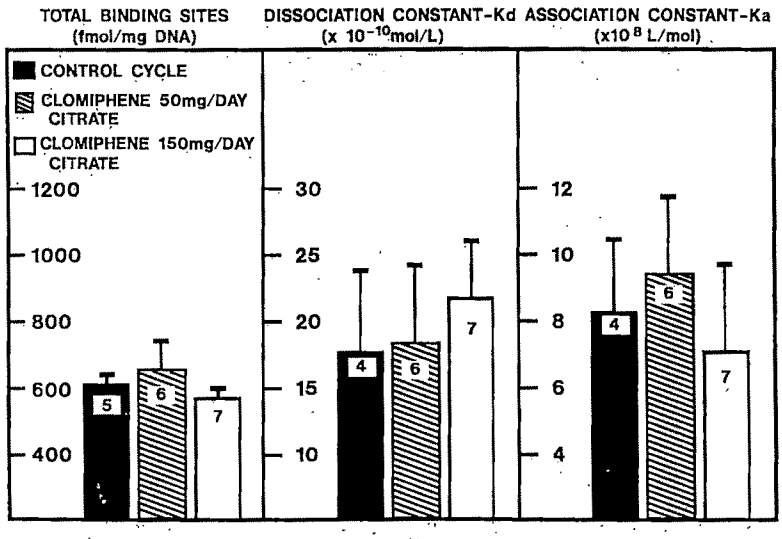

Fig. 2. Mean ± SEM nuclear progesterone receptors, K_d, and K_a in peri-implantation phase (luteal phase) endometrium. Clomiphene citrate treatment (50 mg and 150 mg daily from days 5 through 9 of the cycle) had no significant effect on nuclear progesterone receptor concentrations or binding affinities.

Receptor concentrations and binding affinities. The mean ± SEM concentrations, K_d and K_a of endometrial nuclear estradiol receptors in control cycles and clomiphene citrate–treated cycles are shown in Fig. 1. In control cycles, estrogen receptors levels were 199.6 ± 23.1 fmol/mg DNA (n = 8) and were not significantly different from either treatment with 50 mg clomiphene citrate (180.5 ± 19.1 fmol/mg DNA, n = 6) or 150 mg clomiphene citrate (194.3 ± 35.2 fmol/mg DNA, n = 4). The K_d and K_a were also unaffected by treatment with clomiphene citrate.

Similarly, there was no significant change in the concentrations, K_d, and K_a of nuclear progesterone receptors with 50 mg and 150 mg clomiphene citrate as compared with untreated control cycles (Fig. 2). The concentrations of progesterone receptors were 613 ± 31 fmol/mg DNA in control cycles, 652.8 ± 121 fmol/mg DNA with 50 mg clomiphene citrate, and 592.6 ± 31 fmol/mg DNA with 150 mg clomiphene citrate. Fig. 3 shows representative Scatchard plots for endometrial nuclear estradiol receptors in control, 50 mg, and 150 mg clomiphene citrate–treated cycles from one subject. Representative Scatchard plots for nuclear progesterone receptors in control and clomiphene citrate–treated cycles from one patient are shown in Fig. 4.

Comment

Because of the disparity between ovulation rates and viable pregnancy rates in women undergoing ovulation induction with clomiphene citrate,[16] we examined the estrogen and progesterone nuclear receptors of endometrial tissues for inappropriate changes around the time of implantation during the luteal phase. Given in doses of 50 mg and 150 mg daily from days 5 through 9 of the cycle, clomiphene citrate did not produce a demonstrable effect on either the concentrations or the binding affinities of both estrogen and progesterone nuclear receptors in luteal phase peri-implantation endometrium. The use of rapid LH determinations in urine and plasma enabled us to obtain endometrium of similar luteal ages for all cycles studied. To eliminate any potential endometrial factors unrelated to clomiphene citrate use (which may be present in infertile women) and to obtain adequate endometrial tissues for dependable Scatchard analysis of the receptors studied, only fertile normal ovulatory women not desirous of pregnancy were studied. In addition, each subject acted as her own control by having her own untreated ovulatory cycle studied.

Previous limited studies[12, 15] have examined the effect of clomiphene citrate on endometrial steroid receptors but differed in either the type of subjects, the cycle time when medication was given, or the analysis and type of receptors measured. Clomiphene citrate given to ovulating women during the luteal phase depressed both cytosolic and nuclear estrogen receptors but only cytosolic progesterone receptors.[21] However, there is no clinical indication to give clomiphene citrate in the luteal phase. Both total and cytosolic estrogen and progesterone receptors were reported to be significantly reduced but the corresponding nuclear receptors were significantly increased in endometrium obtained at oocyte retrieval after follicle recruitment with clomiphene, human menopausal gonadotropin, and human chorionic gonadotropin for in vitro fertilization.[13] With the measurement of only luteal phase endometrial cy-

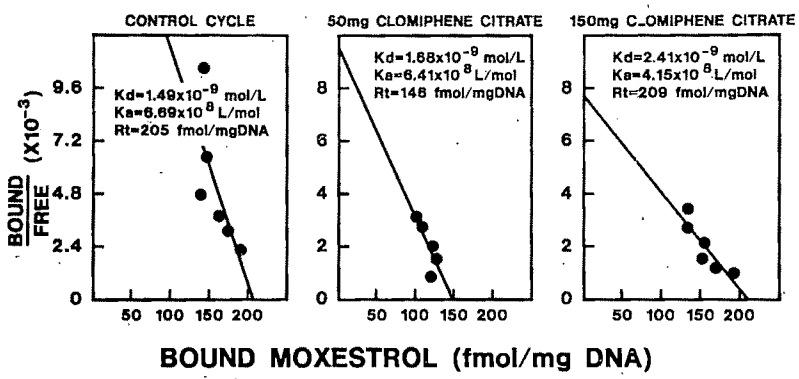

Fig. 3. Representative Scatchard analysis of luteal phase (peri-implantation) human endometrial nuclear estrogen receptor binding activity in one patient during a control cycle and in cycles treated with 50 mg/day and 150 mg/day of clomiphene citrate from days 5 through 9.

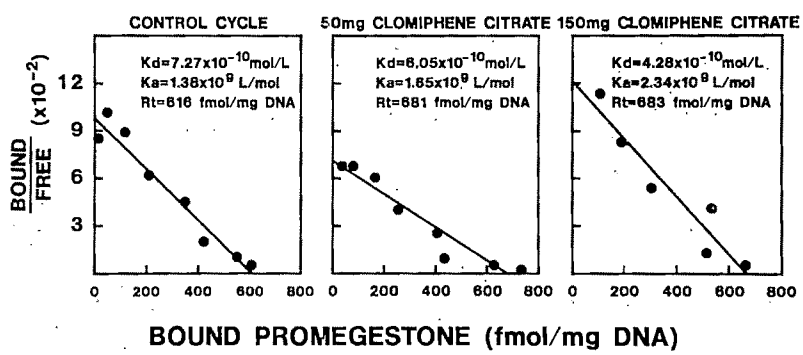

Fig. 4. Representative Scatchard analysis of luteal phase (peri-implantation) human endometrial nuclear progesterone receptor binding activity in one patient during a control cycle and in cycles treated with 50 mg/day and 150 mg/day of clomiphene citrate from days 5 through 9.

tosol estrogen and progesterone receptors in infertile women given clomiphene to induce ovulation, Aksel et al.[15] found decreased levels of these receptors without any correlation with luteal phase defects. In postmenopausal women, clomiphene given to antagonize the proliferative effects of estrogen replacement induced a significant decrease in cytosolic estrogen and progesterone receptors.[14] Whereas these studies are interesting, current concepts about the localization of steroid hormone receptors being in the nucleus[20] and not in the cytosol render interpretation of the findings difficult at best, if not impossible, when the nuclear receptors are not measured. It is precisely for this reason that we undertook to measure receptors in the nuclear material.

It is noteworthy that tamoxifen, another triphenylethylene derivative with mixed agonist-antagonist properties, given during the follicular phase for up to 21 days did not cause any significant change in late luteal phase endometrial estrogen receptor and progesterone receptor concentrations.[21] Whereas we found no appreciable effect of clomiphene on peri-implantation phase endometrial steroid receptor concentrations and binding affinities, it does not exclude possible effects on mechannisms at the postreceptor translational level. The results of our study lend biochemical support to the currently evolving challenge that clomiphene may actually have no adverse effect on the endometrium[22, 23] and that the discrepancy between successful ovulation and pregnancy rates disappears when life-table analysis of pregnancy and other infertility factors are carefully considered.[24] That the antiestrogenic effects of clomiphene may have attained unearned significance is further compounded by the difficult and controversial diagnosis of luteal phase defect,[25] a condition often overdiagnosed. Furthermore, the currently marketed formulations of clomiphene consist of a mixture of enclomiphene and zuclomiphene isomers, each of which has a different ratio of agonist-antagonist properties so that the ratio of estrogenic and antiestrogenic effect may vary from preparation to preparation.

In conclusion, it is reassuring from a clinical standpoint that clomiphene citrate in customarily used doses of 50 mg and 150 mg from day 5 through 9 of the cycle does not produce any significant change in the con-

centrations and binding affinities of peri-implantation phase endometrial estrogen and progesterone receptors.

We thank Serono Laboratories, Inc., Randolph, Mass., for providing the clomiphene citrate (Serophene) and Clay Adams Division of Becton Dickinson and Company, Parsippany, N. J., for providing the Q test ovulation test kits used in this study.

Aromatase in human fetal tissues

Kevin J. Doody, MD, and Bruce R. Carr, MD
Dallas, Texas

The placenta has been shown to be the major source of estrogen production during pregnancy. This investigation was undertaken to compare the content and activity of aromatase in the placenta and various other human fetal tissues. Tissues were obtained from first- and second-trimester human abortuses. The amount of aromatase P-450 (aromatase cytochrome P-450) in tissue homogenates was determined after sodium dodecyl sulfate-polyacrylamide gel electrophoresis and immunoblotting by use of a polyclonal antibody directed against aromatase cytochrome P-450. The activity of aromatase in microsomal preparations was assayed by determining the rate of incorporation of tritium from 1-[^{3}H]androstenedione into [^{3}H]water. The greatest amount of aromatase cytochrome P-450 (55 kd) was detected in placenta and lesser amounts were detected in other tissues. Aromatase activity also was highest in placental microsome fractions (368 ± 62.4 pmol/mg/hr [mean ± SE], n = 9). A significant amount of aromatase activity was also detected in fetal liver (19 ± 4.8 pmol/mg/hr, n = 7). Much less activity was found in brain (2.8 ± 1.0 pmol/mg/hr, n = 6) and intestine (2.7 ± 1.3 pmol/mg/hr, n = 7). Minimal activity was noted in adrenal (n = 5), spleen (n = 4), stomach (n = 4), and muscle (n = 5) (1.2 to 1.5 pmol/mg/hr). Activity in kidney (n = 7), heart (n = 4), and lung (n = 4) was extremely low (<0.8 pmol/mg/hr). In conclusion, the placenta is a major site of conversion of C19 steroid precursors to estrogens because of the amount of enzyme and the high rate of activity of aromatase compared with those of other fetal tissues. However, considering the size and rate of aromatase activity in other fetal tissues such as liver, brain, and intestine, these tissues also may contribute to the total estrogen production in the fetal-placental unit. (Am J Obstet Gynecol 1989;161:1694-7.)

Key words: Aromatase, placenta, aromatase cytochrome P-450

The enzyme aromatase P-450 (aromatase cytochrome P-450) catalyzes the formation of C18 estrogens from C19 steroid precursors. During pregnancy the placenta is considered to be the principal site of estrogen synthesis. However, aromatase activity is known to be present in several other tissues. The ability of the fetal liver to convert C19 steroids to estrogens is well documented.[1-5] The metabolism of androstenedione to estrogens by the human fetal brain also has been previously demonstrated.[1, 6-8] Additionally, the fetal adrenal, kidney, lung, and thymus appear to be capable of converting androstenedione to estrone.[1-4] The methods used by previous investigators include radioisotope infusion of previable fetuses[9] or single- and double-isotope incubations followed by thin-layer chromatography and crystallization to homogeneity with the use of homogenates or slices of fetal tissues.[1-8]

The physiologic role of the large quantity of estrogens synthesized by the fetal-placental unit is not completely understood. It has been proposed that estrogen may regulate or fine-tune the events leading to parturition since pregnancies are often prolonged when estrogen levels in maternal blood and urine are low, as in placental sulfatase deficiency, or when associated with anencephaly.[10, 11] Estrogens also may play a role in fetal organ maturation and development. This investigation was undertaken as an attempt to further define the mechanisms of fetal estrogen production. Our primary goal was to quantitate the activity of aromatase and the content of aromatase cytochrome P-450 in the placenta and various other human fetal tissues.

Material and methods

Source and preparation of tissue. Tissues were obtained from fetuses of 12 to 18 weeks' gestation at induced abortion. Tissues were obtained in accordance with the Donors Anatomical Gift Act of the State of Texas after consent in writing from the woman who was to undergo the abortion. Consent form and protocol were approved by the Human Research Review Committee of the University of Texas Southwestern Medical Center at Dallas. Fetal tissues were transported on ice and homogenates and microsomal fractions were prepared as rapidly as possible (usually <1 hour).

Preparation of homogenates. A homogenizing buffer containing 0.25 mol/L sucrose, 10 mmol/L tris(hydroxymethyl)aminomethane hydrochloride

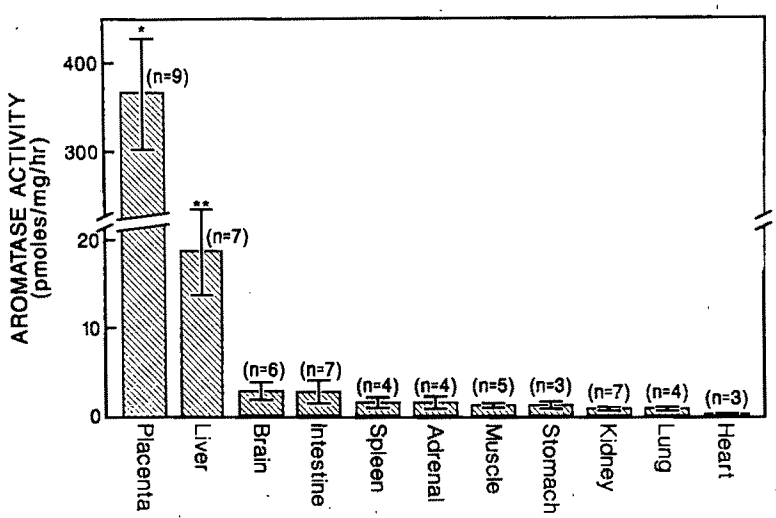

Fig. 1. Aromatase activity in various human fetal tissues. Aromatase activity was determined by the measurement of the formation of [^{3}H]water from 1[^{3}H]androstenedione as described in Material and methods. Each *bar* represents the mean ± SEM of the results obtained. *n*, Number of fetuses used for each determination. Data are expressed as picomoles per milligram of microsomal protein per hour of aromatase activity; *asterisk*, $p < 0.01$ where placental activity differed significantly from other tissues; *double asterisk*, $p < 0.05$ where liver activity differed significantly from other fetal tissues.

(Tris-HCl), 1 mmol/L ethylenediaminetetraacetic acid (EDTA), and 1 mmol/L dithiothreitol was used. The protease inhibitors phenylmethylsulfonyl and fluoride (1 mmol/L), pepstatin (10 μg/ml), leupeptin (10 μg/ml), and antipain (10 μg/ml) were added to the homogenization buffer to prevent degradation. Tissues were homogenized in the above buffer at pH 7.6 with a Teflon-glass homogenizer. Samples were then centrifuged at 100 *g* for 10 minutes at 4° C to remove cellular debris.

Preparation of microsomal fractions. Homogenates were centrifuged at 20,000 *g* for 20 minutes at 4° C. The supernatant fraction was centrifuged at 100,000 *g* for 1 hour at 4° C. The microsomal fractions were stored in liquid nitrogen until assayed for aromatase activity.

Sodium dodecyl sulfate and polyacrylamide gel electrophoresis and immunoblotting of aromatase cytochrome P-450. One-dimensional electrophoresis was conducted with a 3% polyacrylamide stacking gel and a 10% polyacrylamide running gel. Samples were applied to the gel in buffer containing 0.2% sodium dodecyl sulfate, 50 mmol/L Tris-HCl, 10% glycerol, 2 mmol/L EDTA, 2 mmol/L β-mercaptoethanol, and 0.05% bromophenol blue. Electrophoresis was carried out at 15 mA at 4° C for 16 hours in an electrode buffer containing Tris base (50 mmol/L), glycine (383 mmol/L), sodium dodecyl sulfate (0.1%), and EDTA (2 mmol/L). Proteins were transferred from gels onto nitrocellulose paper in a Trans-Blot cell apparatus (Bio-Rad Laboratories, Richmond, Calif.). A second electrophoresis was carried out at 170 mA for 16 hours at 4° C with an electrode buffer of Tris base (20 mmol/L), glycine (50 mmol/L), and methanol (20%). After transfer, the nitrocellulose was preincubated in phosphate-buffered saline solution–Tween (0.5%) for 30 minutes at room temperature. Incubation with the primary antibody (polyclonal anti–aromatase cytochrome P-450) was carried out for 1 hour. Fresh phosphate-buffered saline solution–Tween containing the second antibody [^{125}I]goat antirabbit immunoglobulin G (New England Nuclear, Boston; 500 μCi) was added for 2 hours. In other experiments [^{125}I]protein A (New England Nuclear, 1×10^6 cpm/ml) was used (data not shown). The nitrocellulose was washed three times with water and four times with phosphate-buffered saline solution–Tween. After an additional rinse with water, the nitrocellulose was blotted dry, wrapped in plastic, and exposed to Kodak Omat-X film for 48 hours with the use of enhancing screens. Polyclonal rabbit anti–aromatase cytochrome P-450 was generously provided by Drs. Carol Mendelson and Evan Simpson, Departments of Biochemistry and Obstetrics and Gynecology, University of Texas Southwestern Medical School, Dallas.[12-15]

Assay of aromatase activity. 1β[^{3}H]Androstenedione (28 Ci/mmol) was purchased from New England Nuclear. Aliquots of microsomal fractions were assayed for protein content by the method of Lowry et al.[16] Microsomal fractions (50 to 100 μg protein per sample) were incubated in buffer containing 50 mmol/L monofasic potassium phosphate and 3 mmol/L magnesium chloride at a pH of 7.4., A β-nicotinamide adenine dinucleotide phosphate, reduced form, generating sys-

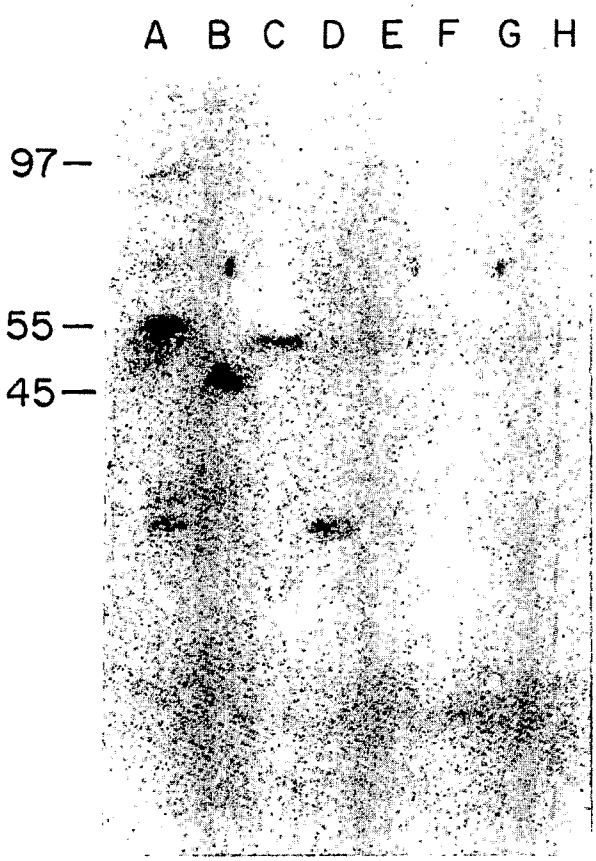

Fig. 2. Sodium dodecyl sulfate and immunoblotting of aromatase cytochrome P-450 of various fetal tissues. Lane *A*, Placenta; *B*, liver; *C*, brain; *D*, intestine; *E*, lung; *F*, kidney; *G*, muscle; *H*, skin; 200 μg of protein was subjected to electrophoresis in polyacrylamide gels containing 0.1% sodium dodecyl sulfate. The proteins were transferred electrophoretically to nitrocellulose paper and incubated with polyclonal antiaromatase antibody and then incubated with [^{125}I]goat antirabbit immunoglobulin (10^6 cpm/ml) as discussed in Material and methods. Molecular weight standards were in kilodaltons as shown.

tem of 1 mmol/L β-nicotinamide adenine dinucleotide phosphate, reduced form, 10 mmol/L glucose-6-phosphate, and 1.2 U/ml glucose-6-phosphate dehydrogenase was used. 1β[^{3}H]Androstenedione was added to a final concentration of 150 nmol/L (final volume 200 μl). Aromatase activity was assayed by determining the incorporation of tritium from 1β[^{3}H]androstenedione into [^{3}H]water as previously described.[17, 18]

Materials. All reagents, unless otherwise specified, were purchased from Sigma Chemical Co., St. Louis.

Statistical analysis. One-way analysis of variance and Student–Newman-Keuls test were used.

Results

The specific activity of aromatase was determined in individual microsome preparations of the various tissues obtained from each fetus (Fig. 1). The rate of aromatase activity is expressed as picomoles of 1β[^{3}H]androstenedione metabolized to estrogen per milligram of protein per hour. The level of aromatase activity did not appear to vary significantly with gestational age in any of the tissues studied (data not shown). Placental microsome fractions exhibited the greatest level of aromatase activity (368 ± 62.4 pmol/mg/hr, mean ± SE, $n = 9$). The liver also demonstrated a significant ability to aromatize androstenedione (19 ± 4.8 pmol/mg/hr, $n = 7$).

A lower level of activity of aromatase was found in the other fetal tissues. Activity in the brain microsome preparations was 2.8 ± 1.0 pmol/mg/hr ($n = 6$). Similar aromatase activity was seen in intestine (2.7 ± 1.3 pmol/mg/hr, $n = 6$). Aromatase activity in the adrenal and spleen microsomes was 1.5 ± 0.7 pmol/mg/hr ($n = 6$) and 1.5 ± 0.6 pmol/mg/hr ($n = 5$), respectively. Muscle aromatase activity was 1.2 ± 0.3 pmol/mg/hr ($n = 7$). Some activity was also measured in the stomach (1.2 ± 0.4 pmol/mg/hr, $n = 3$). Minimal aromatase activity was observed in kidney (0.78 ± 0.2 pmol/mg/hr, $n = 7$), lung (0.75 ± 0.3 pmol/mg/hr, $n = 5$), and heart (0.19 ± 1 pmol/mg/hr, $n = 4$).

Immunoblot analysis of tissue homogenates demonstrated a large quantity of immunoreactive aromatase cytochrome P-450 (55 kd) in the placenta (Fig. 2). A smaller (45 kd) band was noted to be consistently present in liver homogenates. In addition, a 52 kd immunoreactive protein was found to be present in brain tissue.

Comment

In this study we demonstrated that the placenta is the major site of aromatase activity and contains the greatest amount of aromatase cytochrome P-450 of all fetal tissues; thus it is confirmed as the primary location of conversion of C19 steroid precursors to estrogens. Furthermore, it also appears probable that the fetal liver (in view of its size, blood flow, and aromatase activity) also contributes substantially to the total estrogen production of the fetal-placental unit.

All of the other fetal tissues studied had significantly lower levels of aromatase activity, and it is unlikely that they contribute significantly to overall estrogen production. However, it is possible that estrogens produced in these tissues act locally to induce metabolic effects. The significance of estrogens produced in these other sites is a subject for further investigation.

From our study only placental tissue demonstrated immunoreactive protein for aromatase cytochrome P-450 at 55 kd. The significance of the smaller immunoreactive proteins noted in brain and liver tissue is unclear. Posttranslational modification of the enzyme

may account for the presence of the smaller immunoreactive protein. Protein inhibitors were used to minimize the possibility that these findings were artifactual in origin. The consistency of the finding of an immunoreactive band at 45 kd in the fetal liver (which had the highest aromatase activity of any nonplacental tissue), together with the lack of this finding in the many other tissues tested, is evidence that tends to support the possibility of posttranslational modification. Control immunoblots that used only the second antibody did not demonstrate these smaller bands, thus excluding the possibility of nonspecific binding of this antibody. The possibility that the 45 kd band results from nonspecific binding of the polyclonal antibody cannot be excluded altogether. Currently, absolute identification of this band is not possible. Development of other antibodies against aromatase in the future may help to clarify this issue.

Previous investigators have reported similar qualitative results for aromatase activity by use of isotope incubations with homogenates from fetal tissues obtained from a relatively small number of fetuses. George and Wilson[19] reported that total estrogen formation in tissue slices incubated with testosterone and androstenedione was greatest in fetal ovaries. However, we were unable to obtain enough fetal ovaries to prepare a microsomal fraction in this study.

This investigation is believed to be the first to report use of the [^{3}H]water assay to measure aromatase activity in fetal tissues, as well as to measure the amount of immunoreactive aromatase cytochrome P-450. In summary, the placenta exhibits significant amounts of aromatase cytochrome P-450 and a high rate of aromatase activity. Significant activity is also found in the fetal liver when compared with other fetal tissues.

We thank Sandy Nance for editorial assistance and Nora Cline for expert technical assistance.

Comparison of in vivo bioavailability of progestational agents into the rat uterus and liver and the effect of plasma protein binding

Bradley Van Voorhis, MD, Dennis W. Matt, PhD, Maria L. Tedeschi, and Kenneth A. Steingold, MD

Richmond, Virginia

The in vivo bioavailabilities of three clinically available progestational agents were evaluated with a previously described rat model. With this model a single-injection, double-isotope technique was performed to calculate and compare the unidirectional extractions of progesterone, 19-nortestosterone, and medroxyprogesterone acetate into the rat uterus and liver. To assess the role of plasma protein binding in the extraction of these agents, steroids were presented in four different vehicles: (1) Ringer's solution, 0.1% bovine serum albumin; (2) Ringer's solution, 4% bovine serum albumin; (3) Ringer's solution, 0.8 mg/ml, α_1-acid glycoprotein; (4) human pregnancy serum. The results revealed that liver extraction always exceeded uterine extraction for each progestin, regardless of the vehicle, and that liver extraction was approximately 100% for all steroids. With regard to the uterus, when binding proteins were not present in the injectate, the extraction of the three steroids was similar; the uterine vasculature was relatively permeable to these progestins, and bovine serum albumin and α_1-acid glycoprotein had no major effect on the uptake into the uterus. However, when human pregnancy serum was in the injectate, the extractions of progesterone and 19-nortestosterone into the rat uterus were significantly diminished. In contrast, pregnancy serum had no effect on the uptake of medroxyprogesterone acetate into the uterus, with the extraction equal to that of Ringer's solution alone. This suggests that, regardless of potential binding proteins, medroxyprogesterone acetate displays greater bioavailability than that of the other progestogens studied. (Am J Obstet Gynecol 1989;161:1698-703.)

Key words: Progestin bioavailability, plasma protein binding, albumin, α_1-acid glycoprotein, progesterone

The uterine and hepatic bioavailability of various progestational agents is an important variable in the determination of the optimal progestogen. Whereas the uterus is an important target organ for progestational activity, the liver assumes a key role as a site of metabolism of progestins and a possible site of adverse reactions that result from the first-pass effect of oral administration of certain progestins.[1]

Previous in vitro studies have shown that medroxyprogesterone acetate is poorly bound to known steroid binding proteins and may be more bioavailable than other progestins.[2] Therefore this study was designed to evaluate and compare the in vivo bioavailability of three progestins into the rat uterus and liver, and to assess whether plasma or plasma proteins affect the bioavailability of these hormones.

The progestins studied were progesterone, medroxyprogesterone acetate, and 19-nortestosterone, chosen as a test steroid to represent the potential derivatives of 19-nortestosterone currently available. The hepatic and uterine bioavailabilities were assessed with a previously described in vivo rat model.[3] With this model, the influxes of the progestins from the microcirculation into the rat uterus and liver were evaluated. In addition, the effects of two plasma proteins, albumin and α_1-acid glycoprotein (AAG), and of the potential steroid binding proteins found in human pregnancy serum on the influx of these steroids were examined.

Previous studies have similarly used this model to evaluate available estrogens used for replacement therapy.[4] Differential effects in the uterine and hepatic vasculature relating to differences in membrane permeability and plasma protein binding of these individual agents were described. This study expands these data to include progestational agents.

Material and methods

Radiolabeled progesterone, medroxyprogesterone acetate, and butanol were obtained from New England Nuclear Corp. (Boston, Mass.); the 19-nortestosterone isotope was obtained from Amersham Laboratories

From the Department of Obstetrics and Gynecology, Medical College of Virginia.

Presented in part at the Thirty-fifth Annual Meeting of the Society for Gynecologic Investigation, Baltimore, Maryland, March 17-20, 1988.

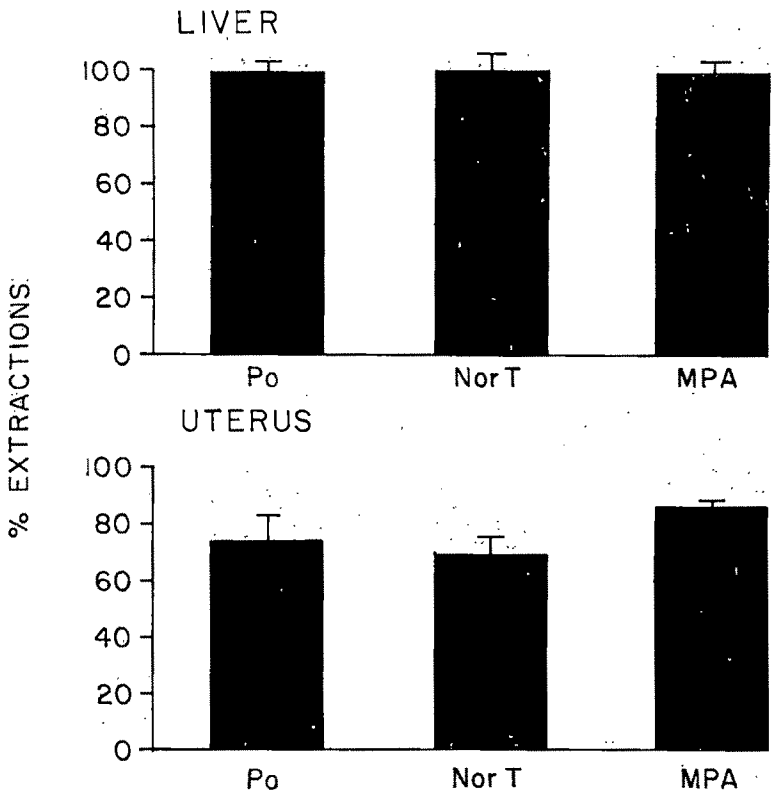

Fig. 1. Mean percent extraction (±SEM) of progesterone *(Po)*, 19-nortestosterone *(NOR-T)*, and medroxyprogesterone acetate *(MPA)* with Ringer's solution (0.1% BSA) as injection vehicle; liver *(upper panel)* and uterine *(lower panel)* extractions are shown.

(Buckinghamshire, England). The specific activities were as follows: [1, 2, 6, 7 - ^{3}H (N)]progesterone, 106.8 Ci/mmol; 6α - [1, 2, - ^{3}H(N)]medroxyprogesterone acetate, 50.0 Ci/mmol; 19-[6, 7 (N) - ^{3}H]nortestosterone, 19 Ci/mmol; n - [1 - ^{14}C]butanol, 0.9 mCi/mmol. The radiolabeled steroids were separated from the solvent by evaporation, and buffered Ringer's solution that contained 0.1% bovine serum albumin (BSA) was added to the steroids. The BSA and AAG were purchased from Sigma Chemical Co. (St. Louis, Mo.). Human serum obtained from volunteers during the third trimester of pregnancy was pooled and frozen at −20° C. The unidirectional extractions of test substances by the uterus and liver were measured by a previously described single bolus injection, double-isotope technique.[5, 6] Female Long-Evans rats, 100 days old, were ovariectomized 7 to 14 days before the injection studies. After ketamine (235 mg/kg) was administered intramuscularly to induce anesthesia, the right common iliac artery and left femoral artery were surgically exposed and clamped for studies that involved the uterus. The test solution was administered by a 250 μl rapid bolus injection into the lower abdominal aorta. The left uterine horn was resected 15 seconds after the injection. The portal vein was cannulated and a similar bolus injection was used immediately after ligation of the hepatic artery for studies that involved the liver. The right major lobe of the liver was removed 18 seconds after the injection. These time intervals were determined in previous studies to be sufficiently long to allow the injectate to exit the vasculature in question but sufficiently short to prevent reentry of the test substances into the circulation after they have passed out of the intravascular space.[5, 6]

The injectate contained either tritiated progesterone, 19-nortestosterone or medroxyprogesterone acetate. Butanol labeled with carbon 14 was present in each injectate as the freely diffusable reference, with the ratio of the tritiated steroid to [^{14}C]butanol between 10 and 30. The different injection vehicles evaluated were (1) Ringer's solution with 0.1% BSA; (2) Ringer's solution with 4% BSA; (3) Ringer's solution with AAG at the human physiologic concentration of 0.8 mg/ml; and (4) third-trimester human pregnancy serum. When serum was used as the injection vehicle, the concentration of labeled test substances was deliberately set to be less than the concentration of previously determined unbound serum globulin binding sites. The concentration of test steroids in serum was 6 nmol/L, and in the

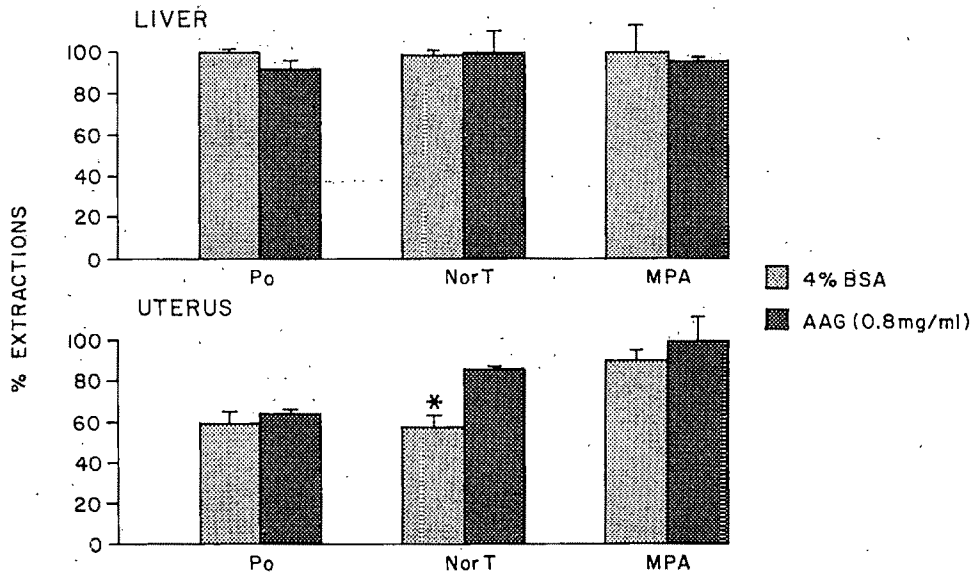

Fig. 2. Mean percent extraction (±SEM) of progesterone *(Po)*, 19-nortestosterone *(NOR-T)*, and medroxyprogesterone acetate *(MPA)* with 4% BSA in Ringer's solution compared with AAG (0.8 mg/ml) in Ringer's solution as injection vehicles; liver *(upper panel)* and uterine *(lower panel)* extraction are shown. $*p < 0.005$.

Ringer's solution it was 24 nmol/L. In both organs studied, three to six injections were performed with each of the progestogens in each of the injection vehicles.

The resected tissues were then solubilized in 2.0 ml Soluene-350 (Packard Instrument Co., Downers Grove, Ill.). The tissue and the injection solution samples were counted by double-isotope liquid scintillation measurements for disintegrations per minute (DPM) with quench correction. The liver or uterine uptake was computed as follows:

$$\text{Uptake} = \frac{(^3H/^{14}C)\ \text{DPM in tissue}}{(^3H/^{14}C)\ \text{DPM in injectate}} \times 100$$

The results are depicted as the unidirectional extraction for each progestin. The organ uptake can be converted to extraction if the extraction of butanol is known. It is assumed that there is 100% extraction of butanol into the uterus and liver, but butanol effluxes these organs at a rate on the basis of blood flow. It has previously been shown that the extraction of butanol in the uterus at 15 seconds is 77%,[5] and in the liver at 18 seconds is 84%.[6] Therefore all uptake determinations were converted to unidirectional extraction as follows: uterine extraction = uterine uptake × 0.77; liver extraction = liver uptake × 0.84.

All results are reported as mean ± SEM extraction of test steroid. Statistical analysis was performed with the Student *t* test.

Results

The tissue unidirectional extractions of the tritiated progestogens by the uterus and liver with Ringer's solution (0.1% BSA) as the injection vehicle are shown in Fig. 1. There was 100% extraction of progesterone, 19-nortestosterone, and medroxyprogesterone acetate by the liver. For the uterus, somewhat lower values were noted for each of the steroids studied, with extractions of 74 ± 8% for progesterone, 69 ± 7% for 19-nortestosterone, and 86 ± 2% for medroxyprogesterone acetate. Because essentially no binding proteins were present in the injectate, the data show that all test substances are freely diffusible into the liver, and are relatively freely diffusible into the uterus.

The effect of the potential serum binding proteins (albumin and AAG) on progestogen extraction can be seen in Fig. 2. With regard to the liver, there was no inhibition of extraction of any of the test steroids by these two binding proteins, with levels ranging from 94% to 121%. In the uterus there was no difference in the percent of progesterone extraction when 4% BSA was compared to AAG. However, the values noted here are slightly, but not significantly, decreased as compared to the 74% extraction in Ringer's solution illustrated in Fig. 1. When 4% BSA was used as the injection vehicle for 19-nortestosterone, the percent extraction was significantly lower than the extraction with AAG ($p < 0.005$), but not different from Ringer's solution. However, for medroxyprogesterone acetate there was no inhibition of extraction with either BSA or AAG. In general, all three progestins did display relatively high extraction rates into the uterus despite the presence of these binding proteins, inasmuch as the extraction of all three steroids was ≥60%.

Fig. 3 shows the extraction of the progestins when

human pregnancy serum was the injection vehicle. Again, with regard to the liver, all three progestins were freely diffusible despite the presence of potential binding proteins in pregnancy serum. In the uterus, the extractions of progesterone and 19-nortestosterone were significantly diminished, as compared with their extraction in Ringer's solution ($p < 0.02$), with the percent extraction of progesterone, 34 ± 8%, and 19-nortestosterone, 26 ± 4%. In contrast, medroxyprogesterone acetate displayed marked bioavailability into the rat uterus with a percent extraction of 84 ± 8%, despite pregnancy serum in the injectate. Therefore in the presence of binding proteins and serum globulins that are normally found in human serum, the apparent bioavailability of progesterone and 19-nortestosterone into the uterus was significantly diminished, as compared with that of medroxyprogesterone acetate ($p < 0.005$).

Comment

Progestins are commonly used in clinical practice to prevent the effects of unopposed estrogen on the endometrium. A variety of progestins are available to the clinician including natural progesterone and progesterone derivatives. Oral administration of progesterone in a micronized form is available and has displayed adequate oral absorption with decreased metabolism.[7] The 19-nortestosterone derivatives, such as norethindrone acetate, norgestrel, and norethynodrel are some of the active progestational agents found in oral contraceptives. These compounds may also be administered as single agents, both in the progestin-only contraceptives and for estrogen opposition in the anovulatory or postmenopausal female. Medroxyprogesterone acetate is also widely used for these purposes as single-agent therapy. For these reasons, progesterone, 19-nortestosterone, and medroxyprogesterone acetate were evaluated in this study.

In choosing among these progestational agents, clinical parameters including efficacy and safety need to be considered. One of the key concerns with regard to safety is the potential effect of the various progestins on hepatic metabolism. For example, the effects of progestins on hepatic lipoprotein production are major factors in the comparison of various agents.[8-10] Therefore in this study the uterus and liver were chosen as specific organs to evaluate extraction of these three steroids.

To determine whether these clinically observed differences in hepatic effects could be a result of differing bioavailability of the progestins to the liver, we first looked at hepatic uptake of the progestins. No difference was observed, as all progestins displayed 100% extraction into the liver despite the presence of pregnancy serum. One interesting observation was that hepatic uptake always exceeded uterine uptake, regardless of the progestin or injection vehicle studied. This finding may result from differences in anatomical architecture and in capillary transit time. The capillary transit time of an organ is the time required for a substance to pass from the afferent to the efferent vessels through the capillaries. The capillary transit time in the liver is between 5 and 10 seconds, whereas the transit time for the uterus is not known but is believed to be between 1 and 3 seconds.[11] Thus circulating hormones have a longer time to pass from the circulation into the liver than into the uterus. In addition, the liver vasculature has wide sinusoidal pores that allow equilibration of plasma proteins and steroids between intravascular and interstitial spaces.[12] This allows for a larger surface area for steroid influx in the liver, as compared with the uterus. In a previous study of clinically available estrogens,[4] similar findings were shown for the liver with enhanced bioavailability of these estrogenic compounds, as compared with uterus and brain.

The second portion of this study evaluated the unidirectional extraction of these progestogens by the rat uterus. Availability to the uterus is an important prerequisite for the protective progestin action on the endometrium. The effects of membrane permeability and plasma protein binding can be separated in this model by altering injection vehicles. It was observed that in the absence of binding proteins (Ringer's solution), all three progestins were relatively permeable to the rat uterus. Furthermore, the presence of physiologic concentrations of the binding proteins, albumin and AAG, had little effect on uptake of any of the progestins into the uterus. Corresponding values for extraction into the uterus were always less than those found for the liver.

Human pregnancy serum was also studied as an injection vehicle. This particular physiologic state was chosen for its known high concentrations of the binding globulins—sex hormone binding globulin and transcortin.[13, 14] In pregnancy serum, the extractions of progesterone and 19-nortestosterone into the uterus were significantly diminished, as compared with Ringer's solution alone, albumin, and AAG. Therefore proteins in pregnancy serum exhibited binding to both progesterone and 19-nortestosterone effectively to prevent the in vivo uptake into the rat uterus. In marked contrast, medroxyprogesterone acetate remained freely permeable into the rat uterus, despite the presence of human pregnancy serum in the injectate. Regardless of potential binding proteins that are found in significant concentrations in pregnancy serum, medroxyprogesterone acetate exited the uterine vasculature at a level similar to that found when Ringer's solution alone (0.1% BSA) was used as the injectate. The extraction of medroxyprogesterone acetate was signifi-

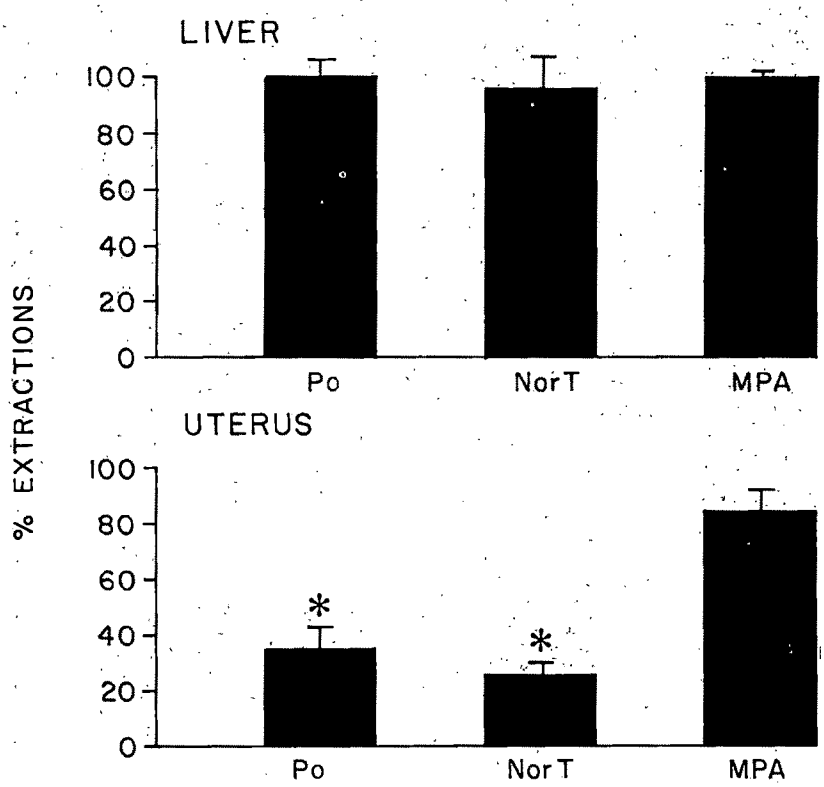

Fig. 3. Mean percent extraction (±SEM) of progesterone *(Po)*, 19-nortestosterone *(NOR-T)*, and medroxyprogesterone acetate *(MPA)* with human pregnancy serum as injection vehicle; liver *(upper panel)* and uterine *(lower panel)* extractions are shown. $*p < 0.005$.

cantly greater than that found for progesterone or 19-nortestosterone in the presence of pregnancy serum.

In vitro studies support our in vivo data with regard to the lack of effect of serum globulins on the bioavailability of medroxyprogesterone acetate. Results from competitive binding analysis and polyacrylamide gel electrophoresis suggest that medroxyprogesterone acetate does not demonstrate significant binding to sex hormone binding globulin or corticosteroid binding globulin.[2] In contrast, progesterone is known to bind with corticosteroid binding globulin, whereas 19-nortestosterone and its derivatives bind with varying affinity to sex hormone binding globulin.[15-18] There are also differences in circulating plasma levels of progestins achieved after clinical administration with decreased levels of medroxyprogesterone acetate, as compared with 19-nortestosterone derivatives.[19, 20] This is believed to be a result of differences in compartmentalization of the drugs, in addition to decreased affinity for plasma proteins, medroxyprogesterone acetate exhibits extravascular storage. These differing properties may lead to the greater uterine in vivo bioavailability of medroxyprogesterone acetate seen in our study.

However, in vitro studies also suggest binding of progesterone and 19-nortestosterone to albumin; progesterone also has affinity for AAG.[17, 19] In this study albumin and AAG did not inhibit uptake of these compounds into the uterus, although the BSA values for 19-nortestosterone were lower than those for AAG. These compounds were still relatively free for transport into this target organ, despite these proteins, which is compatible with previous in vivo studies.[20]

In summary, using an in vivo model, hepatic and uterine extraction of these three progestins with and without potential binding proteins were evaluated. Because of characteristics of the hepatic vasculature, these agents were essentially 100% available to the liver despite the presence of potential binding proteins. This effect is believed to be an inherent property of the architecture of hepatic vasculature. In contrast, uterine extraction was always lower than that found for hepatic tissue at each corresponding point. Progesterone and 19-nortestosterone behaved relatively similarly and uptake from the uterine vasculature was diminished in the presence of binding proteins found in human pregnancy serum. Medroxyprogesterone acetate displayed a marked difference in that extraction from the vasculature of the uterus was greater at all corresponding points, and the presence of potential binding in pregnancy serum resulted in no diminution of uterine bioavailability. This study emphasizes the effect of binding globulins on progestogen bioavailability, an effect that

varied among the progestational agents tested and may influence hormone actions.

Androgen sulfate and glucuronide conjugates in nonhirsute and hirsute women with polycystic ovarian syndrome

Robert K. Matteri, MD, Frank Z. Stanczyk, PhD, Elisabet E. Gentzschein, BA, Clara Delgado, BA, and Rogerio A. Lobo, MD

Los Angeles, California

Peripheral androgen action largely determines the occurrence of hirsutism in women. Although serum 5α-androstane-3α,17β-diol (3α-diol) glucuronide signifies skin 5α-reductase activity and has been used as a marker of hirsutism and peripheral androgen metabolism, other C_{19} androgen conjugates have recently been measured and may also be useful markers of hirsutism in women. In addition to normal controls we studied both hirsute and nonhirsute patients with polycystic ovarian syndrome who had similar levels of circulating androgen precursors. In these three groups we measured various C_{19} sulfates and glucuronides including serum 3α-diol glucuronide. Serum androgen precursors were elevated, but were equal in the hirsute and nonhirsute patients. Serum androsterone sulfate and glucuronide, and 3α-diol sulfate and glucuronide clearly differentiated the hirsute from the nonhirsute group. Among the conjugates, androsterone glucuronide was most reflective of the difference between the two groups (100.3 ± 28.0 versus 42.9 ± 4.0 ng/ml, $p < 0.05$). In hirsute compared with nonhirsute patients with polycystic ovarian syndrome, serum 3α-diol glucuronide was increased by the smallest amount (32%), followed by androsterone sulfate (38%), 3α-diol sulfate (59%), and androsterone glucuronide with the largest increase (134%). Serum androsterone glucuronide and 3α-diol glucuronide both correlated with androstenedione and dehydroepiandrosterone sulfate in hirsute women but not in nonhirsute women. These data suggest that besides serum 3α-diol glucuronide, other C_{19} sulfate and glucuronide conjugates may reflect peripheral androgen action. (AM J OBSTET GYNECOL 1989;161:1704-9.)

Key words: Hirsutism, polycystic ovarian syndrome, 5α-reductase, androsterone sulfate, androsterone glucuronide, 5α-androstane-3α,17β-diol sulfate, 5α-androstane-3α,17β-diol glucuronide

Circulating androgens, which reflect ovarian and adrenal production, such as total or free testosterone and dehydroepiandrosterone (DHEA) sulfate may not always explain hirsutism in women.[1] Hirsutism is largely determined by skin 5α-reductase activity, but serum dihydrotestosterone unreliably reflects this peripheral androgen action.[2, 3] A dihydrotestosterone metabolite, 5α-androstane-3α,17β-diol glucuronide (3α-diol glucuronide), has been shown to be a good indicator of peripheral androgen action and reflects 5α-reductase activity.[4-9] In our preliminary work we found that other C_{19} conjugates such as androsterone sulfate and glucuronide as well as 3α-diol sulfate are not only different in men and women but also reflect hirsutism in women.[10] Also androsterone glucuronide was the most elevated conjugate in hirsute women, which implies an important role for the androsterone pathway in androgen metabolism of hirsute women. Increased production of androsterone was also seen in our previous studies on androgen metabolism in the skin of hirsute patients.[10]

Many women with polycystic ovarian syndrome who have elevated levels of serum androgens are not hirsute.[11] Further evidence that serum 3α-diol glucuronide reflects 5α-reductase activity was suggested in our studies of nonhirsute women with polycystic ovarian syndrome who, despite elevated levels of circulating androgens, have normal levels of serum 3α-diol glucuronide.[3] Whether other androgen conjugates reflect 5α-reductase activity directly or through changes in ovarian and adrenal precursors is unknown. Therefore the purpose of our study was to investigate the usefulness of androgen sulfates and glucuronides in patients with polycystic ovarian syndrome who were hirsute or nonhirsute. Besides the determination of how these conjugates reflect 5α-reductase activity, we specifically compared their measurements with a well-characterized androgen marker, serum 3α-diol glucuronide.

Table I. The mean (±SE) age, weight, height, and Ferriman-Gallwey score in normal women, nonhirsute women with polycystic ovary syndrome, and hirsute women

	Age (yr)	*Weight (kg)*	*Height (cm)*	*Ferriman-Gallwey score*
Normal women (n = 8)	31.3 ± 2.3	67.2 ± 5.8	162.6 ± 1.3	5.2 ± 1.4
Nonhirsute women with polycystic ovarian syndrome (n = 10)	27.8 ± 1.3	71.9 ± 2.7	158.2 ± 1.3	7.2 ± 1.6
Hirsute women (n = 10)	29.5 ± 2.5	70.1 ± 5.1	163.9 ± 6.4	18.3 ± 3.2*

*For Ferriman-Gallwey score, the difference between hirsute versus normal or nonhirsute women was significant at $p < 0.001$.

tion, or hirsutism. All patients met the criteria for polycystic ovarian syndrome including inappropriate gonadotropin secretion (luteinizing hormone/follicle-stimulating hormone ratio >2:1), perimenarchial onset of oligomenorrhea, and evidence of androgen excess, either having elevated serum testosterone or DHEA sulfate levels, or hirsutism.[12] The patients were divided into two groups of 10 patients solely on the basis of the presence or absence of hirsutism as reflected by an elevated Ferriman-Gallwey score.[13] Besides the gynecologic endocrine abnormalities, patients had no other endocrine or systemic medical diseases (normal thyroid function studies, normal glucose screening, normal prolactin, and no evidence of congenital adrenal hyperplasia). Patients were compared with a control group of eight normally ovulating women in the early follicular phase, who were matched for age, weight, and height. Venous blood (10 ml) was drawn between 8 and 10 AM in each subject.

Reagents. 9,11-^{3}H-androsterone (specific activity, 53.3 Ci/mmol), 1α,2α-^{3}H-testosterone (specific activity, 55.2 Ci/mmol), and 7-^{3}H-DHEA sulfate (specific activity, 16.3 Ci/mmol) were obtained from NEN Research Corp. (Boston, Mass.). 1α,2α-^{3}H-5α-androstane-3α,17β-diol (specific activity, 52.8 Ci/mmol) was obtained from Amersham (Clearbrook, Ill.). ^{3}H-3α-diol glucuronide was a gift from Nichols Institute (San Juan Capistrano, Calif.). All ^{3}H-labeled steroids were purified by Celite column chromatography before use.

Assays. DHEA sulfate and androstenedione were measured directly by radioimmunoassay with an iodine 125–DHEA sulfate kit (Diagnostic Products Corporation, Los Angeles, Calif.) and an ^{125}I-androstenedione kit (ICN Biomedicals Inc., Carson, Calif.), respectively. Serum testosterone, androsterone, and 3α-diol were measured by radioimmunoassay after extraction and separation by Celite column chromatography.[14] The non-sex hormone-binding globulin-bound testosterone was measured by ammonium sulfate precipitation of sex hormone-binding globulin as previously described.[15] The glucuronide and sulfate conjugates of 3α-diol and androsterone were measured either after β-glucuronidase hydrolysis of the glucuronides or solvolysis of the sulfates. Briefly, after removal of unconjugated steroids from serum by extraction with diethyl ether, the glucuronide conjugates were hydrolyzed at 37° C by addition of β-glucuronidase (type VIII, Sigma Chemical Co., St. Louis, Mo.) to the serum, which was first adjusted to pH 6.8. After 16 hours of hydrolysis, unconjugated hormones were extracted with diethyl ether, and 3α-diol and androsterone were separated by Celite column chromatography, and the specific fractions were measured by radioimmunoassay. The method for hydrolysis of sulfates also involved previous extraction of unconjugated steroids with diethyl ether, and preceded addition of sodium chloride to the serum and extraction with ethyl acetate. Acid solvolysis was performed at 37° C for 2 hours after adjustment of the pH of the ethyl acetate to

Table II. Correlations between serum androsterone glucuronide and androstanediol glucuronide (3α-diol glucuronide) and androgen precursors* with linear regression analysis

	r Value	*p Value*
Hirsute women		
Androsterone glucuronide versus DHEA sulfate	0.880	<0.004
3α-diol glucuronide versus DHEA sulfate	0.672	<0.10
Androsterone glucuronide versus androstenedione	0.597	<0.12
3α-diol glucuronide versus androstenedione	0.846	<0.02
Androsterone glucuronide versus testosterone	0.142	<0.74
3α-diol glucuronide versus testosterone	0.030	<0.94
Nonhirsute women

3α-diol glucuronide versus DHEA sulfate	0.709	<0.11
Androsterone glucuronide versus androstenedione	0.231	<0.77
3α-diol glucuronide versus androstenedione	0.870	<0.13
Androsterone glucuronide versus testosterone	0.822	<0.04
3α-diol glucuronide versus testosterone	0.763	<0.08

*Androstenedione and testosterone.

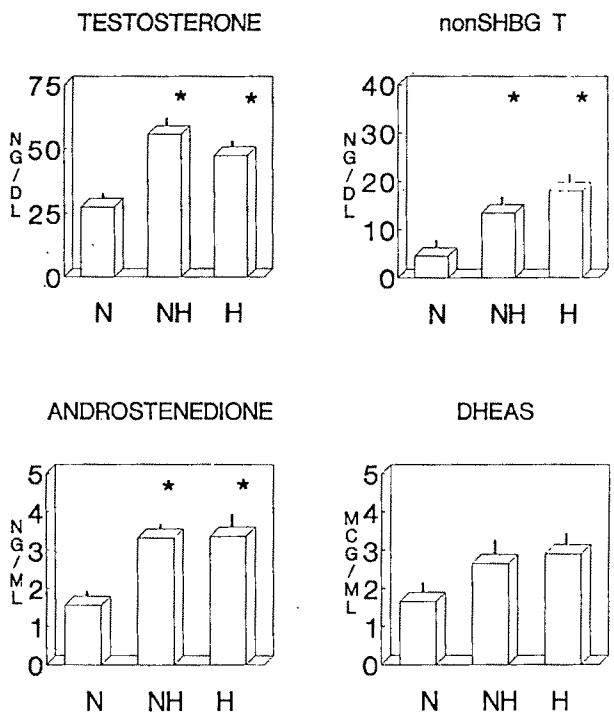

Fig. 1. Mean (± SE) of serum testosterone, androstenedione, and DHEA sulfate in normal women (*N*, $n = 8$), nonhirsute women with polycystic ovarian syndrome (*NH*, $n = 10$), and hirsute women (*H*, $n = 10$). *Significance of difference of *NH* and *H* compared with normal women was $p < 0.01$.

l with a modification of the solvolysis procedure of Aso.[16] After neutralizing the serum with sodium carbonate, the unconjugated steroids were extracted with diethyl ether, separated by Celite column chromatography, and measured by radioimmunoassay. ^{3}H-androsterone and ^{3}H-3α-diol were added to the serum immediately after hydrolysis of the sulfates and glucuronides to allow for monitoring of procedural losses. It was estimated that the percentages of hydrolysis of the sulfates and glucuronides were 67 and 100, respectively.

Analysis of data. The sulfate conjugate values were corrected to reflect 100% solvolysis. All statistics were performed with the Statgraphics statistical package (Statistical Graphics Corporation, Rockville, Md.). The Mann-Whitney U test was used to compare values between different sample groups. Linear regression analysis was used to obtain correlations between groups.

Results

The heights, weights, and ages of normal women who served as controls, nonhirsute women with polycystic ovarian syndrome, and hirsute women are shown in Table I. There was no significant difference between groups for any category except in the Ferriman-Gallwey score ($p < 0.001$). The Ferriman-Gallwey score in hirsute women (18.3 ± 3.2) was significantly greater than that of both normal and nonhirsute women, (5.2 ± 1.4 and 7.2 ± 1.6, respectively; $p < 0.001$). There was no significant difference between the normal and nonhirsute groups.

When the common serum markers of ovarian and adrenal androgens were compared between patients and controls, total testosterone, non-sex hormone-binding globulin-bound testosterone, and androstenedione were significantly greater ($p < 0.001$) compared with controls in both nonhirsute and hirsute patients (Fig. 1). Serum DHEA sulfate was higher in nonhirsute and hirsute patients, as compared with the control group, but this difference was not significant. None of these serum androgens were significantly different between nonhirsute and hirsute patients. Also, there were no significant differences among the three groups with respect to serum 3α-diol or androsterone levels (Fig. 2).

Levels of the sulfate conjugates in all groups were higher than the corresponding glucuronide levels. The sulfates were 9.3 times higher in the case of 3α-diol, and 22.1 times higher for androsterone. In the normal and nonhirsute groups, the conjugates of 3α-diol and androsterone were similar. However, hirsute women had values significantly greater than those of nonhirsute women, not only for serum 3α-diol glucuronide (5.5 ± 0.8 versus 4.2 ± 0.5 ng/ml), but also for 3α-diol sulfate (53.5 ± 9.6 versus 31.7 ± 6.3 ng/ml), and serum androsterone glucuronide (100.3 ± 28.0 versus 42.9 ± 4.1 ng/ml) ($p < 0.05$, Fig. 2). When the conjugate levels were compared between nonhirsute and hirsute women, serum 3α-diol glucuronide was increased by the smallest amount (32%), followed by androsterone sulfate (38%), 3α-diol sulfate (69%), and androsterone glucuronide, which exhibited the largest increase (134%).

The hirsute and nonhirsute groups showed different types of correlations between the conjugates and precursor steroids (Table II). In hirsute, but not in nonhirsute women, serum androsterone glucuronide correlated with DHEA sulfate ($r = 0.880$, $p < 0.004$) and 3α-diol glucuronide with androstenedione ($r = 0.846$, $p < 0.02$). For androsterone glucuronide and 3α-diol glucuronide there was no correlation with testosterone in hirsute women, but there was a correlation between androsterone glucuronide and testosterone in nonhirsute women. In addition, serum 3α-diol sulfate correlated with androsterone sulfate ($r = 0.923$, $p < 0.03$), but 3α-diol glucuronide did not correlate with androsterone glucuronide ($r = 0.708$, $p < 0.12$).

Because androstenedione has been shown to be the most important precursor of peripherally derived androgens, we compared ratios of the C_{19} conjugates to

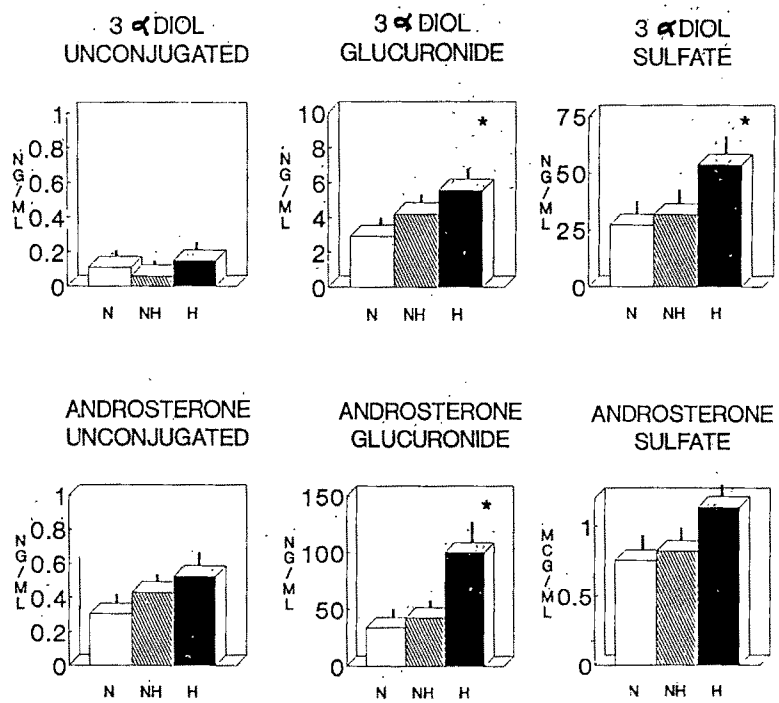

Fig. 2. Mean (± SE) of serum unconjugated 3α-diol and androsterone as well as their glucuronide and sulfate conjugates in normal women *(N)*, nonhirsute women with polycystic ovarian syndrome *(NH)*, and hirsute women *(H)*. *Significance of difference of *H* women compared with either *N* or *NH* women was $p < 0.05$.

Table III. The mean (±SE) of the ratios of serum androgen conjugates to androstenedione in nonhirsute women with polycystic ovarian syndrome and hirsute women

	Androsterone glucuronide/ androstenedione	*Androsterone sulfate/ androstenedione*	*3α-diol glucuronide/ androstenedione*	*3α-diol sulfate/ androstenedione*
Nonhirsute women with polycystic ovarian syndrome	13.1 ± 1.2	244.3 ± 41.9	1.29 ± 0.15	9.8 ± 2.1
Hirsute women	26.2 ± 4.7*	438.0 ± 163.3	2.03 ± 0.40	20.2 ± 4.1

*Between nonhirsute and hirsute women, only androsterone glucuronide/androstenedione is significant at $p < 0.02$.

serum androstenedione between nonhirsute and hirsute women (Table III). Changes in the ratio of androsterone glucuronide/androstenedione most clearly reflected differences between nonhirsute and hirsute women; androsterone glucuronide/androstenedione was 98% higher in hirsute women than in nonhirsute women. For 3α-diol glucuronide, 3α-diol glucuronide/androstenedione was only 57% higher in hirsute women.

Comment

Our finding of elevated C_{19} conjugate levels in hirsute patients confirms, at least for androsterone sulfate, previous data by others with the use of different methodology. Elevations in androsterone sulfate levels in hirsute women confirms the earlier work of Mauvais-Jarvis[17] for urinary androsterone sulfate and Conrad et al.[18] for plasma androsterone sulfate. Our data are novel in that we have measured in serum several androgen conjugates simultaneously and compared these measurements to one another and to precursor steroid levels.

In this study we compared serum 3α-diol and androsterone sulfate and glucuronide levels in hirsute patients who have equivalent circulating levels of non-sex hormone-binding globulin-bound and total testosterone, DHEA sulfate, and androstenedione. Our finding of an increase in these conjugates in only the hirsute group suggests that these androgens, like 3α-diol glucuronide, reflect peripheral androgen action. In contrast with differences seen in previous work,[3] neither unconjugated serum 3α-diol nor androsterone was different among the three groups. Because dihydrotestosterone was not found to be elevated in our previous

work and is not considered to be reflective of the hirsute state, we did not pursue measurements of dihydrotestosterone conjugates.

For all groups, the sulfate conjugates (3α-diol sulfate and androsterone sulfate) were approximately tenfold to twentyfold higher than the glucuronide conjugates (3α-diol glucuronide and androsterone glucuronide). Similarly, androsterone conjugates (androsterone glucuronide and androsterone sulfate) were approximately tenfold higher than their corresponding 3α-diol conjugates. In this study, we confirmed that serum 3α-diol glucuronide clearly differentiates between the nonhirsute and hirsute patients. However, the other androgen conjugates better differentiated the hirsute and nonhirsute groups. Androsterone glucuronide showed the largest increase and was found to best reflect the hirsute state.

In our previous in vitro studies in genital skin, we showed that androstenedione is the most important substrate for 5α-reductase activity and is an important precursor of 3α-diol glucuronide in women.[19] Only in hirsute patients did 3α-diol glucuronide correlate with androstenedione. When we compared androgen conjugates to possible precursor steroids with serum androstenedione as a model to further examine possible substrate use, we found that the conjugate that increased the most in hirsute women was androsterone glucuronide. The ratios of the conjugates to their principal substrate (androstenedione), presumably reflecting 5α-reductase activity, clearly demonstrated a difference between nonhirsute and hirsute women. In this regard, androsterone glucuronide was more reflective than 3α-diol glucuronide.

Our study does not address whether some of these conjugates, such as androsterone glucuronide, are produced directly by the skin, as has been shown for 3α-diol glucuronide. However, the differences in conjugate levels between two groups of very similar women with the exception of hirsutism implies that these other androgen conjugates also reflect peripheral androgen action. The sulfate conjugates of androsterone and 3α-diol were highly correlated, implying a possible androsterone sulfate to 3α-diol sulfate conversion. There was no correlation between the glucuronide conjugates of androsterone and 3α-diol, which supports Rittmaster's finding with the use of isomers of 3α-diol glucuronide, and suggests that there is no significant interconversion between 3α-diol glucuronide and androsterone glucuronide.[20] The fact that androsterone glucuronide is the conjugate most elevated in hirsute women, and that the androsterone glucuronide/androstenedione ratio was most reflective of the hirsute state, gives further support to an alteration in the pathway of peripheral androgen metabolism in hirsutism. The elevation of androsterone conjugates implies perhaps that androsterone glucuronide and androsterone sulfate production by means of androstenedione and androsterone in hirsute women is at least as important, if not more important than the production of 3α-diol glucuronide and 3α-diol sulfate by means of androstenedione and dihydrotestosterone.

In conclusion, we have found that several C_{19} sulfate and glucuronide conjugates reflect peripheral androgen action in hirsute patients, and that androsterone glucuronide may be more valuble than 3α-diol glucuronide in this regard, particularly when androstenedione is elevated. There appears to be a close correlation between these androgen conjugates and both serum androstenedione and DHEA sulfate. Further examination of the interconversions between androsterone sulfate and 3α-diol sulfate, as well as efforts to determine the source of these androgen sulfate and glucuronide conjugates, will allow us to further understand the altered androgen metabolism of hirsute patients.

In vivo administration of allopurinol affects ovulation and early embryonic development in rabbits

Toyohiko Miyazaki, MD, PhD, Tsung-Cheng Kuo, MD, PhD, Arunasalam M. Dharmarajan, PhD, Susan J. Atlas, PhD, and Edward E. Wallach, MD

Baltimore, Maryland

The potential role of the hypoxanthine–xanthine oxidase system in human chorionic gonadotropin–induced ovulation, nuclear maturation, and preimplantation development was investigated in the rabbit by use of the xanthine oxidase inhibitor allopurinol. Allopurinol (50 mg/kg) or vehicle was injected, followed by human chorionic gonadotropin (100 IU). Administration of inhibitor or vehicle was repeated 3 hours later. Ovaries and ovulated ova were inspected 12 or 24 hours after human chorionic gonadotropin administration for follicle rupture, cumulus dispersal, and nuclear maturation. Ova were inseminated in vitro and assessed for development to the blastocyst stage, up to 96 hours after insemination. Allopurinol significantly reduced ovulatory efficiency, defined as the percent of large follicles that ovulate, and decreased the percent of ova with cumulus dispersal. Allopurinol significantly inhibited morula and blastocyst formation. These data suggest that the xanthine oxidase system may play a role in ovulation and early embryonic development. (Am J Obstet Gynecol 1989;161:1709-14.)

Key words: Allopurinol, ovulation, early embryonic development, oocyte maturation, free radicals

We have recently reported that oxygen free radicals play a role in ovulation in the in vitro perfused rabbit ovary (Miyazaki T, et al. The role of oxygen free radicals in ovulation in the in vitro perfused rabbit ovary [Abstract 007]. Presented at the Forty-fourth Annual Meeting of the American Fertility Society, Atlanta, Ga., October 10-13, 1988). The (hypo)xanthine-xanthine oxidase system is one of the physiologic mechanisms of free radical generation. This system generates superoxide anion radicals during the oxidation of hypoxanthine and xanthine to uric acid. Although the source of oxygen free radicals involved in the process of ovulation is not known, hypoxanthine has been found in the follicular fluid of several species and is reported to inhibit oocyte nuclear maturation.[1-3] Xanthine oxidase has been found in endothelial cells of many organs,[4, 5] and the metabolism of hypoxanthine by cumulus-oocyte complexes[3] suggests the presence of this superoxide-generating enzyme system within the follicle.

Allopurinol inhibits the enzyme xanthine oxidase, which results in maintenance of the substrates hypo-

xanthine and xanthine and in inhibition of superoxide anion radical generation.[5,6]

The objective of this study was to determine, through the use of allopurinol, whether the hypoxanthine-xanthine oxidase system plays a role in ovulation and oocyte maturation in the rabbit. In order to address this question, we assessed the effects of administering allopurinol, together with an ovulation-inducing dose of human chorionic gonadotropin (hCG), on follicle rupture, nuclear maturation, cumulus dispersal, and early embryonic development.

Material and methods

Sexually mature New Zealand White female ($n = 32$) and male ($n = 6$) rabbits were used in all experiments. Female rabbits weighing 3.5 to 4.5 kg were isolated for a minimum of 3 weeks before the experimental procedure. Epididymal spermatozoa were collected from male rabbits of proved fertility. Animals were caged individually and fed water and a diet of Purina Rabbit Chow (Purina Mill, Richmond, Ind.) as desired under conditions of controlled light and temperature. All studies were performed in accordance with the *Guidelines for the Use of Experimental Animals at the Johns Hopkins University*. Female rabbits (treated and control) were given hCG (100 IU; Organon Inc., West Orange, N.J.) to induce ovulation via a marginal ear vein. The treated group also received allopurinol (50 mg/kg; Sigma Chemical Co., St. Louis) simultaneously via a marginal ear vein, while the control group received an equal volume of vehicle alone. The allopurinol solution was prepared according to the methods of Baker et al.[7] A second dose of allopurinol (50 mg/kg) or vehicle was administered 3 hours later. This dose of allopurinol was selected on the basis of its effectiveness in inhibiting free radical generation via xanthine oxidase in vivo[7,8] and was within the effective dose response range observed in vitro.[9]

Experiment 1. Eleven female rabbits (control, $n = 4$; allopurinol, $n = 7$) were put to death with an intravenous overdose of pentobarbital sodium 24 hours after administration of hCG and the initial dose of allopurinol or vehicle, and the ovary and oviduct were removed. Ovaries were examined for number of unruptured follicles and corpora lutea, and ovulated ova were recovered from the oviduct by injection of Brackett's defined medium[10] into the oviduct adjacent to the tubouterine junction. Ova were assessed for both the stage of nuclear maturation and the degree of attachment of cumulus cells by phase-contrast microscopy. The ovum maturity was expressed as the percentage of ova achieving germinal vesicle breakdown. Cumulus dispersal was expressed as the percentage of retrieved ova with less than one layer of cumulus cells. Ovulatory efficiency, defined as the percent of large follicles (≥1.5 mm) that proceed to rupture, also was calculated.

Experiment 2. Twenty-one female rabbits (control, $n = 11$, allopurinol, $n = 10$) were used. Animals were anesthetized with 32 mg/kg pentobarbital sodium, and ovaries and oviducts were removed 12 hours after administration of hCG and the initial dose of allopurinol or vehicle. Ovaries were examined for number of unruptured follicles and corpora lutea, and ovulatory efficiency was calculated as described in experiment 1. Cumulus-oocyte complexes were retrieved by flushing oviducts with Brackett's medium and were then fertilized in vitro.

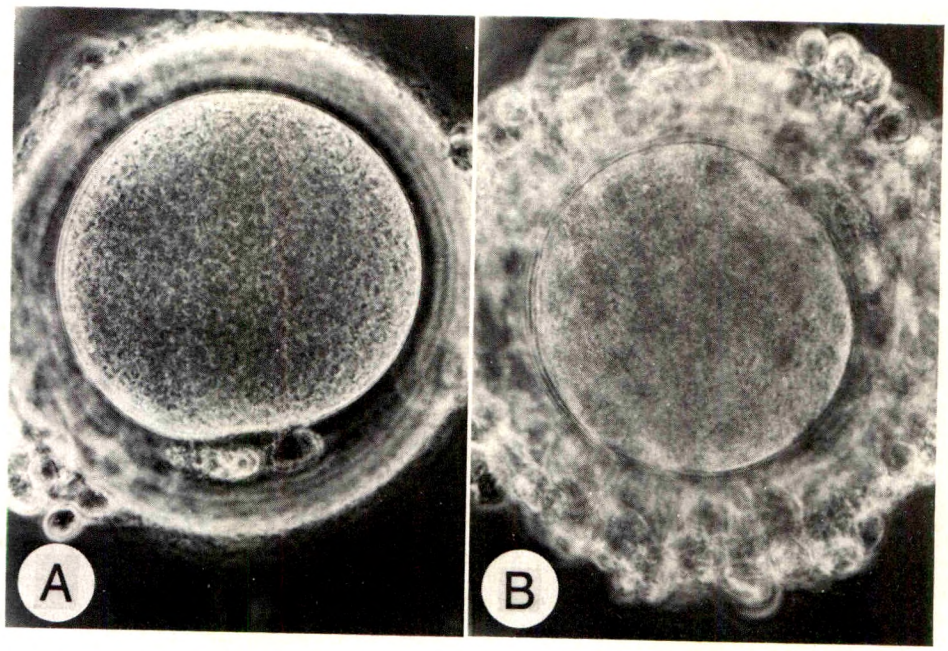

Fig. 3. Ovulated ova retrieved from oviducts 24 hours after hCG administration. **A,** Control. Cumulus cells dispersed (less than one layer). (Original magnification ×500.) **B,** Treatment with allopurinol. Ovum surrounded by cumulus cells. (Original magnification ×500.)

In vitro fertilization. The male rabbit was anesthetized with pentobarbital sodium, the scrotum was incised, and the epididymis with attached vas deferens was removed from the testis. Epididymal spermatozoa were collected as previously described.[11] Washed sperm were resuspended in 1.0 ml of Brackett's medium to yield 1 to 2 × 10^6 spermatozoa per milliliter and preincubated for 10 hours with 5% carbon dioxide in air at 37° C and 100% humidity. Only sperm suspensions with good motility were used for insemination.

Retrieved cumulus-surrounded oocytes were washed three times in Brackett's medium and inseminated with preincubated sperm. Twelve hours later inseminated ova were transferred to Ham's F10 medium (Gibco Laboratories, Grand Island, N.Y.) with 20% heat-inactivated fetal calf serum (Gibco Laboratories). The inseminated ova were examined by phase-contrast microscopy daily for 4 days after insemination, and their developmental stage was assessed. Cleavage rate, defined as the percentage of inseminated ova containing two or more cells, was determined 36 hours after insemination. Sixty hours after insemination, morula formation rate, defined as the percentage of inseminated ova that had proceeded to morula or blastocyst stage, was determined. Ninety-six hours after insemination, morula formation rate and blastocyst formation rate, defined as the percentage of inseminatd ova that had proceeded to blastocyst stage, were determined. Degeneration rate, defined as the percentage of inseminated ova that showed evidence of degeneration (vacuolation, cytolysis, necrosis, changes in the shape of early embryo, and fragmentation), was calculated at each time point.

Statistical analysis. The χ^2 method was used to assess ovulatory efficiency, percent of ova with dispersed cumulus, percent germinal vesicle breakdown, percent degeneration, and developmental stage. A probability of <0.05 was considered to be significant.

Results

Experiment 1. Twenty-four hours after hCG administration, 38 ruptured follicles were observed in 8 control ovaries and 49 ruptured follicles were seen in 14 allopurinol-treated ovaries. Ovulatory efficiency was lower in the treated group (59.0%) than in control (73.1%), but this difference was not statistically significant (Fig. 1). Thirty-five ovulated ova were recovered from controls and 41 from the treated group. No significant difference was noted in percentage of ova achieving germinal vesicle breakdown (control, 94.3%; allopurinol, 92.7%; Fig. 2). Allopurinol significantly inhibited cumulus dispersal (Fig. 3, *A* and *B*) and reduced the percentage of cumulus dispersal from 71.4% to 14.6% ($p < 0.001$; Fig. 2).

Experiment 2. Twelve hours after hCG administration, 114 ruptured follicles were recorded in 22 control ovaries and 96 ruptured follicles in 20 allopurinol-treated ovaries. Allopurinol significantly reduced ovulatory efficiency ($p < 0.001$) from 88.4% to 58.9% (Fig. 1). Totals of 68 and 61 ovulated ova were recovered from control and treated groups, respectively, and used for in vitro fertilization. At this early stage both control

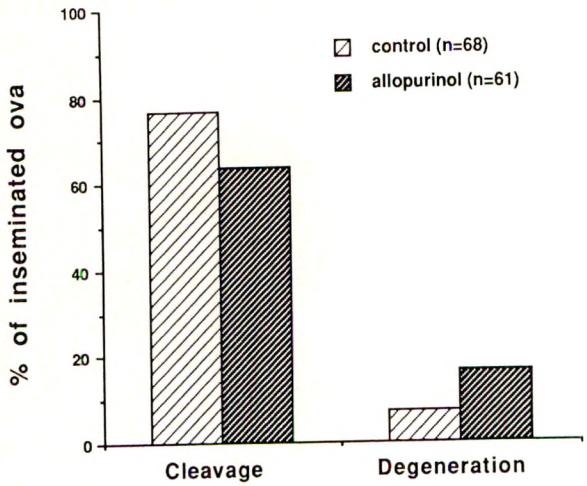

Fig. 4. Cleavage rate (percentage of inseminated ova containing two or more cells) and degeneration rate of ova observed 36 hours after insemination.

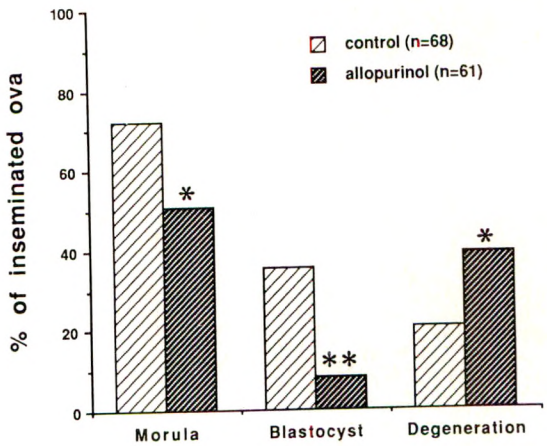

Fig. 6. Morula and blastocyst formation rate (percentage of inseminated ova proceeding to blastocyst stage) and degeneration rate observed 96 hours after insemination. *Asterisk*, $p < 0.025$, compared with control. *Double asterisks*, $p < 0.005$, compared with control.

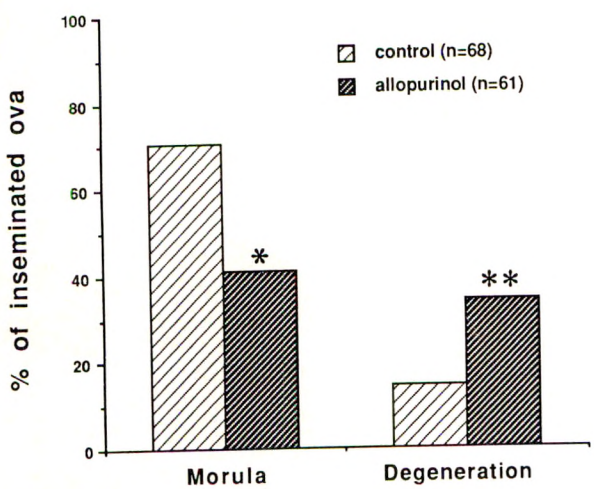

Fig. 5. Morula formation rate (percentage of inseminated ova proceeding to morula or blastocyst stage) and degeneration rate observed 60 hours after insemination. *Asterisk*, $p < 0.05$, compared with control. *Double asterisks*, $p < 0.01$, compared with control.

and treated ova were still surrounded by cumulus cells. Thirty-six hours after insemination, cleavage rate was lower in the treated group (63.9%) than in the control group (76.5%) and degeneration rate was higher (treated, 16.4%; control, 7.4%), but these differences were not statistically significant (Fig. 4). Morula formation rate 60 hours after insemination was significantly reduced ($p = 0.005$) by treatment with allopurinol (41.0%) when compared with the controls (70.6%; Fig. 5). Allopurinol significantly increased ($p < 0.01$) degeneration rate 60 hours after insemination from 14.7% to 34.4% (Fig. 5). Ninety-six hours after insemination, allopurinol significantly reduced morula formation rate from 72.1% to 50.8% ($p < 0.025$) and blastocyst formation rate from 35.3% to 8.2% ($p < 0.005$; Fig. 6). Furthermore, degeneration rate was significantly increased ($p < 0.025$) by treatment with allopurinol (39.3%) as compared with the control group (20.6%; Fig. 6).

Comment

Many factors are involved in ovulation, oocyte maturation, and early embryonic development. Recently, we demonstrated that oxygen free radicals play a role in the process of ovulation in the in vitro perfused rabbit ovary. Since this ovarian perfusion technique is performed with synthetic medium in the absence of blood cells, circulating neutrophils could not have been the source of free radical generation during in vitro ovulation. The possible sources of free radical generation include mitochondrial, endoplasmic reticular, and nuclear membrane electron transport systems. Oxidant enzymes such as cytochrome P_{450}, xanthine oxidase, and lipoxygenase, and the nicotinamide adenine dinucleotide phosphate, reduced form, oxidase of phagocytic cells also are involved in the production of oxygen free radicals.[12, 13] High concentrations of hypoxanthine, a substrate of xanthine oxidase, have been found in both pig and mouse follicular fluid,[1, 2] and endothelial cells are a rich source of xanthine oxidase.[4, 5] The apical follicular region contains evidence of ischemia in hCG-induced ovulation in the rabbit,[14] and hypoxanthine is produced via breakdown of adenosine triphosphate during ischemia.[15] In addition, hypoxanthine is reported to be metabolized within cumulus-oocyte complexes.[3] These observations support the possibility that the superoxide-generating hypoxanthine–xanthine

oxidase system could play a role in ovulation and oocyte maturation.

Allopurinol (4-hydroxypyrazolo[3,4-*d*]pyrimidine) prevents generation of oxygen radicals and maintains the concentration of hypoxanthine by inhibiting xanthine oxidase. In these experiments allopurinol inhibited ovulation, cumulus dispersal, and early embryonic development in rabbits. These effects may have been due either to a decrease in free radical generation or to a direct toxic effect on the ovary. Oxygen free radicals have been found to exert a direct effect on cell membrane, connective tissue, and hyaluronic acid degradation.[12, 16] Hyaluronic acid is a major component of the intercellular matrix that connects cumulus cells to one another and to the oocyte. Inhibition of cumulus dispersal by allopurinol in this study suggests that free radicals generated during follicle rupture degrade hyaluronic acid and result in cumulus dispersal. Allopurinol most likely acts to prevent generation of the superoxide anion radical by inhibiting xanthine oxidase. Since both allopurinol and oxypurinol (4,6-dihydroxypyrazolo[3,4-*d*]pyrimidine), a major metabolite of allopurinol and xanthine oxidase inhibitor,[6] are also free radical scavengers,[9, 17] allopurinol's action on the ovary may be via inhibition of xanthine oxidase and/or scavenging free radicals.

The oocyte and cumulus cells are metabolically coupled through gap junctions[18, 19] that are thought to be involved in the control of oocyte maturation.[20] Meiotic resumption in the oocyte has been thought to be related to either a quantitative or a qualitative change in the signal from cumulus cells to the oocyte[20-22] or to termination of gap junctions, thus interrupting the transfer of substances that inhibit oocyte maturation.[23, 24] That allopurinol treatment did not affect nuclear maturation in ovulated ova in this experiment, despite the maintenance of cumulus-oocyte contacts, supports the hypothesis that a change in the cumulus cell-oocyte signal, rather than termination of gap junctions, is responsible for resumption of oocyte maturation.

Hypoxanthine is known to be a potent inhibitor of oocyte nuclear maturation.[1-3] If a hypoxanthine–xanthine oxidase system exists within the ovary, allopurinol treatment, which maintains the concentration of hypoxanthine, would be expected to inhibit oocyte nuclear maturation. However, allopurinol did not affect the percentage of ovulated ova achieving germinal vesicle breakdown 24 hours after hCG administration. Since nuclear maturation occurs once oocytes are removed from their follicles,[25, 26] in these experiments allopurinol may have exerted its inhibitory influence on oocytes while still contained within the follicles. However, once follicle rupture occurred, approximately 12 hours after hCG administration, the released oocyte would have been liberated from this inhibitory influence. It has been reported that gonadotropins can overcome the inhibitory influence of hypoxanthine on oocyte nuclear maturation.[27]

Although allopurinol did not significantly affect cleavage and degeneration rates, it was associated with a significant reduction of morula and blastocyst formation and increased degeneration of fertilized ova, when assessed 60 and 96 hours after insemination, respectively. These results suggest that allopurinol affects cytoplasmic maturation of oocytes either through a direct cytotoxic effect or as a result of maintaining high concentrations of hypoxanthine. Our data are consistent with previous findings that hypoxanthine inhibits early embryonic development in the mouse.[28]

In conclusion, allopurinol affects hCG-induced ovulation and suppresses cytoplasmic maturation of ovulated ova in this rabbit model. These data suggest that the (hypo)xanthine–xanthine oxidase system may play a role in the periovulatory interval.

We wish to thank Ms. Fran Karas for her assistance in preparation of the manuscript.

Platelet activating factor is rapidly gaining acceptance as a potent mediator in many reproductive processes. This study presents data that indicate a direct role of platelet activating factor in fertilization. Plate et activating factor was shown to significantly increase ($p < 0.001$) the fertilization rate of mouse oocytes in vitro. Furthermore, CV3988, an inhibitor of platelet activating factor, was noted to significantly decrease in vitro fertilization rates at 10^{-5} and 10^{-4} mol/L concentrations. (Am J Obstet Gynecol 1989;161:1714-7.)

Key words: Platelet activating factor, in vitro fertilization

Platelet activating factor (PAF) [1-0-alkyl-2-acetyl-*sn*-glyceryo-3-phosphocholine (AGEPC)] is a potent phospholipid with a diverse spectrum of biologic activities.[1]

Recently, Abisogun et al.[2] noted that ovulation was inhibited in human chorionic gonadotropin (hCG)–primed rats with platelet activating factor receptor antagonist BN 52021. This inhibition of ovulation was overcome by the administration of additional platelet activating factor.[2] Our laboratory reported the presence of platelet activating factor–like activity in human spermatozoa.[3] Platelet activating factor was also noted to increase the motility of human spermatozoa up to 53%.[4] Human and mouse preimplantation embryos have been reported to produce and secrete platelet activating factor into the culture medium in vitro.[5, 6] Embryo-derived platelet activating factor is associated with a mild thrombocytopenia during the first week of preg-

nancy in mice.[7] Thrombocytopenia has also been observed in women who receive fertilized human embryos after in vitro fertilization–embryo transfer.[8] There is also evidence for the role of platelet activating factor in early pregnancy in humans, mice, rats, and rabbits.[9-12] This study reports the involvement of platelet activating factor in mouse oocyte fertilization in vitro.

Material and methods

Superovulation and oocyte recovery. Six- to 10-week-old virgin $B_6D_2F_1/J$ mice were maintained on a cyclic 14-hour light/10-hour-dark schedule and were superovulated with intraperitoneal injections of 5 IU pregnant mare's serum gonadotropin followed by 10 IU hCG 48 hours later. Mice were killed by cervical dislocation 14 to 16 hours after hCG administration and ovulated oocytes were recovered from excised oviducts by tearing the dilated ampulla with a 30-gauge needle.

Sperm capacitation and treatment with platelet activating factor inhibitor CV3988 or platelet activating factor. Spermatozoa were collected from the cauda epididymides of proven fertile male mice and allowed to capacitate for 90 minutes at 37° C in a 5% carbon dioxide atmosphere in Ham's F-10 medium supplemented with 30 mg/ml bovine serum albumin. After 90 minutes 1×10^5 spermatozoa were transferred to 1 ml of preequilibrated Ham's F-10 medium (3 mg/ml bovine serum albumin) containing varying concentrations (1×10^{-7} through 1×10^{-4} mol/L) of CV3988 [*rac*-3-(*N*-*n*-octadecylcarbomyloxy)-2-methoxypropyl-2-thiazolyoethyl phosphate], a structural analog and inhibitor of platelet activating factor, or 1×10^{-7} mol/L platelet activating factor and further incubated for 30 minutes before the addition of oocytes.

In vitro fertilization with CV3988-treated sperm. Oocyte-cumulus masses were randomly distributed to Falcon center well tissue culture dishes (Becton Dickinson, Lincoln Park, N.J.) that each contained CV3988-treated sperm. Six hours after insemination oocytes were examined for second polar body extrusion and pronuclei formation. Fertilized ova were transferred to 100 λ microdrops of fresh growth medium (Ham's F-10, 3 mg/ml bovine serum albumin) overlaid by equilibrated mineral oil. Eighteen hours later the fertilized oocytes were scored for two-cell formation. To evaluate for the possibility of parthenogenetic activation of oocytes caused by CV3988, oocytes ($n = 50$) were cultured for 6 hours in the presence of varying concentrations (10^{-7} through 10^{-4} mol/L) of the inhibitor CV3988 in the absence of spermatozoa.

In vitro fertilization with platelet activating factor–treated sperm. Oocyte-cumulus masses were transferred to platelet activating factor–treated spermatozoa or untreated (control) spermatozoa and coincubated for 5 minutes. After coincubation, the oocytes were treated with 300 U/ml of hyaluronidase for 2 to 5 minutes to remove remaining cumulus cells. The oocytes were washed three times with fresh culture medium before culture in 100 λ microdrops (Ham's F-10, 3 mg/ml bovine serum albumin) under equilibrated mineral oil. Six hours later oocytes were assessed for second polar body extrusion and pronuclear formation. Eighteen hours later the fertilized oocytes were scored for two-cell formation. To evaluate for the possibility of parthenogenetic activation of oocytes caused by platelet activating factor, oocytes ($n = 50$) were exposed to 1×10^{-7} mol/L platelet activating factor for 5 minutes in the absence of spermatozoa. Data were subjected to χ^2 analyses.

Results

In the experiment to evaluate the effects of CV3988 on in vitro fertilization of mouse oocytes, 90% fertilization (second polar body extrusion) and 84% two-cell formation rate were observed for control oocytes. In the presence of 10^{-7} and 10^{-6} mol/L CV3988 fertilization rates (88%, 90%) and two-cell formation rates (78%, 80%) were similar to controls. At higher concentrations of the inhibitor (10^{-5} mol/L and 10^{-4} mol/L) a statistically significant reduction in fertilization rates (70%, $p < 0.01$; 12%, $p < 0.001$) and two-cell formation (65%, $p < 0.01$; 8%, $p < 0.001$) were noted (Table I). CV3988 did not parthenogenetically activate oocytes at experimental concentrations.

At the 10^{-4} mol/L concentration of CV3988 10% to

*5-minute coincubation period.
†$p < 0.001$.

15% of the sperm were noted to be agglutinated with a mild reduction in motility.

Oocytes exposed to sperm cells for only 5 minutes resulted in a 29% fertilization rate with 26% of the oocytes developing to the two-cell stage. In the presence of platelet activating factor, 54% of the oocytes were fertilized ($p < 0.001$) with 50% developing to the two-cell stage ($p < 0.001$, Table II). Almost twice the number of spermatozoa were noted to be bound to the zona pellucida in the platelet activating factor group when compared with the non-PAF-treated control group. A 5-minute exposure of oocytes to platelet activating factor in the absence of sperm did not result in parthenogenetic activation of control oocytes.

Comment

The mouse in vitro fertilization system is highly efficient with fertilization rates of 85% to 90%. The two approaches used in the past to demonstrate stimulatory effects on the system are reduction of spermatozoa insemination concentration, or drastic reduction of sperm-egg coincubation time.[13, 14] Recently Pomeroy et al.[15] reported the enhancement of mouse ova in vitro fertilization by treatment of spermatozoa with caffeine. This effect was only demonstrable when the sperm-egg coincubation time was reduced to 15 minutes.[15] In this study we note a twofold increase in the in vitro fertilization and cleavage rate after a very short exposure of oocytes to spermatozoa in the presence of platelet activating factor and a decreased fertilization rate in the presence of platelet activating factor inhibitor CV3988. Harper et al.[16] reported a statistically significant reduction in the number of rabbit oocytes fertilized in vivo when does were artificially inseminated with 10^{-5} and 10^{-4} mol/L CV3988-treated ejaculated semen. In their study they observed moderate spermatozoa agglutination at 10^{-5} mol/L CV3988 with reduction in motility. After treatment with 10^{-4} mol/L CV3988 they noted severe sperm agglutination and a large decrease in motility but still observed a 77% fertilization rate.[16] In our study with mice we did not observe sperm agglutination at 10^{-5} mol/L CV3988 or a decrease in motility. After 10^{-4} mol/L CV3988 treatment we noted 10% to 15% spermatozoa agglutination, with a mild decrease in motility. The reduction in mouse oocyte fertilization in the presence of 10^{-4} mol/L CV3988 is unlikely to be a result of the mild sperm agglutination or reduced motility. These discrepancies with regard to agglutination and motility reduction may be species specific or a result of the presence of seminal fluid in the rabbit study. In a recent report Kuzan et al.[17] also noted a twofold to threefold increase in the fertilization rate of mouse oocytes in the presence of 1×10^{-8} mol/L platelet activating factor using low sperm concentration (1×10^3/ml). A significant reduction in the fertilization rate of oocytes in the presence of Webb 2086, a specific platelet activating factor receptor antagonist, was also observed by them.[17] These data indicate a direct role for platelet activating factor in the fertilization process. Platelet activating factor binding to target cells is followed by an increase in phosphatidylinositol-4,5-bisphosphate breakdown and the subsequent formation of diacylglycerol, an important second messenger.[18] Phosphatidylinositol-4,5-bisphosphate breakdown generates inositol-1,4,5-triphosphate, which is involved in calcium mobilization.[19] It is possible that calcium mobilization may promote the capacitation and acrosome reaction of spermatozoa. From this study we conclude that platelet activating factor, in addition to its involvement in ovulation, implantation, and parturition, may also have an important role in sperm-egg interaction during fertilization. Previous studies from our laboratory with regard to the presence of platelet activating factor in human spermatozoa and its enhancement of human sperm motility, in conjunction with the preliminary data noting increased fertilization rates of mouse and rabbit oocytes in the presence of platelet activating factor, are highly suggestive for the potential therapeutic value of platelet activating factor in the treatment of various forms of human infertility.[3, 4, 19] Further research will be directed to elucidate the involvement of platelet activating factor in gamete interaction from a mechanistic point of view.

Release of tumor necrosis factor-α by human peritoneal macrophages in vivo and in vitro

Jouko Halme, MD, PhD

Los Angeles, California, and Chapel Hill, North Carolina

Tumor necrosis factor is a product of activated monocytes, macrophages, and lymphocytes that exerts a variety of effects in the host. Its cytotoxicity toward gametes has been suggested as a mechanism of how activated macrophages may cause subfertility, inasmuch as detectable levels of tumor necrosis factor have been reported in the peritoneal fluid of infertile patients. To further examine this issue we measured tumor necrosis factor activity in peritoneal fluid and its release in vitro from monocytes or peritoneal macrophages of patients undergoing laparoscopy because of either tubal ligation or infertility. Cytolytic activity was determined with a bioassay with sensitized mouse fibrosarcoma cells as target. Significant tumor necrosis factor activity (>5 U/ml) was detected in 38% of the peritoneal fluid samples. A total of 43% of the peritoneal macrophage samples released significant tumor necrosis factor activity in vitro and all samples tested including peripheral monocytes released high levels of activity in the presence of bacterial endotoxin. The activity was released in vitro in a time-dependent manner. Thermal stability characteristics and neutralization with a specific antibody indicated that most of the activity in peritoneal fluid or released in vitro was that of tumor necrosis factor-α. Statistical analysis of tumor necrosis factor activity in peritoneal fluid in various diagnostic categories revealed a significantly elevated level in patients with endometriosis, as compared with fertile women. Endometriosis and pelvic adhesions were also significantly more likely to be associated with measurable levels of tumor necrosis factor activity released by peritoneal macrophages in vitro. Overall, because tumor necrosis factor-α levels were frequently detectable, it suggests that activation of peritoneal macrophages either by bacterial products or inflammatory conditions can occur in vivo. Moreover, these cells remain competent to release tumor necrosis factor in vitro. (Am J Obstet Gynecol 1989;161:1718-25.)

Key words: Tumor necrosis factor, monocytes, macrophages, endometriosis

Several constituents of the peritoneal fluid environment have been suggested to possess the potential to adversely (or positively) influence fertility.[1] Increased numbers of peritoneal macrophages and lymphocytes in addition to soluble enzymes and inflammation mediators have been documented in infertile patients with and without endometriosis.[2-5] Second, direct experiments have documented adverse effects on the viability of gametes or preimplantation embryos by peritoneal fluid and media from incubated (peritoneal) inflammatory cells.[6-9] Third, several purified products of activated macrophages or constituents of peritoneal fluid have been shown to exert adverse influence on gametes, fertilization, or embryonic development when tested in vivo.[10-12] Such products include interleukin-1, interleukin-2, interferon-gamma, and tumor necrosis factor (TNF-α).

TNF-α (cachectin) is a cytotoxic protein released by stimulated monocytes and macrophages that is an important component of the host inflammatory response.[13] This compound activates neutrophils,[14] alters the properties of vascular endothelial cells,[15] and regulates the metabolic activity of several tissues.[16] Because TNF-α is cytotoxic against some tumor cells[17] and has been shown to significantly reduce the motility of human sperm in vitro, it has been postulated to be a local mediator of subfertility.[11, 18] Indeed, TNF-α has been detected in peritoneal fluid in approximately one third of asymptomatic infertility patients undergoing laparoscopy, and significantly elevated levels were shown to be associated with advanced endometriosis.[19]

This article reports our studies on the presence of TNF-α in peritoneal fluid in vivo and production of this compound in vitro by peritoneal macrophages from healthy patients. We also examined factors that control secretion of TNF-α in vitro such as macrophage activation and adherence.

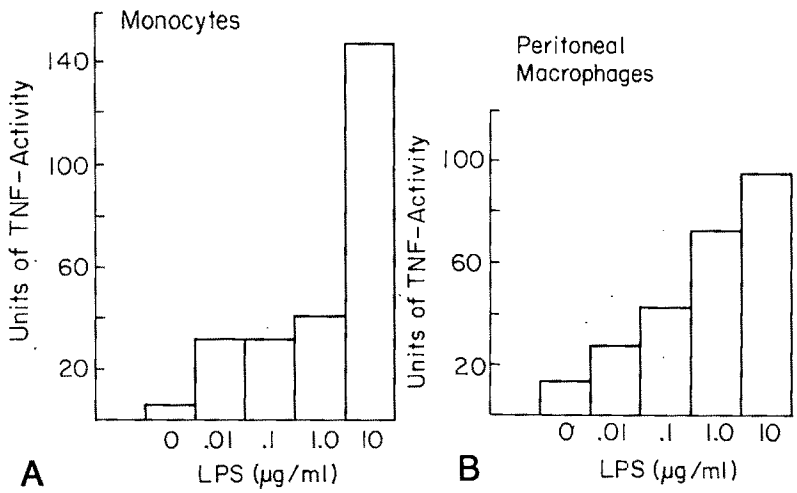

Fig. 1. Release of TNF by monocytes and peritoneal macrophages in response to bacterial endotoxin (lipopolysaccharide) in vitro. *Bars* represent means of triplicate measurements.

Material and methods

Patient population. Peritoneal fluid was obtained with prior consent from a total of 78 patients undergoing either diagnostic laparoscopy or elective laparoscopic tubal sterilization. The age range was from 23 to 42 years and the laparoscopic procedure was performed under general anesthesia between days 2 to 29 of the menstrual cycle. Of the 29 patients who had normal pelvic findings, 9 were undergoing tubal sterilization and the remainder has unexplained infertility. A total of 15 women had tubal occlusion or pelvic adhesions. There were 34 women who were found to have endometriosis, which according to the American Fertility Society classification was stages I to II in 23 women, stage III in 7 women, and stage IV in 4 women. All fertile women had regular menstrual cycles and were neither taking oral contraceptives nor using an intrauterine contraceptive device. The infertility patients had ≥1 year of primary or secondary infertility and had undergone a basic infertility evaluation before laparoscopy.

Collection and isolation of peritoneal cells and peripheral blood monocytes. Peritoneal fluid was collected at laparoscopy with a laparoscopic cannula from the cul-de-sac before any manipulative procedures or tubal insufflation. Peritoneal fluid samples were centrifuged to separate cells from the supernatant, which was stored in aliquots at −70° C until assayed for cytotoxic activity.[20] The macrophages were isolated by discontinuous Ficoll-Paque centrifugation gradient, as previously described.[20] Peripheral blood mononuclear cells were subjected to further purification by a stepwise Percoll gradient to obtain approximately a 90% pure monocyte population.

Monocyte-macrophage cultures. Peritoneal macrophages or monocytes (usually 500,000 cells) were plated in 1.5 cm diameter tissue culture wells (Costar, Cambridge, Mass.) in 1.0 ml of serum-free Dulbecco's modified Eagle's medium-high glucose (DMEM-H) (Irvine Scientific, Irvine, Calif.) for 1 hour. The media was then replaced with 1.5 ml of fresh DMEM-H and the macrophages were incubated as an adherent monolayer for 24 hours in 5% carbon dioxide at 37° C in a humidified incubator. The cells were incubated either in the absence or presence of 0.01 to 10 μg/ml of lipopolysaccharide from *Escherichia coli* 026:B6 (Sigma Chemical Company, St. Louis, Mo.). Cell viability was assessed at the end of incubation by microscopic visualization of cell morphology and adherence. After incubation the monocyte or macrophage culture medium was rendered cell free by centrifugation at 1500 rpm for 10 minutes to remove any cellular debris and then stored in aliquots at −70° C until assayed for cytotoxic activity.

To demonstrate the time dependency of TNF-α release by peritoneal macrophages, either 500,000 or 1 million cells per well were plated as described above and incubated in DMEM-H at 37° C. The medium was harvested and replaced with fresh medium after various time intervals of incubation. Other wells were incubated for the same intervals without replacement of the medium to ascertain that inactivation of cytolytic activity did not occur during prolonged incubation in assay medium.

In experiments to test the role of cell adherence on the release of cytotoxic activity, 500,000 isolated peritoneal macrophages were incubated in triplicate with DMEM-H in polypropylene tubes with continuous agitation to prevent adherence. After incubation for various intervals, the cells were centrifuged at 1500 rpm for 10 minutes and supernatants were assayed for cytotoxic activity.

Assay for TNF activity. A neutral red stain cytotox-

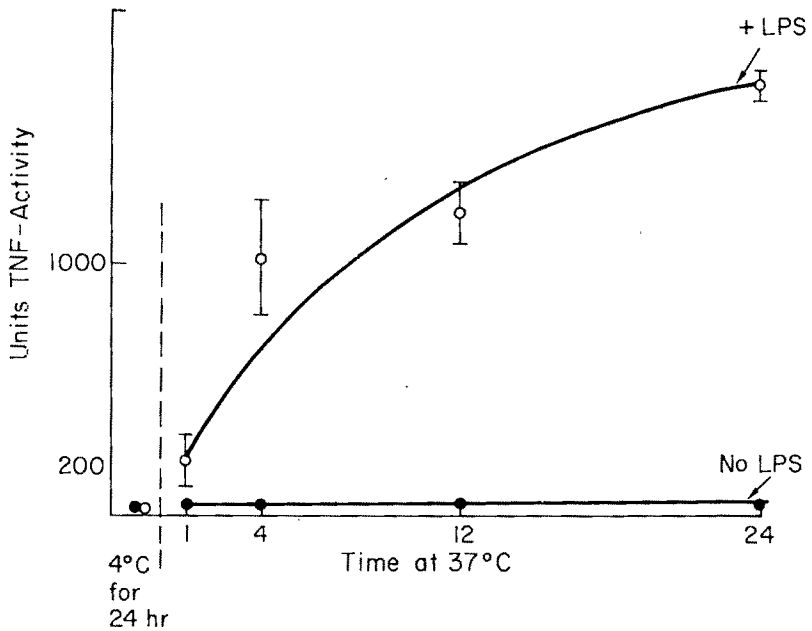

Fig. 2. Time-dependent release of TNF by peritoneal macrophages in vitro. In the example, lipopolysaccharide induces a significant release of activity. *Open* or *closed circles* denote means of triplicate wells. *Vertical lines* represent ±SE.

icity assay was used to measure the percent of surviving target cells.[21] In brief, target cells (WEHI-164 mouse fibrosarcoma cells were seeded in 96 well microwell plates at a concentration of 20,000 cells per well in 100 μl of growth medium (Roswell Park Memorial Institute with 10% calf serum) for 18 hours and incubated overnight at 37° C. To sensitize the cells, the medium was replaced with new medium that contained actinomycin D at a concentration of 1 μg/ml and incubation was continued for 2 hours. Medium was again replaced with fresh medium that contained different dilutions of macrophage culture medium or standard dilutions of recombinant TNF-α, which ranged from 0.1 to 3000 U/ml. The detection limit of the assay was 1 U/ml. The recombinant TNF used as a standard has a specific activity 2.39×10^7 U/mg. After an 18-hour incubation at 37° C, the medium with nonattached target cells was aspirated, and 100 μl of 0.006% neutral red stain in ethanol was added to each well. The plates were agitated and then read on a semiautomatic microplate reader with a test wavelength of 550 nm. Samples were considered to have significant activity if >5 U/ml.

Immunoinhibition. Samples of macrophage-conditioned media or peritoneal fluid were incubated at 22° C for 24 hours with neutralizing rabbit antihuman TNF-α (Olympus Corporation, Lake Success, N.Y.). The antibody contained a gamma globulin concentration of 1 μg/ml and neutralized recombinant TNF at a dilution of 1:100 to 1:100,000. As a control, nonimmune serum was preincubated with macrophage culture medium. Aliquots of macrophage culture medium were then assayed for cytotoxicity on WEHI-164 cells as described above.

Statistical analysis. Statistical evaluation of the data was performed with the unpaired Student *t* test or χ^2 analysis. Data are expressed as means ± SE.

Results

To determine whether TNF activity is produced in vitro, both peripheral monocytes and several samples of peritoneal macrophages were incubated in the presence and absence of lipopolysaccharide and the conditioned medium was assayed for TNF activity. Nonstimulated monocytes produced a negligible amount of TNF activity during a 24-hour incubation. The effect of lipopolysaccharide on production of tumor necrosis factor was dose-dependent with the maximal increase in the presence of 10 μg/ml (Fig. 1, *A*). Incubation of peritoneal macrophages resulted in release of TNF activity in some samples, but in others this was seen only after lipopolysaccharide stimulation. Incubation with increasing concentrations of lipopolysaccharide greatly augmented the production of TNF-α activity by most peritoneal macrophages tested (Fig. 1, *B*).

To establish whether cytolytic activity is produced in vitro in a time-dependent manner, representative samples of peritoneal macrophages were incubated for various intervals at 37° C in the presence or absence of

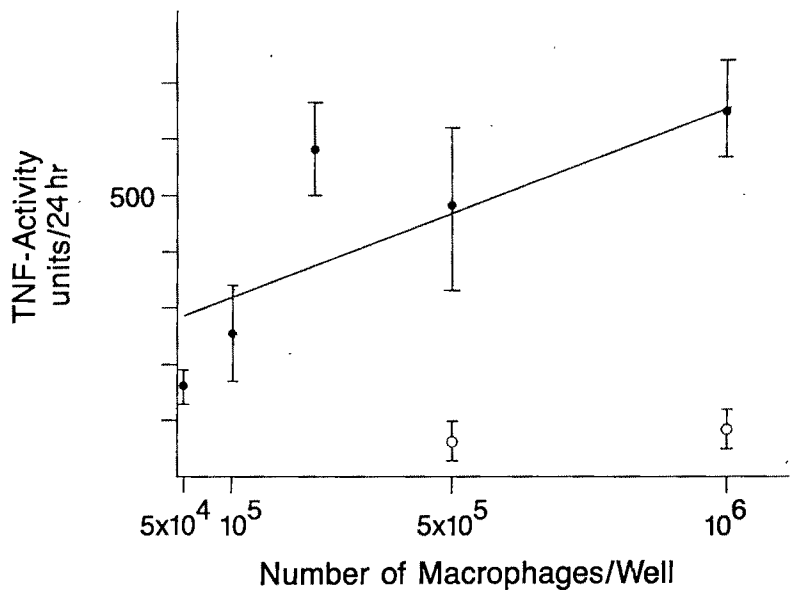

Fig. 3. Release of TNF by varying concentrations of peritoneal macrophages in vitro. *Open circles* denote means of triplicate wells not including lipopolysaccharide. *Closed circles* with 10 μg/ml of lipopolysaccharide. *Vertical lines* represent ±SE. *Regression line* is drawn to indicate relationship between number of incubated macrophages and stimulated release of TNF activity ($r = 0.817$).

lipopolysaccharide (Fig. 2). TNF-α activity was released during the 24-hour period in the absence of lipopolysaccharide. There was no detectable activity without lipopolysaccharide or if the incubation with lipopolysaccharide was carried out at 4° C.

In a similar fashion, increasing numbers of peritoneal macrophages were incubated for 24 hours at 37° C to determine the influence of cell concentration on the release of cytolytic activity (Fig. 3). There was a significant linear correlation between these parameters in the range of 5×10^4 to 1×10^6 cells per well when incubations were carried out in the presence of lipopolysaccharide.

To assess correlation between spontaneous (basal) and lipopolysaccharide–induced TNF-α release in vitro, samples of peritoneal macrophages from a variety of patients were incubated with and without lipopolysaccharide (Fig. 4). Great variability was seen in the level of basal activity and all samples released high levels of activity in response to lipopolysaccharide. However, there was no significant correlation between spontaneous release and induced release (correlation coefficient, $r = 0.2$).

Peritoneal macrophages are obtained and isolated as nonadherent cells. After incubation they become adherent to plastic. Because the adherence to plastic may induce an artificial stimulus, TNF-α production by adherent peritoneal cells was compared with cells that were incubated in identical conditions in a nonadherent state. There was no statistically significant difference in baseline TNF activity between adherent and nonadherent conditions. In some samples lipopolysaccharide–induced activity was significantly higher in adherent conditions, whereas in others this was not the case. However, there appeared to be no difference in heat resistance characteristics of TNF activity produced in either condition. The activity was resistant to heat at 56° C but was generally destroyed at temperatures of 80° C (data not shown). These heat stability characteristics observed in our macrophage culture medium supernatants are consistent with physical properties of human TNF previously published.[22]

To identify the cytolytic activity released by peritoneal macrophages in vitro as TNF activity, neutralization with a specific antibody to human TNF-α was performed. In these experiments, 96% of the cytolytic activity of recombinant human TNF-α was abolished by preincubation with antihuman TNF (data not shown). Furthermore, 82% of the activity in macrophage-conditioned medium and 76% of that in peritoneal fluid was inhibited by the same antibody. These results suggest that the cytolytic activity produced by peritoneal macrophages in vivo or in vitro is, for the most part, identical to human TNF-α.

The cytotoxic activity present in peritoneal fluid in patients in different diagnostic categories was compared, and is depicted in Fig. 5. Thirty of 78 peritoneal fluid samples had detectable activity, with the maximum cytotoxicity found in an infertile patient with pelvic adhesions. There was no significant difference between the mean levels of activity in fertile versus infertile patients ($p < 0.1$) or in the presence versus absence of

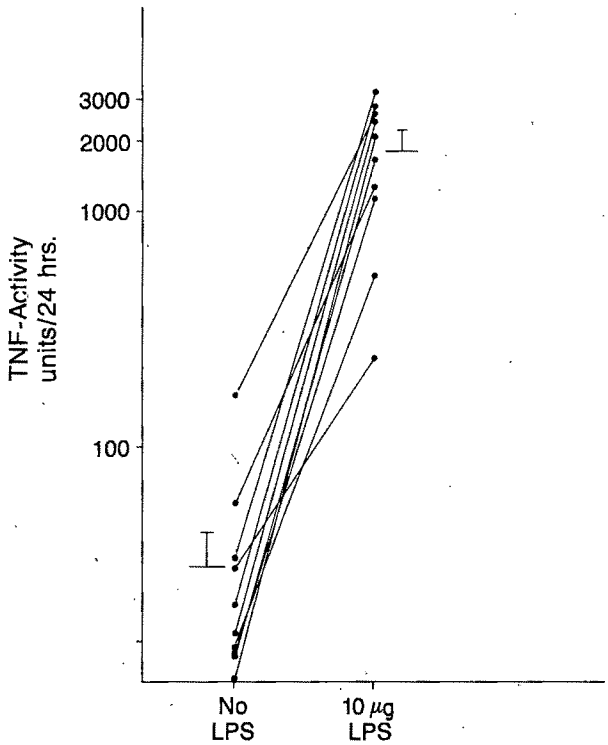

Fig. 4. Spontaneous and lipopolysaccharide–induced release of TNF in vitro by peritoneal macrophages from 10 patients. *Circles* represent means of duplicate wells. *Horizontal lines* are means + SE of group.

endometriosis ($p < 0.2$). However, the mean level of cytotoxic activity was higher in patients with endometriosis than that in fertile women ($p < 0.05$).

Significant TNF activity was also released by peritoneal macrophages in vitro (Fig. 6). Of 71 samples tested, 28 samples had measurable activity. Macrophages from 10 of 38 patients without endometriosis released TNF-α in vitro, as compared with 18 out of 33 patients with endometriosis. A statistical evaluation revealed significant differences in the frequency of detectable TNF release between fertile patients versus those with adhesions ($p < 0.025$), fertile patients versus those with endometriosis ($p < 0.01$), and between all patients with and those without endometriosis ($p < 0.025$). Thus it appears that the presence of cytolytic activity is quite common in peritoneal fluid and that peritoneal macrophages are often capable of releasing TNF activity even without appreciable in vitro exposure to lipopolysaccharide.

Comment

Tumor necrosis factor is a secretory protein that is increasingly recognized as an important biologic mediator.[13] It induces a variety of inflammatory responses in vivo in experimental animals, and recent reports have implicated TNF in critically ill cancer patients,[23] in endotoxin shock,[24] and in several inflammatory states.[25-27] Monocytes and macrophages, which are known to be also present in the peritoneal cavity have been shown to release TNF-α and may respond to a variety of inflammatory stimuli in vivo. The peritoneal cavity represents an environment in which several potentially inflammatory stimuli are often present. Retrograde menstruation, ovulation-associated rupture of follicular contents, and antigenic components of sperm, are all such stimuli. In addition, pelvic infections (both clinical and subclinical) may promote TNF-α production after macrophage activation by a variety of microorganisms.[28]

In this article, we have shown that human peritoneal macrophages from healthy women with or without evidence of some pelvic abnormality often are capable of producing a factor(s) cytotoxic for WEHI-164 cells, a TNF-sensitive cell line. This factor is stable when heated at 56° C for 30 minutes, but it is inactivated by heating at 86° C for 30 minutes. Furthermore, more than 80% of this activity is neutralized by monoclonal antihuman TNF-α antibody. These data suggest that this activity is identical to TNF-α.

Under normal circumstances little biologically active tumor necrosis factor is present within circulating peripheral monocytes, because the gene or genes that control its expression are repressed.[29] This was shown in this study by the nondetectable release of TNF in vitro by nonstimulated monocytes, whereas a dose-dependent TNF release was seen after exposure to lipopolysaccharide in vitro. In contrast, a large proportion of human peritoneal macrophages released TNF in vitro during the 24-hour incubation period without any additional stimulus such as lipopolysaccharide. This suggests that peritoneal macrophages have had exposure in vivo (in the peritoneal cavity) to priming effects of substances such as interleukin-1 or granulocyte-macrophage–colony stimulating factor and possibly bacterial endotoxin. The variable increase of TNF release by the peritoneal macrophages in vitro may reflect the amount and type of the previous in vivo stimulus.

The results of this study suggest that cell adherence is a factor that determines macrophage TNF release and sensitivity to lipopolysaccharide, although some peritoneal macrophages were capable of releasing TNF without a stimulus in nonadherent conditions. However, the control of TNF release by the peritoneal cells appears less dependent on adherence than that of production of macrophage-derived growth activity, which is entirely dependent on adherence.[30]

This study also demonstrates that cytolytic activity is detectable in a significant number of peritoneal fluid samples from patients who have little evidence of gross pelvic pathology. Most of this activity (at least in rep-

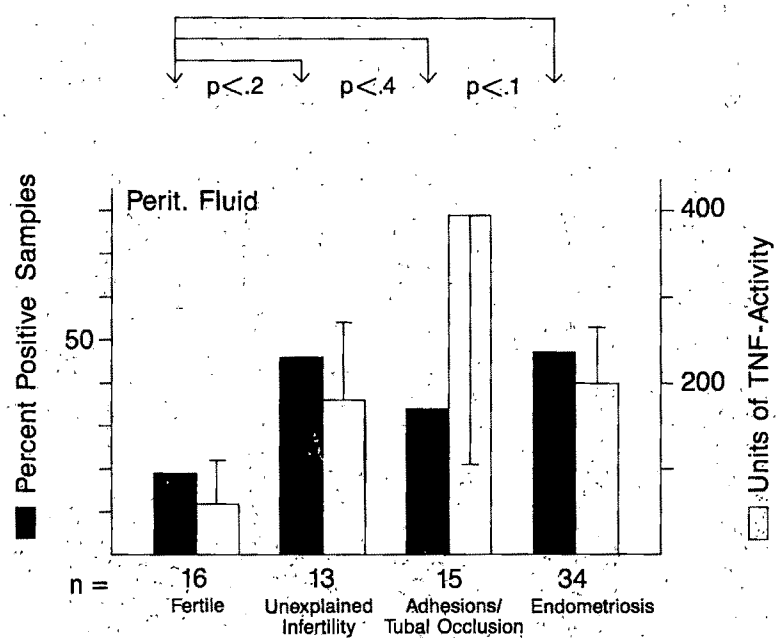

Fig. 5. Comparison of TNF activity in peritoneal fluid of 78 patients. *Open bars* denote means + SE. resentative samples) also is neutralized by monoclonal antibody against human TNF-α. The remaining cytolytic activity may represent TNF-β, a cytolytic factor with identical bioactivity but only 28% homology to TNF-α. This factor is secreted by T-lymphocytes in response to antigen challenge to viruses or lymphocyte mitogens.[31] Alternatively, the nonneutralizable cytolytic activity in macrophage media and peritoneal fluid may be some undetermined type of cytolytic factor that antigenically and structurally is unrelated to TNF. Several

studies have identified "cytotoxic activity" in peritoneal fluid with other types of assays for cytotoxicity such as embryo culture,[9, 12] sperm motility,[11] and antifertilization effects,[6] and it remains to be seen whether these activities are identical to the activity detected in this study. Although the WEHI cell line has been widely used in the detection of TNF-α activity, it is not specific for TNF-α.[21]

What is the biologic implication of the presence of significant cytolytic activity in the peritoneal environment? It is obvious that such activity could have potential adverse effects on reproductive processes such as fertilization and early development of the conceptus, but are there any advantages or benefits from such substances? Release of cytolytic activity by monocytes is considered to be part of their role in immunosurveillance and host response to bacteria and viruses. The peritoneal environment is often exposed to such microorganisms in view of the frequent presence of sperm in the peritoneal fluid. Sperm can serve as vectors for bacteria and viruses (this has been recently demonstrated even for human immunodeficiency virus).[32] This stimulus for peritoneal macrophages to release TNF-α is perhaps a vital component of the local host response while being detrimental to fertility.

Although there is great variability in the level of cytolytic activity in the peritoneal fluid and that released by peritoneal macrophages in vitro, these results are in agreement with a previous report that showed detectable levels of TNF in peritoneal fluid of 35% of 74 patients.[19] As a diagnostic group, only patients with moderate to severe endometriosis had significantly elevated levels in that study. Our results indicate a statistically significant increase in TNF levels released in vitro and in peritoneal fluid in patients with endometriosis. The small number of patients with moderate to severe endometriosis in this study does not allow adequate separate statistical evaluation for that group. Indeed, TNF activity measured either in vitro or in vivo does not appear specific for any particular diagnostic category although macrophages from patients with endometriosis are significantly more likely to release TNF in vitro. Furthermore, it is not clear whether the activity is dependent on levels of circulating or local hormonal factors. Another cytokine, interleukin-1, has been shown to have such a hormonal dependency.[33] Certainly further studies are warranted to determine which factors control the production of these cytokines and to elucidate their role and impact in the female pelvis and reproductive physiology.

The recombinant human TNF-α was a gift from Genentech, Co., San Francisco, Calif., and the WEHI-164 mouse fibrosarcoma cells were a gift from Susanne Becker, PhD. The excellent technical assistance of Eufemia Tsui is acknowledged.

Isolation and sequencing of a complementary deoxyribonucleic acid clone encoding human placental 17β-estradiol dehydrogenase: Identification of the putative cofactor binding site

Michael J. Gast, MD, PhD,[a] Harold F. Sims, BS,[c] Gary L. Murdock, PhD,[a] Peter M. Gast,[a] and Arnold W. Strauss, MD[b, c]

St. Louis, Missouri

17β-Estradiol dehydrogenase (EC 1.1.1.62) catalyzes the interconversion of estradiol and estrone in human term placenta. We have raised a specific polyclonal antibody to this abundant placental enzyme to study its role in late pregnancy events and its molecular biologic characteristics. In this work the 17β-estradiol dehydrogenase antibody was used to isolate and sequence a complementary deoxyribonucleic acid clone encoding about 98% of the amino acid sequence of the 17β-estradiol dehydrogenase molecule. This sequence verifies previous sequence data on the molecule's steroid binding site and also localizes a putative nicotinamide adenine dinucleotide binding region similar to that of many other pyridine nucleotide–dependent dehydrogenases. Isolation of the complementary deoxyribonucleic acid for 17β-estradiol dehydrogenase expands our knowledge of the structure-function relationships of the enzyme and is a major step in our understanding of its biologic function in pregnancy. (AM J OBSTET GYNECOL 1989;161:1726-31.)

Key words: Estradiol dehydrogenase, nicotinamide adenine dinucleotide binding, placenta

Abnormalities of labor, especially when associated with the problems of prematurity and postmaturity, represent the single most common cause of cerebral palsy and mental retardation in the U.S. today. Much of the recent work in this area centers on the critical role of estrogen in the uterine cellular mechanisms responsible for the initiation of labor.[1] The steroid converting enzyme 17β-estradiol dehydrogenase occupies a central position in that enzymatic cascade responsible for the generation of sex steroids in the woman. The enzyme catalyzes the terminal step of estrogen biosynthesis and is required for the interconversion of estradiol, the major female sex hormone, with its weaker, related steroid estrone. 17β-Estradiol dehydrogenase is found in uncommon abundance in the human placenta where its probable role is in the maintenance and regulation of appropriate estradiol levels in the mother and fetus as delivery approaches. Gaining an understanding of the enzyme's structure and mechanisms of action will be necessary to define and correct any steroid-related abnormalities in the process of labor initiation that lead either to preterm labor or to the failure to properly initiate the labor process (postmaturity).

Although it may be isolated in milligram quantities from the placenta, little is known about the physiologic role of 17β-estradiol dehydrogenase in the pregnancy process. Even less is known about the molecular biologic characteristics of the enzyme. We have long been interested in the study of this pyridine nucleotide–dependent enzyme, both because of its potential regulatory role in the dynamics of placental steroid metabolism and because of our interest in the structural and functional concomitants of the nicotinamide adenine dinucleotide– and nicotinamide adenine dinucleotide phosphate–dependent dehydrogenases. Steroid-converting enzymes in different tissues may share some degree of estradiol dehydrogenase–like activity,[2] leading to confusion about specificity and functional relationships within this class of enzymes. For that reason, reliance on activity measurement and gel chromatography have proved inadequate to probe intracellular sites of action and enzyme regulation. Thus recent advances in cloning and nucleic acid sequencing provide a realistic, currently available tool to evaluate periodic changes in the enzyme's levels and to produce the large quantitites of pure enzyme necessary for crystallographic and stereochemical study.

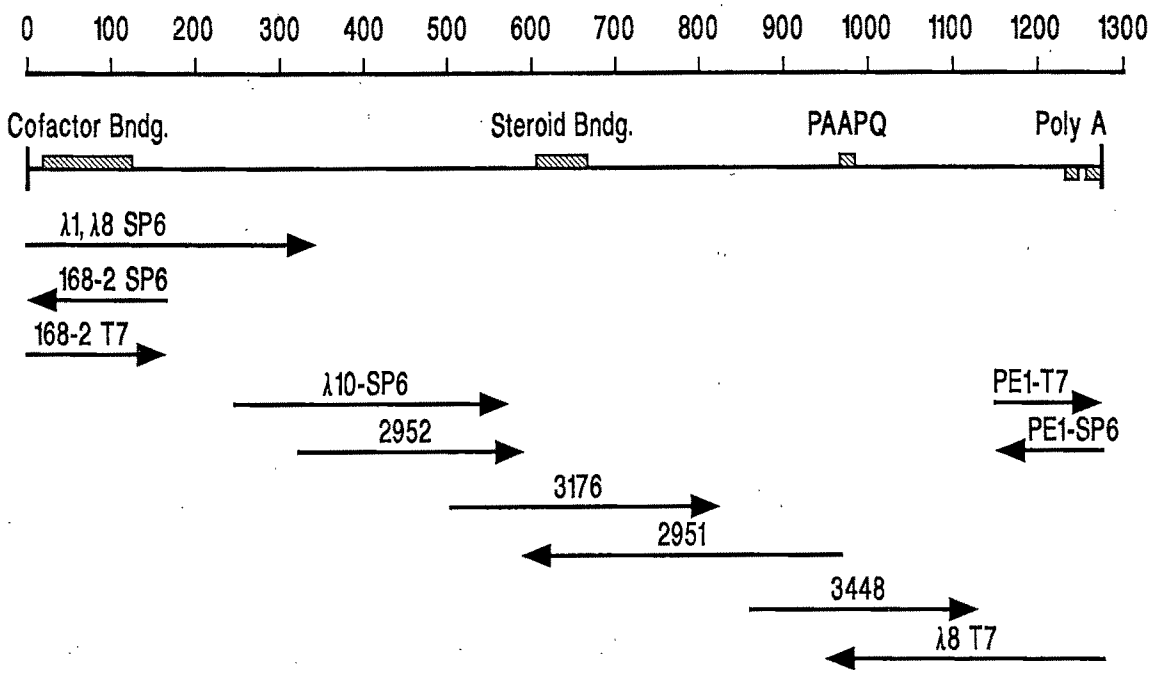

Fig. 1. Sequencing strategy for the 17β-estradiol dehydrogenase cDNA clone. Sequencing was carried out by a modified dideoxy-nucleotide technique[12] that used α[^{35}S]5′-deoxyadenosine triphosphate. Universal primers (SP6 and T7) and specific synthetic oligonucleotides were used as primers for the sequencing reactions. Multiple sequence overlaps were performed for all regions of the clone. The locations of the steroid and cofactor binding sites, as well as the polyadenylation site, may be seen. PAAPQ denotes the carboxyl terminal of the 17β-estradiol dehydrogenase coding sequence.

In the last several years we have extensively studied active site structure and function in the 17β-estradiol dehydrogenase molecule. We have characterized the biochemical and biophysical properties of the purified enzyme, established the kinetics of substrate binding and product inhibition, and probed the active site topography with affinity alkylating steroids and cofactors.[3-5] Collaboration between our department and Dr. Ralph Bradshaw (University of California, Irvine) has produced a putative amino acid sequence for the catalytic site and amino terminus of the 17β-estradiol dehydrogenase molecule.[6] To determine the complete primary structure of the human placental enzyme and to expand our understanding of the polypeptide's substrate and cofactor binding domains, we undertook the isolation and nucleic acid sequencing of a complementary deoxyribonucleic acid (cDNA) clone encoding 17β-estradiol dehydrogenase. Using this clone we hoped to establish the entire primary structure of estradiol dehydrogenase, to verify previously established amino acid sequences for the enzyme's substrate binding domain and its amino terminus, and to identify a putative cofactor binding site. Finally, we wished to compare the nicotinamide adenine dinucleotide binding site's primary and secondary structures with those of other pyridine-dependent dehydrogenases.

Material and methods

Radiolabeled protein A (50 μCi/ml) and high-specific-activity α[^{35}S]5′-deoxyadenosine triphosphate (>1000 Ci/mmol) were obtained from Amersham (Amersham, United Kingdom). pGEM4Z plasmid-DNA was obtained from Promega, Inc. (Madison, Wis.). All reagent-grade chemicals were obtained from Sigma Chemical Co. (St. Louis). 20α-Hydroxysteroid dehydrogenase was generously provided by Dr. Jorge Pineda (Washington University, St. Louis).

To screen a human placental cDNA library for estradiol dehydrogenase clones, it was first necessary to produce a highly specific polyclonal antibody to the enzyme. Highly purified enzyme was isolated by the affinity purification technique of Chin and Warren[7] and evaluated for activity by the method of Langer and Engel.[8] The protein was then used to raise antiserum in male New Zealand White rabbits by a technique described previously.[9] Whole serum was evaluated for sensitivity and specificity of antibody response during the development of a sensitive indirect enzyme immunosorbent assay (data not shown). This enzyme-linked immunosorbent assay proved capable of accurately measuring known quantities of 17β-estradiol dehydrogenase as small as 10 ng. When other proteins, such as bovine serum albumin, creatine phosphokinase, and

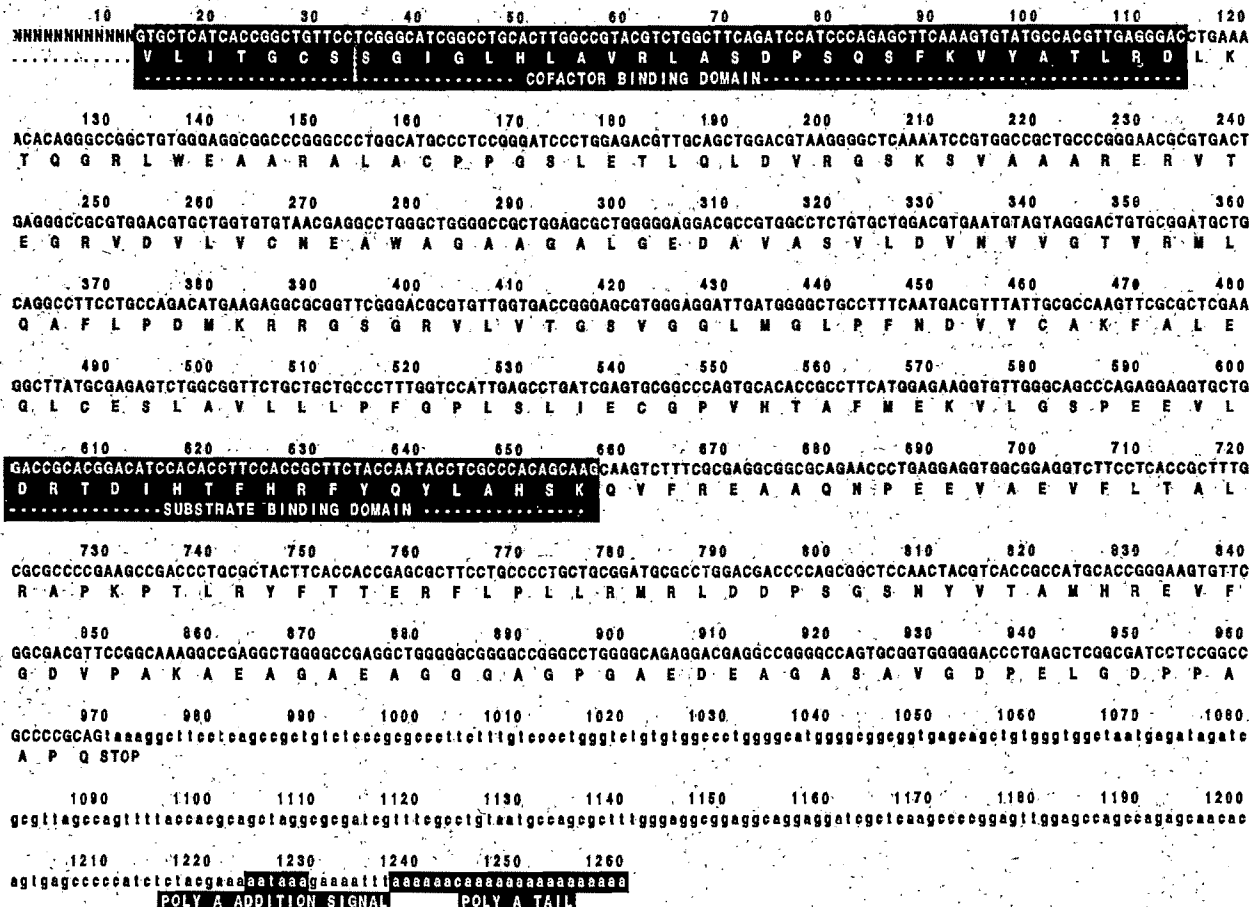

Fig. 2. Translation of 17β-estradiol dehydrogenase into protein. 17β-Estradiol dehydrogenase is a protein of approximately 323 amino acids. This figure delineates the primary structure of the molecule for all but its first four amino acids. The area marked *cofactor binding domain* is extrapolated from the structural motifs derived by Birktoft and Banaszak.[13] The substrate binding domain is the 20-amino acid peptide fragment affinity labeled by Murdock et al.[14] in 1986. The consensus polyadenylation addition signal AATAAA may be seen near nucleic acid 1230.

20α-hydroxysteroid dehydrogenase from bull testes, were used as the preincubation immunosorbent in the enzyme-linked immunosorbent assay, no specific estradiol dehydrogenase—like protein was measured. Having satisfied ourselves that the antibody we had generated was indeed 17β-estradiol dehydrogenase–specific, we decided to identify and purify a series of clones encoding the enzyme from a human placental cDNA library prepared by Dr. Evan Sadler.[10] This library was size-selected for cDNA inserts of >1000 bases. The inserts were ligated into the *Eco*RI site of the bacteriophage expression vector λgt11. The library was transfected into the nonrestrictive ampicillin-resistant host, *Escherichia coli* Y1090, and plated out at an initial concentration of 5×10^4 plaque-forming units of recombinant phage. Multiple plates were screened with the specific 17β-estradiol dehydrogenase antiserum according to the technique of Huynh et al.[11] This method uses the ability of λgt11 to synthesize immunologically competent β-galactosidase–estradiol dehydrogenase fusion proteins from in-frame/coding region cDNAs inserted adjacent to the phage's lacZ promoter. Plaques containing the fusion protein were identified by sequential exposure to a 1:200 dilution of the estradiol dehydrogenase–specific antiserum and iodine 125–labeled *Staphylococcus* protein A (approximately 1 μCi per filter). The labeled plaques were lifted and further purified by rescreening at progressively lower plaque densities until several homogeneous 17β-estradiol dehydrogenase–positive phage populations were identified. These clones were then amplified and their phage DNA was subjected to *Eco*RI digestion. The resulting inserts were subcloned into the double-stranded plasmid pGEM4Z (Promega). DNA sequencing was carried out according to a modification of the dideoxy-chain termination method of Sanger et al.[12]

The cDNA inserts used for futher study were found to hybridize both to a 1400 base pair placental ribonucleic acid and to human genomic DNA by Northern and Southern blot analysis, respectively (data not shown).

Results

Eighteen 17β-estradiol dehydrogenase–positive clones were identified by antibody screening and later by oligonucleotide screening. All or parts of five of these clones were used in the DNA sequencing process. Fig. 1 represents the sequencing strategy used to establish the nucleic acid sequence of the longest of the clones. Universal primers and a variety of specific oligonucleotides were used to provide a series of overlapping sequence data. These established a cDNA of 1270 bases, some 970 of which make up the 17β-estradiol dehydrogenase coding sequence. Also shown in this figure are the relative locations of the substrate and cofactor binding regions within the cDNA sequence. Although a poly(A)tail was identified at the end of the noncoding 3′region of the clone, no ATG start codon was identified in our cDNA.

Fig. 2 details the translation of our nucleic acid sequence into protein. The polyadenylation site and its consensus start sequence AATAAA (located 8 bases upstream) may be seen at the 3′-end of the sequence. The carboxy terminal of the enzyme (proline-alanine-alanine-proline-glutamine) is located at approximately nucleic acid 970.

In 1984, Warren et al.[6] presented a putative *N*-terminal amino acid sequence for estradiol dehydrogenase derived by standard protein chemistry techniques. That sequence began with the amino acids alanine-arginine-threonine-valine. The next series of amino acids from their sequence corresponds to the first 19 amino acids deduced from our cDNA clone and may be seen at its 5′-end. Since no ATG codon was identified by our group, we conclude that this clone ends at least five amino acids shy of the amino terminus of the enzyme.

Two other areas of the estradiol dehydrogenase amino acid sequence also have been published. In 1973, Nicolas and Harris[13] detailed a 17-amino acid fragment that they affinity labeled with a halogenated nicotinamide adenine dinucleotide phosphate derivative. The sequence of this fragment was confirmed by translation of bases 150 to 200 in our nucleic acid sequence. In 1986, Murdock et al.[14] published a 20-amino acid partial sequence from the putative steroid-binding site of 17β-estradiol dehydrogenase after purification with a series of radiolabeled derivatized enzyme substrates. This region contains three histidine residues thought to be critical to the enzyme's activity. DNA sequencing of the region, also present in our cDNA, confirms the accuracy of their amino acid sequence. It corresponds roughly to amino acids 195 to 214 in the estradiol dehydrogenase molecule.

Birktoft and Banaszak[15] have analyzed and compared the nicotinamide adenine dinucleotide and nicotinamide adenine dinucleotide phosphate binding domains of more than a dozen of the >250 pyridine-dependent dehydrogenases and their isoforms that have been identified to date. They suggested that the dinucleotide-binding domains of these enzymes contain a common structural motif. This motif consists of several, nearly parallel β-sheets with a single α-helix forming the connection between the first two β-strands. Several invariate glycine residues permit close proximity of the two ribose rings of cofactor to the β-sheet and the pyrophosphate to the α-helix. An acidic group, usually aspartic acid, also interacts with the adenine ribose 2-hydroxyl group of the nicotinamide adenine dinucleotide. Fig. 3 offers a comparison of the amino terminal portion of estradiol dehydrogenase with the nicotinamide adenine dinucleotide–binding regions of several of these other dehydrogenases. When compared with the nicotinamide adenine dinucleotide–binding sites of lactic dehydrogenase, malate dehydrogenase, glyceraldehyde-3-phosphate dehydrogenase, and others, the characteristic β-, α-, β-pattern, multiple proximate glycine residues, and typical acidic amino acid for ribose binding all may be seen within the 34-amino terminal residues of our cDNA-derived protein sequence. The amino terminal location of this portion of the estradiol dehydrogenase molecule is a signature location for the dinucleotide binding regions of other dehydrogenases.

Comment

We have isolated and sequenced a cDNA clone encoding nearly 98% of the protein sequence of 17β-estradiol dehydrogenase. On the basis of this work, estradiol dehydrogenase is a polypeptide made up of approximately 323 amino acids. This corresponds closely to previous molecular weight estimates that were based on gel chromatography[16] and denaturing gel electrophoresis.[16, 17] The relative frequency of individual amino acids in our putative sequence also correlates with earlier estimates that were based on compositional analysis.[16, 17] Finally, the cDNA-derived sequence is nearly identical to a 17β-estradiol dehydrogenase sequence derived in the laboratory of Dr. Ralph Bradshaw using standard protein chemistry techniques (personal communication). This sequence is also in almost complete agreement with the DNA sequence of a human placental 17β-estradiol dehydrogenase cDNA published earlier this year by Peltoketo et al.[18] The six

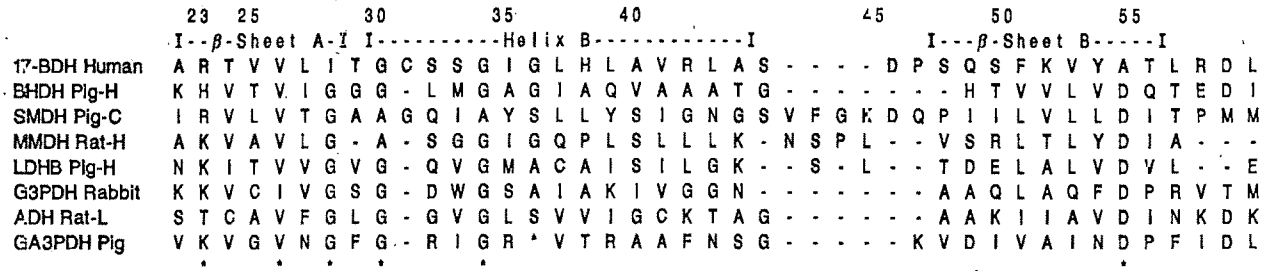

Fig. 3. Comparison of the nicotinamide adenine dinucleotide–binding sites of selected pyridine nucleotide–dependent enzymes with that of 17β-estradiol dehydrogenase. Amino acid sequences of the core dinucleotide-binding domains of various nicotinamide adenine dinucleotide–binding enzymes are presented. The secondary structure assignments of the proteins are indicated at the top of the figure. The exact starting and ending points for the β-strands and the α-helix vary among proteins. The *stars* at the bottom of the figure indicate the locations of critical or highly conserved residues. Abbreviations for enzyme names are as follows: *17β-BDH,* 17β-Estradiol dehydrogenase; *BHDG,* β-hydroxyacyl-coenzyme A dehydrogenase; *SMDH,* cytosolic malate dehydrogenase; *MMDH,* mitochondrial malate dehydrogenase; *LDHB,* lactic dehydrogenase B; *G3PDH,* glycerol-3-phosphate dehydrogenase; *ADH,* alcohol dehydrogenase; *GA3PDH,* glyceraldehyde-3-phosphate dehydrogenase. The source of each enzyme is included after its abbreviation.

differences in the amino acid composition of our sequence and that of Peltoketo et al. can, in general, be explained by differences in a single nucleic acid within a given area of the DNA sequence. This most likely occurs because the two groups have sequenced slightly different allelic forms of the cDNA.

Since the mid-1970s, identification of the putative nicotinamide adenine dinucleotide binding site of 17β-estradiol dehydrogenase has remained elusive. Sequence analysis, as inferred from our DNA sequencing technique, identifies a putative cofactor binding site of approximately 40 amino acids located in the molecule's amino terminus that is similar in primary and secondary structure to other pyridine-dependent dehydrogenases. This sequence does not contain the 17-amino acid fragment labeled by Nicolas and Harris[13] with derivatized cofactor analog. We believe that this cofactor analog in fact binds at the site that we have identified but that the derivatized ring selectively labels an adjacent area of protein sequence. As may be seen from the sequence of our cloned cDNA, the Nicolas and Harris peptide, which contains none of the structural motifs identified by Birktoft and Banaszak,[15] also lies in the amino terminal half of the molecule and thus is most likely in close proximity to the authentic cofactor binding site. Definitive elucidation of the mechanics of cofactor binding and amino acid residues that are critical for hydrogen transfer awaits crystallographic analysis and study of enzymatic activity after site-directed mutagenesis.

Identification and comparison of steroid-binding domains for several steroid-converting enzymes with the use of affinity labeling with substrate derivatives have suggested similarities in the presumed active sites of these enzymes.[14, 19] However, specific characteristics of these active sites and the importance of individual amino acids within the sites (e.g., histidine or cysteine residues) have yet to be elucidated. The technique of gene modification combined with existing affinity labeling technology now offers an opportunity to study the comparative biologic features of normal and modified active sites and thus the function of specific amino acids and steric influences in the mechanism of steroid conversion.

This work confirms the sequence of the substrate binding domain elucidated by Warren et al.[6] and places its location in the first half of the molecule's carboxy terminal portion. This location is analogous to the locations of the substrate binding regions of other nicotinamide adenine dinucleotide–dependent dehydrogenases. We presume this region includes those amino acid residues that are responsible for catalytic hydrogen ion transfer at the D ring of the steroid substrate. Mutagenesis in this region, accompanied by studies with derivatized substrate, offers the opportunity to determine which residues are required for the catalytic event and the molecular mechanisms involved in their participation.

Although the techniques of cDNA cloning and sequencing and gene modification have been popular tools for the evaluation of proteins and hormones for a decade, their use as investigative tools for the class of pyridine nucleotide–dependent dehydrogenases has been limited. The steroid dehydrogenases offer a unique opportunity to study structure-function relationships because of our ability to combine probes of active site topography (using the tool of alkylation with derivatized substrate) with genetically modified point changes in amino acids located at the enzyme's active site. In the future we hope to isolate a full-

length cDNA, which will allow us to sequence the remaining coding region of the molecule and its untranslated 5′-region. We also hope to use the clone to identify the biologic concomitants of 17β-estradiol dehydrogenase expression and to transfect 17β-estradiol dehydrogenase–bearing plasmid into prokaryotic and eukaryotic expression vectors to explore structure-function relationships of the molecule through the techniques of site-directed mutagenesis and affinity alkylation with derivatized substrates. Kinetic and crystallographic study of the high-quantity, homogeneous material produced by transformed cell lines is a first step in the understanding and possible modification of the role of estrogen in clinical conditions characterized by abnormal labor.

Molecular scanning of Yq11 (interval 6) in men with Sertoli-cell-only syndrome

Mark D. Johnson, MD,[a] Sandra P. T. Tho, MD,[a] Ali Behzadian, PhD,[a, b] and Paul G. McDonough, MD[a]

Augusta, Georgia

Data suggesting that probes pDP105/B and 50f2/C,E may identify sequences on distal Yq11 (interval 6) that are critical for spermatogenesis stimulated a study of this region by means of these two probes in azoospermic 46,XY men with biopsy-proved Sertoli-cell-only syndrome. Deoxyribonucleic acid samples from controls and study subjects were digested with the restriction enzymes *Taq*I, *Eco*RI, and *Bam*HI. These samples were blotted and hybridized with pDP105/B, 50f2/C,E, and two more proximal Yq11 probes 4B-2 and pAS1. The sequence hydridizing to 50f2/C was absent in one study subject. No deletions were detected with pDP105/B and the two more proximal probes. (AM J OBSTET GYNECOL 1989;161:1732-7.)

Key words: Spermatogenesis, Y chromosome, Sertoli-cell-only syndrome, DNA

Spermatogenesis is one of the most complicated and poorly understood differentiation processes in higher eukaryotes.[1] Genes on the Y chromosome that regulate spermatogenesis are highly conserved in evolution from *Drosophila* through mouse to man. Chromosomal deletions and rearrangements in the Yq11 region of azoospermic men with germ cell aplasia (Sertoli-cell-only syndrome) and maturation arrest suggest that sequences critical for spermatogenesis are present within the Yq11 region.[2-4]

An ordinal mapping of the human Y chromosome by Vergnaud et al.[5] has divided it into seven deletion intervals with each interval being defined by hybridization of contained dexoyribonucleic (DNA) restriction fragments with specific probes. On the basis of Yq deletions, intervals 5, 6, and 7 are assigned to Yq with deletion interval 6 defining a region of distal Yq11.[5] A molecular deletion of distal Yq11 (interval 6) was reported in a 45,X,14p+[45,X,t(Y;14)] azoospermic man with biopsy-proved germ cell aplasia (Sertoli-cell-only syndrome)[6] and an azoospermic 45,X,15p+[45,X,t(Y;15)] man without histologic diagnosis[7] by means of interval 6–specific probes pDP105/B and 50f2/C,E. These two probes distinguished fertile men from some infertile azoospermic men. On the basis of these data, Andersson et al.[6] hypothesized that DNA sequences critical for spermatogenesis are located on distal Yq11 within interval 6.

6/6/15960

The present study screened for molecular deletions in distal Yq11 (interval 6) in cytogenetically intact 46,XY men with germ cell aplasia (Sertoli-cell-only syndrome) using probes pDP105/B[6] and 50f2/C,E.[8] Two other probes, 4B-2[9] and pAS1,[10] screened for the integrity of Yq11 sequences proximal to interval 6.

Material and methods

The methods used in this study had prior approval of the Human Assurance Committee of the Medical College of Georgia.

Study subjects. Six azoospermic men with normal G-banded 46,XY karyotypes and biopsy-proved germ cell aplasia (Sertoli-cell-only syndrome) were enrolled in this study. The study subjects were from 24 to 44 years old and had no history of significant chronic medical illnesses, previous genital injury, infection, or orchitis, toxic environmental exposures, or urologic surgical procedures before biopsy and vasography. Physical examination revealed a normal male phenotype without evidence of anomalous genitalia or gynecomastia. Testes were in the normal range for volume and consistency in four patients; two individuals had smaller than normal testes. Serum testosterone levels were within the normal range except for one individual with a mildly decreased level (testosterone = 316 ng/dl). Luteinizing hormone levels ranged from 3.3 to 21.5 mIU/ml. Follicle-stimulating hormone levels ranged from 14.8 to 40.6 mIU/ml, the last value being elevated in only one individual. Semen analyses were all azoospermic at the time of biopsy with normal seminal volumes. Vasography revealed intact ductal systems in all individuals. Bilateral testicular biopsies were done in all individuals except for one.

DNA probes. Probe pDP105(DYZ4) is a 5.5 kb *Hin*dIII genomic fragment inserted into the *Hin*dIII

site of pUC13. It detects multiple Y-specific sequences in deletion interval 3 on Yp (pDP105/A) and in interval 6 on distal Yq11 (pDP105/B) (Page DC, personal communication). A 5.2 kb *Taq*I fragment (pDP105/B) is a marker for deletion interval 6.[7]

Probe 50f2[8] is a 1.7 kb *Eco*RI fragment from a Y-chromosome library inserted into the *Eco*RI site of plasmid pBR322. It defines five Y-specific *Eco*RI loci and one autosomal locus. It detects *Eco*RI fragments of 10 kb (50f2/A) and 7.5 kb (50f2/B) in deletion interval 3 on Yp. Probes 50f2/C and 50f2/E hybridize with *Eco*RI fragments of 6 and 1.7 kb, respectively, in deletion interval 6 of distal Yq11. The 50f2/D probe is a marker for an *Eco*RI 4.5 kb centromeric fragment. The autosomal locus is defined by an *Eco*RI 2.4 kb fragment.[5]

Probe 4B-2 (DYZ-15) is a recombinant phage construct developed from a Y-DNA library inserted into plasmid pBR322 at the *Eco*RI site. It contains a 3.3 kb *Eco*RI fragment that maps to the subcentromeric portion of Yq11 distal to the pAS1 sequence.[9]

Probe pAS1 represents an arginosuccinate synthetase pseudogene and is a 1.55 kb sequence constructed from a complementary DNA library inserted into the plasmid pBR322 at the *Pst* I site. It detects a 4.3 kb *Eco*RI fragment and a 2.45 kb *Bam*HI sequence, both of which map to Ycen-Yq11.

These recombinant plasmids were amplified and isolated by conventional methods.[11] The corresponding inserts were released from their vectors by restriction digests with the *Hin*dIII, *Eco*RI, and *Pst*I enzymes, respectively. They were purified by electrophoresis, phenol extraction, and ethanol precipitation. Before hybridization the DNA probes were labeled with phosphorus 32 by oligonucleotide random priming (Amersham International pic, Amersham, United Kingdom) to a high specific activity of 10^8 cpm/μg DNA.[12]

DNA analysis. Genomic DNA from the six study subjects, two normal fertile control men, and two normal control women, was digested with the restriction enzymes *Taq*I, *Eco*RI, and *Bam*HI. Samples of 10 μg DNA per well were electrophoresed in 0.8% high-melting-point agarose gels. DNA was transferred to Gene Screen Plus (New England Nuclear Research Products, Boston) by methods described by Southern[13] and baked in a vacuum for 2 hours at 80° C.

Transferred *Taq*I digests were hybridized with ^{32}P-labeled pDP105. *Eco*RI blots were separately hybridized with ^{32}P-labeled 50f2 and 4B-2 probes. The ^{32}P-labeled pAS1 probe was hybridized with separate *Eco*RI and *Bam*HI blots. All hybridizations were performed at 65° C for 2 days' duration.

The pDP105, 4B-2, and pAS1 hybridized blots were washed at high-stringency conditions at 65° C with decreasing concentrations of sodium chloride–sodium citrate (2 × SSC to 0.1 × SSC) and 1% sodium dodecyl sulfate. The 50f2 hybridized blots were washed at moderate-stringency conditions at 65° C with 2 × SSC and 1% sodium dodecyl sulfate. Autoradiographs were exposed at −80° C with intensifying screens from 1 to 4 days on Kodak XAR-5 film (Eastman Kodak Company, Rochester, N.Y.).

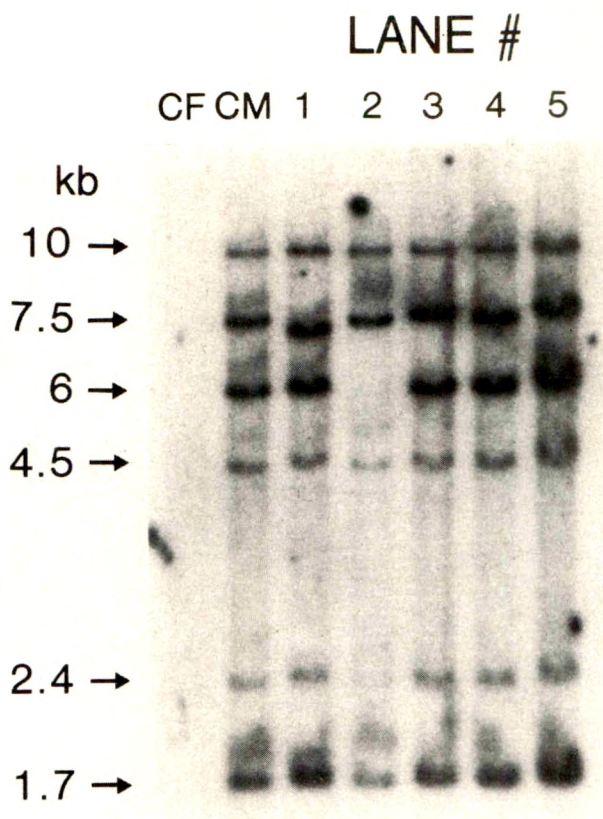

Fig. 1. Probe 50f2 hybridization with a Yq11-specific 6 kb *Eco*RI sequence (50f2/C) and a Yq11-specific 1.7 kb *Eco*RI sequence (50f2/E). Lane *CF* is DNA from a control woman. Lane *CM* is DNA from a fertile control man. Lanes *1* to *5* are DNA from men with Sertoli-cell-only syndrome.

Results

DNA from the azoospermic study subjects with germ cell aplasia (Sertoli-cell-only syndrome) was contrasted with DNA from normal fertile control men and normal control women. Analyses with 50f2/C,E were performed on only five of the six subjects since one azoospermic individual withdrew from the study. Probing distal Yq11 (interval 6) with 50f2/C,E in five azoospermic study subjects revealed absence of the *Eco*RI 6 kb 50f2/C band in only one individual (Fig. 1, lane 2). All other Y-specific bands and one autosomal band were present in the remaining azoospermic individuals and control men. The *Eco*RI 2.4 kb autosomal band was present at very low intensity in the control woman.

Six azoospermic men with Sertoli-cell-only syndrome and the normal fertile control men were studied with pDP105/B and exhibited the *Taq*I 5.2 kb band specific for distal Yq11 (interval 6) when hybridized with probe

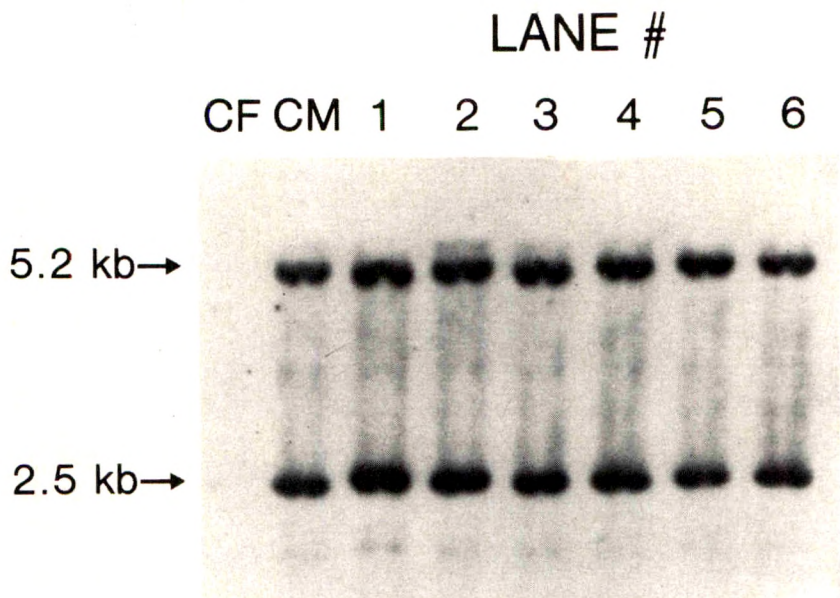

Fig. 2. Probe pDP105 hybridization with a Yq11-specific 5.2 kb *Taq*I sequence (pDP105/B) and a Yp-specific 2.5 kb *Taq*I sequence (pDP105/A). Lane *CF* is DNA from a control woman. Lane *CM* is DNA from a fertile control man. Lanes *1* to *6* are DNA from men with Sertoli-cell-only syndrome.

pDP105/B (Fig. 2). The same six study subjects and normal control men showed the presence of *Eco*RI 3.3 kb (Fig. 3), *Eco*RI 4.3 kb (Fig. 4), and *Bam*HI 2.45 kb (Fig. 5) Yq11-specific bands when hybridized with their respective probes 4B-2 and pAS1. These Yq11-specific hybridization bands were not seen in the DNA from the normal control woman.

Comment

This preliminary molecular scan of cytogenetically intact 46,XY men with biopsy-proved germ cell aplasia (Sertoli-cell-only syndrome) identified one individual (Fig. 1, lane 2) with absence of the *Eco*RI 6 kb 50f2/C band specific for distal Yq11 (interval 6). The significance of the absent 50f2/C band in this azoospermic individual awaits analysis of family members to confirm either a polymorphism or a de novo deletion. The remaining azoospermic subjects and fertile control men had the 50f2/C,E sequences present. Further scanning of Yq11 in these azoospermic study subjects and fertile control men with interval 6–specific pDP105/B and other probes (4B-2 and pAS1) that hybridize to more proximal regions of Yq11 revealed conservation of all intact sequences without evidence of deletion. As noted in Figs. 2 to 5, the probes pDP105/B, 4B-2, and pAS1 hybridized with Yq11-specific 5.2kb *Taq*I, 3.3 kb *Eco*RI, 4.3 kb *Eco*RI, and 2.45 kb *Bam*HI sequences, respectively.

Cytogenetic and molecular evidence in the study of mutations in *Drosophila*, mouse, and man supports the hypothesis that the deletion of certain Y-DNA sequences results in aberrant spermatogenesis.

Genetic loci on the Y chromosome of *Drosophila* responsible for spermatogenesis have been recognized for many years. Brosseau[14] studied X-irradiated male sterile *D. melanogaster* mutants. By using a marked Y chromosome for complementation tests, he defined seven fertility genes. His genetic map of the Y chromosome described two genes on the Y short arm and five genes on the Y long arm.[14] Hardy et al.[15] produced deletions of specific male fertility loci in *D. melanogaster* and correlated specific anatomic lesions in spermatogenic cell development with segmental Y-chromosome deficiencies.[15]

In mice, as in humans, the presence of spermatogenesis genes on the Y chromosome has been based on the study of sterile mutants. Intriguing evidence has accumulated from the study of sex-reversed XO males and associated variant strains.[16-18] In classic Sxr mutants a small segment of the Y-chromosome-containing testis determinants and H-Y antigen expression determinants is meiotically transferred to the X chromosome, thereby creating sex-reversed mice.[16, 19] Adult XO,Sxr male mice have normal-sized testes with all stages of spermatogenesis but are sterile because of defective meiotic divisions postulated to result from the absence of the Y chromosome and abnormal pairing in meiosis.[16]

Sxr′ is another Sxr mutant, which carries Y-chromosome testicular determinants but does not carry H-Y antigen expression determinants.[17] Adult, XO,Sxr′ mice are H-Y antigen negative by T-cell-restricted assay and have severely decreased spermatogonia with severe impairment of developmental stages before meiosis.[18]

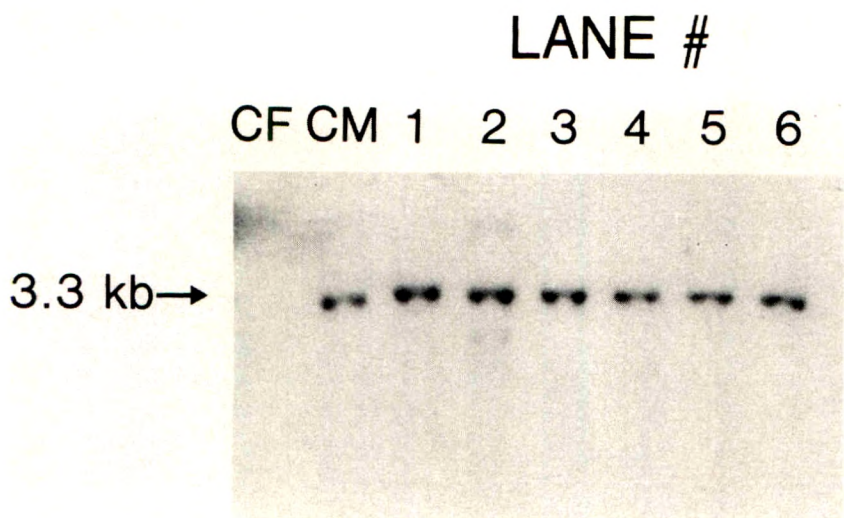

Fig. 3. Probe 4B-2 hybridization with a Yq11-specific 3.3 kb *Eco*RI sequence. Lane *CF* is DNA from a control woman. Lane *CM* is DNA from a fertile control man. Lanes *1* to *6* are DNA from men with Sertoli-cell-only syndrome.

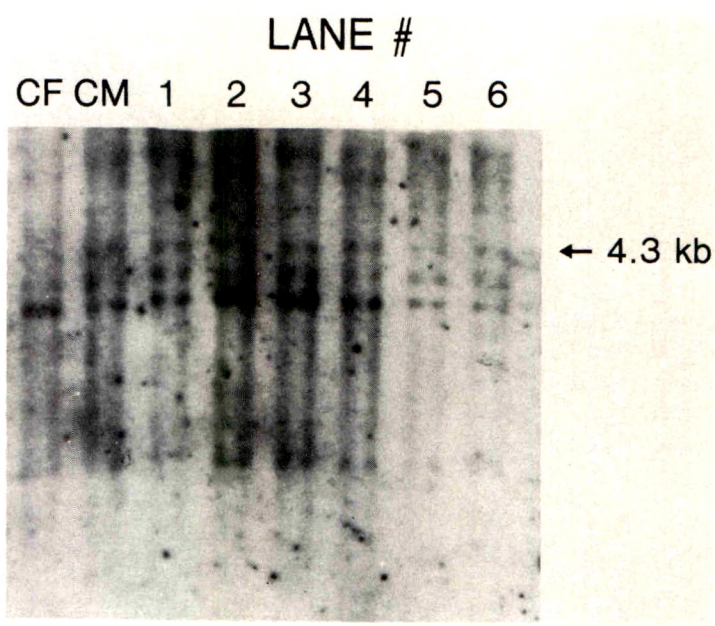

Fig. 4. Probe pAS1 hybridization with a Yq11-specific 4.3 kb *Eco*RI sequence. Lane *CF* is DNA from a control woman. Lane *CM* is DNA from a fertile control man. Lanes *1* to *6* are DNA from men with Sertoli-cell-only syndrome.

The premeiotic defect in spermatogenesis seen in these XO,Sxr′ mice contrasts with the abnormal meiotic divisions in spermatogenesis seen in adult XO,Sxr males with H-Y antigen expression. Burgoyne et al.[18] hypothesized that H-Y antigen may be a product of a "spermatogenesis" gene; however, it is possible that there are separate genes for spermatogenesis and H-Y antigen expression that are closely linked. This work by Burgoyne et al. with the Sxr′ variant clearly separates the genetic loci for Tdy and H-Y antigen and suggests that the protein encoded by H-Y antigen may be involved in the regulation of spermatogenesis.[17, 18]

Some humans with azoospermia have associated abnormalities of the Y chromosome. In 1976, Tiepolo and Zuffardi[2] reported on six azoospermic men with a distal deletion of Yq11. On the basis of these six azoospermic men, as well as two cases of ring Y chromosome with loss of Yq12 and part of Yq11, Tiepolo and Zuffardi[2]

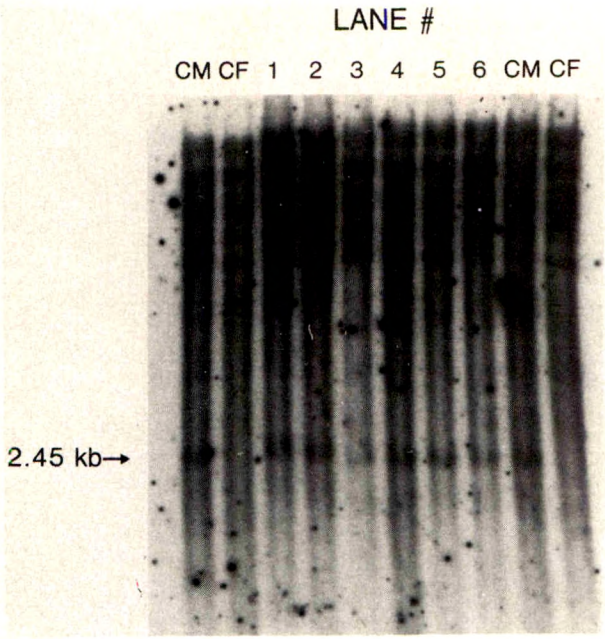

Fig. 5. Probe pAS1 hybridization with a Yq11-specific 2.45 kb *Bam*HI sequence. Lanes *CM* are DNA from fertile control men. Lanes *CF* are DNA from control women. Lanes *1* to *6* are DNA from men with Sertoli-cell-only syndrome.

proposed the presence of spermatogenesis-controlling factors at the distal portion of Yq11. Numerous reports of men with similar deletions of distal Yq11 and azoospermia are in the literature.[2-4, 20-25] Several azoospermic men with ring Y chromosomes [46,X,r(Y) and 45,X/46,X,r(Y)] also have been reported.[4]

Germ cell aplasia (Sertoli-cell-only syndrome) is a frequent histopathologic diagnosis in azoospermic men with absence of the distal Yq11 region. Six of nine azoospermic men with cytogenetic deletions of the distal Yq11-Yq12 region and three of five azoospermic men with r(Y) had histopathologic diagnoses of germ cell aplasia; the remainder had presumptive evidence of this diagnosis.[2, 3, 20-23, 25]

Recent molecular studies support the concept that sequences critical for spermatogenesis are present on distal Yq11 and that deletion of some or all of the sequences can result in extreme conditions such as germ cell aplasia (Sertoli-cell-only syndrome). As described earlier, Andersson et al.[6] and Gal et al.[7] reported on two separate azoospermic individuals with molecular deletions of distal Yq11 (interval 6). The azoospermic individual described in the former study had germ cell aplasia (Sertoli-cell-only syndrome) whereas the azoospermic individual in the latter study lacked a histologic diagnosis. Chandley et al.[25] described an azoospermic man with Yq deletion involving loss of interval 6 that was confirmed by absence of hybridization with pDP105/B. The individual has advanced tubular hyalinization in both testes with minimal germ cell elements.

Probing distal Yq11 (interval 6) with 50f2/C,E and pDP105/B and scanning more proximal Yq11 with 4B-2 and pAS1 screened only finite sequences of several-kilobase lengths within Yq11. It is apparent from these data that further investigation of the potential role of Yq11 deletions in spermatogenesis requires scanning with more Yq11 DNA probes and probing much larger DNA segments of Yq11 fractionated by pulsed-field gel electrophoresis. These techniques will enable us to identify starting points for restriction site mapping of this macroregion of DNA and subsequently assist in characterizing DNA sequences critical in spermatogenesis.

We acknowledge Dr. David Page for providing probe pDP105, Dr. Jean Weissenbach for providing probe 50f2, Dr. Kirby Smith for providing probe 4B-2, and Dr. Arthur Beaudet for providing probe pAS1. We thank Dr. J Rogers Byrd for his support in cytogenetics.

Steroid biosynthesis in the Sertoli-Leydig cell tumor: Effects of insulin and luteinizing hormone

Manubai Nagamani, MD, Charles A. Stuart, MD, and Tung Van Dinh, MD
Galveston, Texas

In vitro steroid production by a virilizing Sertoli-Leydig cell tumor of the ovary was studied. For comparison, stromal tissue from the opposite normal ovary was also incubated under similar conditions. The tumor fragments secreted significantly more testosterone (527 ± 168 versus 48 ± 29 pg/mg tissue, $p < 0.001$), androstenedione (1188 ± 400 versus 40 ± 10 pg/mg tissue, $p < 0.001$), and dehydroepiandrosterone (419 ± 132 versus 73 ± 25 pg/mg tissue, $p < 0.004$) than that of normal ovarian stroma. Measurement of steroids in the ovarian venous serum draining the tumor indicated a peripheral ovarian gradient for both Δ^4 and Δ^5 steroids. Incubation of tumor fragments with luteinizing hormone alone resulted in a significant increase in the secretion of androstenedione and dehydroepiandrosterone ($p < 0.05$). Addition of insulin to luteinizing hormone resulted in significantly greater release of androstenedione than that of treatment with luteinizing hormone alone ($p < 0.04$). Addition of insulin had no effect on the release of dehydroepiandrosterone. Luteinizing hormone and insulin, either alone or in combination, failed to produce any change in the secretion of testosterone. We conclude that (1) increased testosterone secretion by Sertoli-Leydig cell tumor resulted from increased availability of precursors from both Δ^4 and Δ^5 pathways; (2) the tumor was responsive to luteinizing hormone with an increase in the secretion of androstenedione and dehydroepiandrosterone; (3) insulin acts synergistically with luteinizing hormone to increase secretion of androstenedione; (4) the tumor has specific binding sites for insulin; and (5) the increased levels of insulin and luteinizing hormone in polycystic ovarian disease may play a role in the pathogenesis of Sertoli-Leydig cell tumor. (Am J Obstet Gynecol 1989;161:1738-43.)

Key words: Arrhenoblastoma, insulin receptors, steroid biosynthesis

Sertoli-Leydig cell tumors, or arrhenoblastomas, are sex-cord stromal tumors of the ovary with testicular-directed differentiation.[1] Testosterone is the principal androgen secreted by these tumors, which are usually discovered during the investigation of androgen excess as manifested by masculinization, hirsutism, and amenorrhea. Opportunities to study the steroid biosynthesis in these tumors have been limited because of their rarity. Study of their pattern of steroidogenesis will help to identify their origin. Predominance of a Δ^4 pathway of steroidogenesis indicates stromal cell origin of the tumor, whereas predominance of the Δ^5 pathway indicates Leydig cell origin. Ullery[2] has speculated that the arrhenoblastoma may be derived from male cells that persist in the medullary portion of the ovary. The histogenesis of these tumors is not known. Sertoli-Leydig cell tumors have been reported in women with polycystic ovarian disease.[3-6] It is possible that the levels of constantly elevated luteinizing hormone (LH) or hyperinsulinism that are present in polycystic ovarian disease play a role in the pathogenesis of Sertoli-Leydig cell tumors of the ovary.

We undertook this study to investigate (1) the pathway of steroid biosynthesis in the Sertoli-Leydig cell tumors by in vitro and in vivo studies; (2) the effect of LH and insulin on in vitro steroidogenesis by the tumor tissue, and (3) whether the tumor has specific binding sites for insulin.

Material and methods

Patient. The patient was a 44-year-old nulliparous woman with a 10-year history of amenorrhea and progressive hirsutism because of which she had to shave daily. Her cycles had been irregular from menarche at age 12. She also had undergone deepening of her voice, temporal balding, and decrease in breast size.

Physical examination revealed a severely hirsute obese woman with male body habitus. She weighed 220 pounds and was 5 feet 1 inch tall. There was coarse dark hair on her face, chest, and abdomen and marked temporal balding. The clitoris was enlarged to 1 cm in

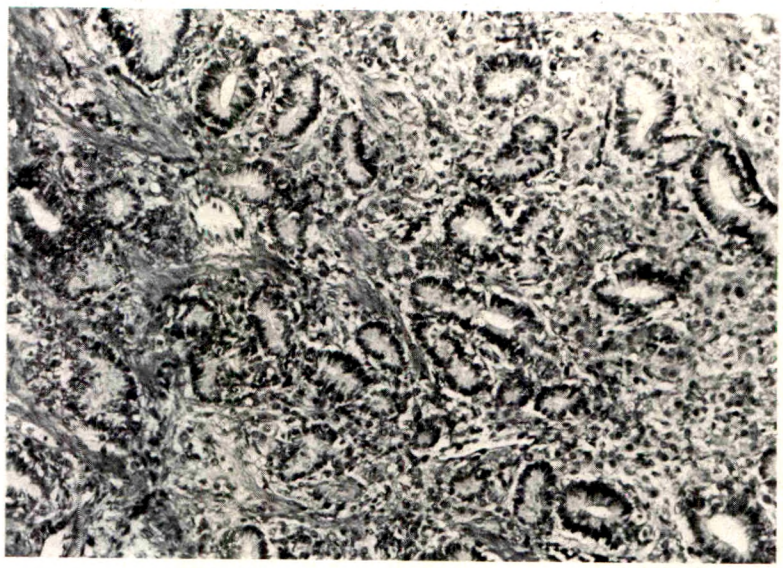

Fig. 1. Microscopic sections of tumor show tubules and prominent interstitial cells.

diameter. Pelvic and ultrasonographic examinations revealed an enlarged right ovary (6.5 × 4 cm); the left ovary was within normal limits.

The patient's serum testosterone level was 420 ng/dl (normal, 30 to 100 ng/dl), dehydroepiandrosterone (DHEA) sulfate was 350 ng/ml (normal, 500 to 3000 ng/ml), LH was 19 mIU/ml, and follicle-stimulating hormone was 10 mIU/ml. An oral glucose tolerance test (GTT) with insulin levels showed a fasting insulin level of 33 μU/ml (normal, 5 to 22 μU/ml). Insulin response to the oral GTT was increased, but glucose levels were normal. Insulin level 1 hour after glucose administration was 310 μU/ml (normal, 20 to 95 μU/ml); at 2 hours, 215 μU/ml (normal, 10 to 50 μU/ml); and, at 3 hours, 146 μU/ml (normal, 3 to 22 μU/ml).

At laparotomy, the right ovary was 7 × 4 × 2 cm. A total abdominal hysterectomy with bilateral salpingo-oophorectomy was performed. Simultaneous blood samples were obtained from the ovarian and peripheral veins at the time of surgery. Histologic examination revealed a well-differentiated Sertoli-Leydig cell tumor of the right ovary. The tumor comprised two major components: small tubules that were lined by a single layer of cells with acidophilic cytoplasm and a proliferation of interstitial Leydig cells (Fig. 1). There was evidence of polycystic ovarian disease in the left ovary and there were nests of luteinized thecal cells in the stroma. The uterus was normal in size; the endometrium was weakly proliferative and showed mild adenomatous hyperplasia and focal dysplastic changes. Six weeks after surgery, the patient's testosterone level was 35 ng/dl.

Tissue culture. Immediately after oophorectomy, a portion of the tissue removed from the center of the tumor was placed in the incubation medium. Under sterile techniques the tissue was sectioned into pieces <2 mm in diameter. All dissections were performed under a laminar flow hood. A portion of the tumor tissue (about 100 mg) was frozen to assess basal steroid content. About 100 mg of tissue was placed with 2 ml of medium in six-well tissue culture plates (Falcon, Becton-Dickinson, Rutherford, N. J.). The culture plates were incubated at 37° C in 5% carbon dioxide in air. For comparison, stromal tissue obtained from the left ovary immediately after its removal was incubated under similar conditions. Dissections of this ovary were carefully performed to obtain only the stromal tissue and to exclude thecal tissue and follicles.

All sections from the tumor were incubated either in medium alone or in medium to which was added LH at 50 ng/ml, insulin at 500 ng/ml, or a combination of the two. These amounts of LH and insulin were selected on the basis of previous dose-response studies reported in experiments with the ovarian stroma.[7, 8] All incubations were done in quadruplicate. Because of a lack of tissue, the stroma from the left ovary was incubated with only incubation medium and no experiments were performed with LH or insulin. After a 4-hour incubation the medium was removed from each well and stored at −72° C until analysis. The tissue sections from each well were weighed at this time, fixed in 10% formalin, and examined histologically with hematoxylin and eosin stain. Tissue fragments were found to be viable with intact cell membranes and the nuclei at the end of incubation.

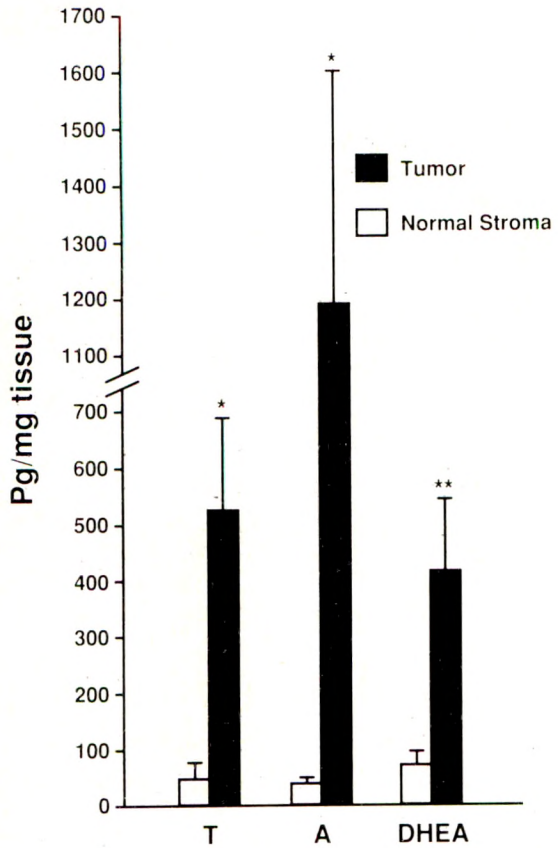

Fig. 2. Testosterone *(T)* androstenedione *(A)*, and dehydroepiandrosterone *(DHEA)* production in vitro by ovarian stromal tissue from left ovary and by Sertoli-Leydig cell tumor (mean ± SD; $n = 4$). *Asterisk*, $p < 0.001$; *double asterisks*, $p < 0.004$.

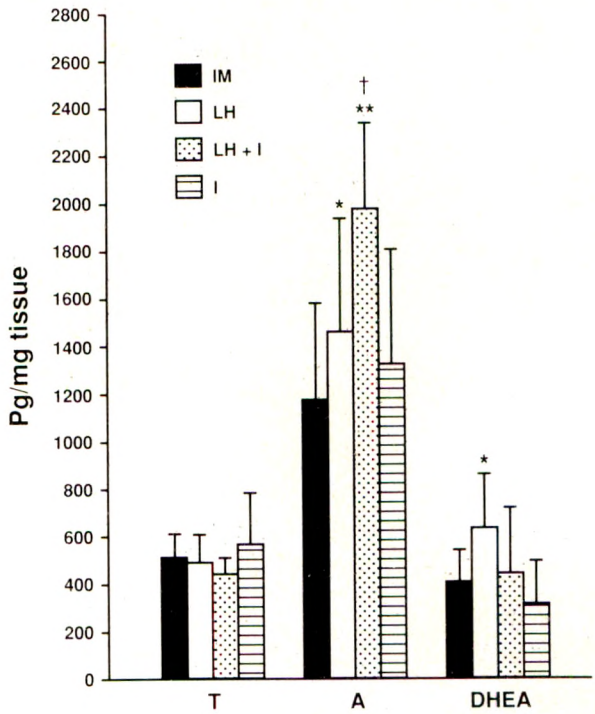

Fig. 3. Effects of LH and insulin on mean (±SD; $n = 4$) testosterone, androstenedione, and DHEA production by Sertoli-Leydig cell tumor tissue in vitro. *IM*, Incubation medium (control); *LH*, LH 50 ng/ml; *I*, insulin 500 ng/ml; *LH + I*, LH 50 ng/ml and insulin 500 ng/ml. *Asterisk*, $p < 0.05$; *double asterisks*, $p < 0.002$ (compared with control); *dagger*, $p < 0.04$ (compared with LH alone). For testosterone, the F ratio was $1.29_{3,12}$ (not significant).

Incubation medium. McCoy's 5a medium with 5% newborn calf serum, penicillin (100 U/ml), streptomycin (100 μg/ml) and L-glutamine (0.29 mg/ml), was used as the medium for all incubations. All media were bubbled in 95% oxygen and sterilized through 0.2 and 0.45 μm filters before use.

Human LH was obtained from the National Hormone and Pituitary Program and human insulin was obtained from Eli Lilly & Co. (Indianapolis, Ind.). McCoy's 5a medium and calf serum were supplied by Gibco (Grand Island, N. Y.). The newborn calf serum did not have detectable levels of LH or insulin.

Studies of insulin binding in the tumor tissue and in the ovarian stroma from 11 normal premenopausal women were performed in accordance with procedures described previously.[9, 10] Serum insulin levels were measured in duplicate by double antibody radioimmunoassay (RIA) as previously described.[10, 11] All steroids were measured by RIA after fractionation by Celite column chromatography as described elsewhere.[12, 13] Serum or incubation medium was extracted three times with three volumes of ether after tritiated tracers were added for recovery calculations. Extracts were dried under nitrogen and subjected to chromatography on micro-Celite columns. The various fractions were collected, dried under nitrogen, and reconstituted with assay buffer. Different volumes were used in the assay and 0.1 ml was used for recovery calculations. All the steroids were measured by specific RIAs as previously described.[12, 13] Recoveries ranged from 70% to 90%. DHEA sulfate was measured by direct RIA.

Steroid secretion by the control ovary and the tumor tissue was compared by the Student t test after log transformation of the data to stabilize heterogenous variances. Steroid production by the tumor tissue under control and different experimental conditions were compared by one-way analysis of variance.

Results

The basal steroid content of the tumor tissue was <5 pg/mg of tissue for all steroids, and the stroma from the left ovary contained <1 pg of steroids per milligram tissue. When incubated for 4 hours, the tumor tissue secreted significantly more testosterone [527 ± 168

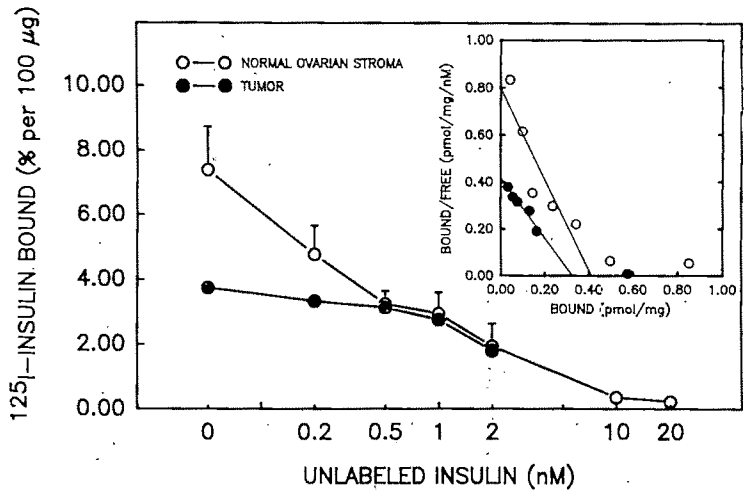

Fig. 4. Insulin binding to membranes from Sertoli-Leydig cell tumor and normal premenopausal ovarian stroma ($n = 11$). Shown are mean (±SE) for studies in normal ovarian stroma. Tumor data points represent means of triplicate determinations. *Inset* shows Scatchard analysis of same data shown in competition curves.

Table I. Peripheral and ovarian vein concentrations of steroids (pg/ml)

Steroid	*Peripheral vein (patient)*	*Right ovarian vein (tumor)*	*Left ovarian vein*	*Normal women (peripheral vein)*
Progesterone	7,407	24,246	5,915	100-350
17OHP	955	80,000	16,941	100-300
17OHΔ⁵P	13,000	110,000	—	1,500-10,000
DHEA	10,105	69,444	3,550	1,600-7,000
Androstenedione	3,325	66,000	7,188	340-1,650
Testosterone	4,337	43,956	6,190	500-900
Dihydrotestosterone	92	290	62	30-220
DHEA sulfate (ng/ml)	350	380	300	500-3,000
17β-Estradiol	26	1,113	51	50-200

(±SD) versus 48 ± 29 pg/mg tissue, $p < 0.001$], androstenedione (1188 ± 400 versus 40 ± 10 pg/mg tissue, $p < 0.001$), and DHEA (419 ± 132 versus 73 ± 25 pg/mg tissue, $p < 0.004$) than that of the ovarian stroma from the opposite ovary (Fig. 2).

Incubation of tumor fragments with LH alone resulted in a significant increase in the secretion of androstenedione (1188 ± 400 versus 1482 ± 483 pg/mg tissue, $p < 0.05$). The addition of insulin alone resulted in a small statistically insignificant increase in the secretion of androstenedione (1349 ± 493 pg/mg tissue). The addition of LH and insulin resulted in a significantly greater release of androstenedione (1956 ± 373 pg/mg tissue) compared with the increase after treatment with LH alone ($p < 0.04$). Incubation of the tumor tissue with LH resulted in a significant increase in DHEA secretion, as compared with the increase after incubation with medium alone (419 ± 132 versus 626 ± 219 pg/mg tissue, $p < 0.05$). The addition of insulin, whether alone or with LH, had no effect on DHEA release (Fig. 3). LH and insulin, either alone or in combination, failed to produce any change in testosterone secretion.

Peripheral and ovarian venous steroid levels are shown in Table I. Peripheral levels of progesterone, 17α-hydroxyprogesterone (17OHP), 17α-hydroxypregnenolone (17OHΔ⁵P), DHEA, androstenedione, and testosterone were increased. Levels of all these steroids were several times higher in the right ovarian venous serum draining the tumor than levels in the left ovarian venous serum. Thus there was a peripheral ovarian gradient for both Δ^4 and Δ^5 steroids. Concentrations of 17OHΔ⁵P and DHEA in the ovarian vein serum were relatively higher than those of progesterone and 17OHP. Although peripheral levels were in the normal range, 17β-estradiol and dihydrotestosterone concentrations in the ovarian vein serum draining the tumor were increased, which indicates the presence of minimal aromatase and 5α-reductase activity in the tumor.

Binding studies with insulin labeled with iodine 125 showed the presence of specific insulin binding sites in

the tumor tissue. The percentage of specific total binding of ^{125}I insulin in tumor tissue was 3.7%/100 μg protein, which is below the normal range seen in premenopausal ovarian stroma (4.3% to 13.0%/100 μg protein). Fig. 4 shows the competition curves for binding of ^{125}I insulin to ovarian microsomal membranes prepared from ovarian stroma from 11 premenopausal women and the membranes from tumor tissue, in the absence and presence of unlabeled insulin at the concentrations shown on the X axis. Shown are the mean and SE for studies in ovarian membranes from 11 premenopausal women. The tumor data points represent the means of triplicate determinations. The Scatchard plots of the high-affinity segments of the data (first five points) were parallel (inset of Fig. 4), which indicates that the difference in insulin binding was a result of a difference in the concentrations of receptors rather than differences in affinity. The affinity constants for the specific high-affinity insulin receptors from these preparations were 1.28×10^9L/mol for the tumor and 2.7 ± 0.5 gm $\times 10^9$L/mol for the normal ovarian stroma.

Comment

There is considerable controversy about the origin of Sertoli and Leydig cells in the arrhenoblastoma of the ovary. Inasmuch as the hilum of the normal ovary contains cells that resemble testicular Leydig cells, it has been speculated that arrhenoblastomas and hilus cell tumors of the ovary arise from these cells. Kurman and colleagues[14] studied the site production of testosterone and 17β-estradiol in Sertoli-Leydig cell tumor tissue with the use of immunohistochemical techniques. They observed that primitive spindle cells, which resemble cells found in the embryonic gonad, are present in Sertoli-Leydig cell tumor and suggested that these cells could be precursors of both Sertoli and Leydig cells. Ultrastructural studies by Genton[15] suggest that the arrhenoblastoma arises from ovarian stroma. The pathogenesis of Sertoli-Leydig cell tumors from these cells is also not well understood. An arrhenoblastoma is often seen in association with polycystic ovarian disease as it was in our patient. Most patients with an arrhenoblastoma have, as did our patient, a long history of obesity and irregular menstrual cycles that preceeded the development of signs of virilization.[16] Our patient had hyperinsulinemia with normal glucose levels, which indicated insulin resistance. Moreover, the tumor removed from our patient had specific binding sites for insulin and responded to insulin and LH with an increase in the release of androstenedione. Sternberg and colleagues[17] observed that the Leydig-like hilus cells of the ovary became more prominent and showed evidence of mitosis when treated with gonadotropins. It is possible that the elevated LH levels and hyperinsulinemia of polycystic ovarian disease may play a role in the histogenesis and development of these tumors.

Both the in vivo and in vitro studies of the tumor indicate that the increase in testosterone secretion resulted from increased availability of precursors from both the Δ^4 and the Δ^5 pathways. The relatively higher levels of 17OHΔ^5P and DHEA in the ovarian venous serum, as compared with levels of progesterone and 17OHP, indicate the predominance of the Δ^5 pathway. These findings are in agreement with the in vitro studies of Maschler and colleagues[18] who observed a decreased conversion of Δ^5P to progesterone and 17OHP in an arrhenoblastoma. With the use of 7^3H-pregnenolone as a substrate, Kase and Conrad[19] observed greater incorporation of radioactivity in DHEA than in progesterone, and concluded that the Δ^5-3βOH pathway was the predominant pathway of steroidogenesis in this tumor. With the use of ^{3}H-Δ^5P and ^{14}C-progesterone as substrates, YoungLai and colleagues[20] observed that arrhenoblastoma tissue used ^{3}H-Δ^5P preferentially via the Δ^5 pathway in the synthesis of androstenedione, which is the direct precursor of testosterone. Although predominance of the Δ^5 pathway indicates a certain similarity between arrhenoblastoma and testicular Leydig cells, the associated increase in Δ^4 precursors that we found supports the contention of Genton and colleagues[15] that an arrhenoblastoma arises from ovarian stromal cells. We believe arrhenoblastomas have a dual origin and probably derive both from ovarian hilus cells and from steroidogenically active stromal cells.

We found no report of previous studies in vitro of the effects of insulin on steroidogenesis in Sertoli-Leydig cell tumors. Because insulin did not affect DHEA secretion, it probably stimulates only the Δ^4 pathway of steroidogenesis. The decreased concentration of insulin receptors in the tumor, as compared with concentrations in normal ovarian stroma, could be a result of down regulation in response to the elevated insulin levels we found in our patient. Because only a small percentage of insulin receptors are occupied at insulin concentrations that have maximal biologic effects, a decrease in receptor binding would not be expected to change the maximal effect of insulin.[21]

Among previous studies of Sertoli-Leydig cell tumor, reports on effects of LH on testosterone secretions in vitro are conflicting. Specific LH binding sites have been demonstrated in Leydig cell tumors of the ovary.[18] Brunsted et al.[22] observed that in doses ≤100 mIU/ml, human chorionic gonadotropin failed to stimulate testosterone secretion by a Sertoli-Leydig cell tumor in vitro. However, Lamberts et al.[23] observed a doubling of testosterone secretion by dispersed Sertoli-Leydig cell tumor cells when 2 μg/ml of LH was added to the medium. It is of interest that, in our patient, there was no increase in testosterone secretion with LH treatment

but there was an increase in androstenedione secretion. This finding could indicate that the final step of the synthesis of testosterone, namely the conversion of androstenedione to testosterone by 17β-hydroxysteroid dehydrogenase, is probably not LH-dependent. Kondo and colleagues[24] did not observe stimulation of 17β-hydroxysteroid dehydrogenase activity in the hypophysectomized rat ovary when treated with LH. In another study,[25] in vitro treatment of *Xenopus* follicles with human chorionic gonadotropin induced a 40% decrease of 17β-hydroxysteroid dehydrogenase activity. The lack of increase in testosterone secretion could also be a result of the limitations of the in vitro system. With in vitro studies, conditions and availability of cofactors may not be the same as in physiologic conditions in vivo.

Our results indicate the following conclusions:

1. Increased testosterone secretion by the Sertoli-Leydig cell tumor results from increased availability of precursors from both Δ^4 and Δ^5 pathways.

2. The tumor responded to LH with an increase in release of androstenedione and DHEA.

3. Insulin had no effect on DHEA release—a result that may indicate that insulin stimulates steroidogenesis in the tumor only via the Δ^4 pathway.

4. The tumor had specific binding sites for insulin.

5. The increased insulin and LH levels that are present in polycystic ovarian disease may play a role in the pathogenesis of Sertoli-Leydig cell tumors.

Fetomaternal hemorrhage—Possible cause of fetal distress and death

To the Editors:

We read with interest the article by Stafford et al. (Stafford PA, Biddinger PW, Zumwalt RE. Lethal intrauterine fetal trauma. AM J OBSTET GYNECOL 1988;159:485-9). In their study they concluded on the basis of eight cases that lethal placental or direct fetal injury may occur with even minor maternal injury. Indeed, abruptio placentae of a severe degree may cause fetal death acutely and direct fetal trauma (i.e., skull fracture may also result in intrauterine fetal death); however, the authors neglect to mention fetomaternal hemorrhage as a possible cause of fetal distress and fetal death.

Rose et al.[1] found significant fetomaternal hemorrhage 28% of the time in gravid women who had undergone recent trauma. Fetal death, anemia, and paroxysmal atrial tachycardia occurred in the group of patients who had fetomaternal hemorrhage. Significant fetomaternal hemorrhage may also be associated with abruptio placentae.[2] The degree of the fetomaternal hemorrhage may be quantitated with Mollison's formula.[3]

We concur with Rose et al. that fetomaternal hemorrhage should be assumed in all cases of maternal trauma. Kleihauer-Betke stains are useful in the detection of fetomaternal hemorrhage and may aid in the management of such cases. Lastly, let us beware that insignificant maternal trauma may lead to significant medicolegal damage as a result of unsuspected fetomaternal hemorrhage.

Reply

To the Editors:

In our article we focused on the extent of maternal, fetal, and placental injuries associated with motor vehicle accidents. In every case, some type of placental abnormality was detected, usually abruption or infarction. We regard fetomaternal hemorrhage as a potential complication of placental injury and a mechanism for fetal distress and fetal death. Although we did not specifically discuss this mechanism, we readily acknowledge its possibility and agree that the Kleihauer-Betke test is useful in the detection of fetomaternal hemorrhage. Nevertheless, we are pleased that Drs. Cardwell and Snyder seem to agree with our major conclusion that lethal intrauterine fetal trauma can occur even though maternal injuries are minor or insignificant.

Dosage and duration differences lead to diverse conclusions

To the Editors:

The very interesting article (Smarr SC, Wing R, Hammond MG. Effect of therapy on infertile couples with antisperm antibodies. AM J OBSTET GYNECOL 1988;158:969-73) raises some important questions. Their well-documented results indicate that the use of prednisone medication in patients who have an infertility problem and who also have shown the presence of sperm antibody activity, was not effective in the improvement of pregnancy rates. Whereas this conclusion is quite valid for the management that they used, the conclusion may be misleading, especially because they seem to be contrasting their results with the highly successful results that we observed with the use of corticosteroid medication in such cases. Nonetheless, their conclusion is quite reasonable, as was ours; this difference in efficacy is a consequence of the tremendous difference in dosage of the steroid and also in the duration.

In our first report of the use of steroid for suppression of the antibody problem,[1] we suggested the use of 96 mg per day of methylprednisolone (Medrol) for a period of 7 days. This was subsequently modified to be a repeated regimen, with the same 7-day course given at monthly intervals. Durations up to 6 months might be used. A large group was studied over several years, and a success rate of 44% in terms of pregnancies achieved was reported.[2] Others also used this intermittent, *high-dose method,* as it became termed, with very satisfying results, as has been reviewed.[3] However, Smarr et al. used a *low-dose method* and gave only 15 mg per day of the steroid prednisone for a duration ≤3 months. This procedure has some similarity to the ear-

lier work of Hendry and his colleagues,[4] although they often continued their regimen (15 mg per day of prednisone) for as long as 12 months. They found that this method could be successful, although not as often as the high-dose method. It may be important to note that Hendry et al. were treating men, and women were treated in the report by Smarr et al. Nonetheless, there may be some importance in a treatment duration longer than 3 months.

We also must consider the methods for the detection of sperm antibody. Smarr et al. have used a particular method of passive hemagglutination[5] and a method of cytotoxicity,[6] both developed by Mathur and colleagues. Whereas these methods may be reasonable and useful, most of the earlier work has been done with the standard methods of sperm agglutination. There has not been any extensive comparison between these two groups of methods. All these methods have been extensively reviewed and described.[7,8] I urge that future studies in the detection of this antibody activity be done with the well-established agglutination techniques to allow comparison with the former findings.

I should also comment on the value of the agglutination techniques. If these are properly done with regard to serum dilution levels, control sera, length of incubation, nature of the reading for minimal reactivity, and repetitions of each test, they have proved to be as reliable and reproducible as any other method.[9] Smarr et al. quote Mettler et al.,[10] "Some fertile women have been shown to have agglutination antibodies; however, immobilizing and cytotoxic antibodies are found almost exclusively in infertile couples." However, in our work published in this JOURNAL many years ago,[11] we showed that very few women from fertile couples had agglutinating antibody and these were at low titers, whereas a much higher number of infertile women showed this activity and at higher titers.

Smarr et al. also quote Hekman and Rümke,[12] "Agglutination assays are less specific in that many factors other than antibodies . . . are known to cause sperm agglutination." This philosophic concept should also be laid to rest as being rather unlikely in the vast majority of serum studies because there are, in fact, low incidences of positive results when sera from fertile individuals are tested; it would be difficult to see why the perturbing and nonspecific factors should only occur in sera from people afflicted with infertility.

Reply

To the Editors:

I would like to respond to Dr. Shulman's insightful comments with regard to our article on treatment of antisperm antibodies. Dr. Shulman has raised several important questions with regard to the diagnosis and treatment of sperm antibody related infertility.

The first question has to do with the appropriate assessment of the results of treatment. In our article we report pregnancy rates that varied between 32% and 48% for patients who received prednisone or other forms of treatment, excluding in vitro fertilization. This "pregnancy rate" is a raw pregnancy rate that determines the number of patients who conceived but does not introduce a factor of time. Dr. Shulman[1] reports a similar pregnancy rate in his treatment groups, again, uncorrected for time. Both studies would benefit from life table analysis, which could report a per cycle pregnancy rate and would eliminate the variable of varying length of treatment and length of follow-up. It is of interest that Dr. Shulman's pregnancy rate is similar to ours but is also similar to our control group of untreated patients. It is important in all studies of infertility treatment to identify and follow up a control group of patients who do not receive treatment to demonstrate a benefit of treatment. There is as yet no controlled study that shows benefit for methylprednisone therapy.

The second area of concern has to do with the di-

agnosis of antisperm antibodies and indeed this is an area of active controversy. Each center has antibody testing procedures that they prefer. A number of methods are used and new methods for the detection of antibodies appear on a regular basis. It is difficult to make a case that one method is better than another. It is most important that the method selected be adequately standardized with local normal populations and performed with care. One of the difficulties in the evaluation of the literature is the fact that no center performs all tests; thus comparison of titers and test results is not possible.

Apparently it was not clear from our article that we treated both male and female partners in our study, treating whichever partner was antibody positive. However, the data were not divided along these lines.

To clarify our statement that agglutinating assays are less specific because of other factors that cause positive sperm agglutination, we refer only to seminal plasma. Males with infections will frequently have positive antibody titers in the semen.

I hope that our article and this discussion will stimulate others to design appropriate evaluation of antisperm antibody treatments that involve the use of a control group, either a well-standardized and widely used assay or multiple antisperm antibody assays, and life table analysis of the results.

Number clarification requested

To the Editors:

I read with interest the article by Wilkins et al. (Wilkins IA, Lynch L, Mehalek K, Berkowitz GS, Berkowitz RL. Efficacy and side effects of magnesium sulfate and ritodrine as tocolytic agents. Am J Obstet Gynecol 1988;159:685-9). The authors attempt to assess the relative efficacy and side effects of these two agents (given alone or in combination). I have a specific question with regard to the number of patients presented in Tables III and IV. In Table IV, the "Total no. of patients receiving drugs" in the magnesium sulfate category is listed as 70. However, if the number of patients listed in Table II (n = 66) and the number of patients who received magnesium sulfate as a second-line drug in Table III (n = 6) are combined, the total number should be 72. Similarly, the total number of patients who received both drugs intravenously in Table IV is listed as 13. However, from Table III, the total number of patients who received both drugs together intravenously should be 11. It would be very helpful if the authors would clarify these discrepancies and, if necessary, re-evaluate the statistical analysis of their data, should the numbers reported be in error.

Although we agree that systemic tocolysis is associated with potentially serious side effects, our data concerning combination therapy[1,2] do not suggest that the incidence of side effects from combination therapy is markedly different from that seen with ritodrine alone. Continuing experience with this type of treatment with the involvement of greater numbers of patients might answer the questions raised.

Reply

To the Editors:

We are greatly flattered by the close attention that Dr. Hatjis paid to our article. He is entirely correct that there is an error in Table III. Although 10 patients who received ritodrine therapy required second-line therapy, 4 of those received magnesium sulfate and 6 received both drugs together. The next column regarding delivery should also be reversed. All of the patients in both groups achieved a 48-hour delay. The remainder of the table is correct, as is Table IV. Because of the small numbers in Table III, we did not perform any statistical analysis; therefore the remainder of our results and the Comment section are unchanged.

Of course, we are aware of Dr. Hatjis' work with regard to combination tocolytic therapy and agree wholeheartedly that more work needs to be done to clarify this issue.

Pulmonary artery agenesis

To the Editors:

The title of the article recently published by Stiller et al. (Stiller RJ, Soberman S, Turetsky A, Lockwood C, Haddad R. Agenesis of the pulmonary artery: An unusual cause of dyspnea in pregnancy. Am J Obstet

GYNECOL 1988;158:172-3) attracted my attention because I was unfamiliar with the entity of pulmonary artery agenesis. However, in describing their patient's lesion, the authors stated that the computerized tomographic scan revealed the main right pulmonary artery and proximal descending portions to be "hypoplastic" compared with the left side. The authors reviewed findings in other reports of patients with pulmonary artery *agenesis* and referred to their own patient's lesion as such.

In 1978, a working group on nomenclature published proposed definitions to describe abnormal biologic developmental processes.[1] Agenesis is defined as "absence of a part of the body due to an absent anlage (primordium)"; hypoplasia is "underdevelopment of normally structured and formed organism, organ or tissue." The definition of agenesis is essentially the same in *Dorland's Medical Dictionary*, 25th edition, 1974, and *Webster's Seventh New Collegiate Dictionary*, 1972. In addition, the references cited by Stiller et al. clearly describe "absence" of a pulmonary artery rather than hypoplasia.[2, 3]

Whereas other dictionaries may define agenesis somewhat differently, I believe that the medical community uses the terms as defined above and that it is useful to maintain the distinction between agenesis and hypoplasia.

Other routes charted after description of adventurous journey of CA 125

To the Editors:

With great interest I read the article by Quirk et al. (Quirk JG, Brunson GL, Long CA, et al. CA 125 in tissues and amniotic fluid during pregnancy. AM J OBSTET GYNECOL 1988;159:644-9). I agree with the authors that the decidua is one of the sites of CA 125 synthesis. However, to "explain the distribution of CA 125 in maternal blood, decidua, and amniotic fluid during gestation" a hypothesis describing a rather adventurous journey of CA 125 through the fallopian tubes to the peritoneal cavity is presented. This mechanism of tubal reflux was published earlier by others[1] and served as an explanation for elevated serum levels during menstruation. With the aforementioned hypothesis, raised maternal CA 125 concentrations that occur after the first trimester of gestation[2] can hardly be explained.

A wide distribution of CA 125 in benign and malignant tissues and body fluids has been reported.[3-6] Furthermore, except in ovarian carcinoma, elevations in the serum of women with different benign[1, 2, 5] and malignant[5, 6] disorders were reported. In agreement with Fleuren et al.[7] it is concluded that in malignant tumors CA 125 gains access to the circulation by a leakage of the antigen. In addition, a diffusion of antigen from body fluids (ascites, cervical mucus, amniotic fluid) into veins and lymph vessels during infiltrative growth, inflammation, and gestation is conceivable.

Thus elevations of CA 125 in patients with advanced cervical and endometrial carcinoma,[6] carcinoma and cirrhosis of the liver,[5] and pelvic inflammation[2] can be explained. Consistent with this assumption would be an antigen transfer into the maternal circulation from the amniotic fluid and the decidua.

Reply

To the Editors:

We appreciate Dr. Fuith's thoughtful reading of our article and agree that during infiltrative growth and inflammation, CA 125 likely gains access to the circulation directly from its source. Indeed, the elevated levels of CA 125 found in maternal serum in the first trimester may simply reflect infiltrative growth of the

immature placenta within the decidua. The "adventurous journey" that we hypothesized for CA 125 in pregnancy needs to be tested, but we were pleased to learn that Bast thinks "tubal reflux" is a possible mechanism for the rise in serum CA 125 observed during menses.[1]

With respect to understanding the biologic function of CA 125, its method of entry into the circulation is probably of little significance. However, we do not think nor do the available data support the notion that CA 125 simply diffuses into the maternal serum from the amniotic fluid and the decidua. Rather, it seems that for most of pregnancy, CA 125 of putative decidual origin gains access to the amniotic fluid compartment and is excluded from the maternal circulation.[2-4] Ultimately, it will be important to discover why this large-molecular-weight glycoprotein of decidual origin is found in such high concentrations in amniotic fluid throughout pregnancy.

Perinatal death as a result of social factors

To the Editors:

The perinatal death rate of normally formed infants at or after term pregnancy as a result of social conditions is nearly 40% in the article by Delke et al. (Delke I, Hyatt R, Feinkind L, Minkoff H. Avoidable causes of perinatal death at or after term pregnancy in an inner-city hospital: medical versus social. AM J OBSTET GYNECOL 1988;159:562-6). The authors conclude, "It would seem reasonable to assume that efforts to improve perinatal mortality rates will need to be played out in a broader arena than the hospital. Indeed, these efforts may be dependent on society's willingness to address the problem of endemic poverty."

The social problems that need to be addressed go beyond education, which the authors also advocate, and elimination of poverty. Substance abuse, pregnancy in teenagers, multiparity much greater than three or four (which should satisfy the fictional parity of 2.2 required for population maintenance and account for those who remain childless either by choice or infertility), pregnancy in the single unemployed mother, pregnancy in the woman with chronic life-shortening disease, and pregnancies in others unable to provide adequate nourishment, clothing, shelter, education, and love until the child reaches maturity all need to be addressed. An ounce of contraceptive prevention may well be worth far more than several pounds of a bouncing newborn who may survive the perinatal period only to suffer when growing up and be destined to repeat the cycle.

Is it reasonable to conclude that if society has an interest in addressing the problem of perinatal death as a result of social factors that it may as well have an interest, both logically and legitimately, in addressing the question of who gets pregnant, how often, and when?

This is a personal communication of the author's and is not to be construed as representing either Kaiser Permanente or the Southern California Permanente Medical Group.

Reply

To the Editors:

We must confess to being somewhat taken aback by what we perceive to be the subtly laid out agenda of Dr. Fribourg's letter. Hidden beneath laudable sentiments about the "clothing, shelter, education, and love" necessary to rear children are comments that come dangerously close to having undertones of racism and social engineering. Society does *not* have a moral "interest" in addressing the question of who gets pregnant beyond empowering women to choose their family size. Once we develop criteria to link family size to employment status and marital status, we approach the edge of a slippery slope that augers poorly for reproductive rights.

Techniques differ in use of Doppler ultrasonography

To the Editors:

We are pleased that Lee et al. confirmed our findings that Doppler technique is an accurate means to noninvasively measure cardiac output in pregnancy (Lee

W, Rokey R, Cotton DB. Noninvasive maternal stroke volume and cardiac output determinations by pulsed Doppler echocardiography. AM J OBSTET GYNECOL 1988;158:505-10). With growing acceptance of the method, a great potential exists to broaden our understanding of hemodynamics in pregnancy. However, we must take exception to their criticisms of our technique.

Dr. Lee suggests on theoretic grounds that his method is superior to ours. We measure the aortic diameter with A-mode ultrasonography just distal to the excursion of the valve leaflets. The velocity profile is measured with continuous Doppler ultrasonography from a suprasternal window.[1] Dr. Lee measures the aortic diameter at the valve annulus with a two-dimensional imaging system. He measures the velocity profile with pulsed Doppler ultrasonography from an apical five-chamber window.

Notwithstanding theoretic concerns, the accuracy of a method must be determined on the basis of data. Although Dr. Lee's study produced results very similar to ours, our regression line more closely approximates the ideal line, $y = x$. The following examples generated from each regression line demonstrate the differences:

	Cardiac output (L/min)	
Thermodilution	5.0	11.0
Easterling et al.	4.6	11.2
Lee et al.	4.3	12.4

We believe that Doppler technique is the best available noninvasive method to measure cardiac output. The concordance of Dr. Lee's work with ours with the use of slightly different techniques should enhance the growing acceptance of the method.

Reply

To the Editors:

In the process of effectively evaluating new methods it is often important to compare techniques with other reported work. However, it should not be too surprising that both continuous-wave Doppler and pulsed wave Doppler determinations of maternal stroke volume correlate well with thermodilution studies since this application has been extensively evaluated in nonpregnant subjects.[1] In this regard, it is extremely difficult to imply that any particular method is clearly superior over other techniques because of the limited number of pregnant patients who have been simultaneously studied by pulmonary artery catheterization. We do agree that Doppler ultrasonography is probably the best noninvasive method for the estimation of maternal stroke volume and cardiac output. However, if optimal aortic waveform data cannot be obtained because of technical reasons then one should consider a variety of other echocardiographic windows and Doppler techniques. In our experience, this will depend on body habitus, position, patient cooperation, anatomic variation, and availability of appropriate instrumentation. These factors will often determine whether a particular Doppler technique is more effective for a given patient.

There are certain advantages and limitations to both techniques. For example, pulsed-wave Doppler estimations of maternal stroke volume by the apical five-chamber window is primarily useful in the lateral and supine positions only. In contrast, application of continuous-wave Doppler through the suprasternal notch may be applied to several positions as recently demonstrated by Dr. Easterling.[2] Furthermore, there is less cost for a dedicated nonimaging continuous-wave Doppler system as compared with instrumentation with pulsed-wave Doppler capabilities. Occasionally, there may be difficulty with consistent acquisition of good quality aortic velocity waveforms by continuous-wave Doppler from the suprasternal notch when compared with pulsed-wave Doppler through the apical view. However, these discrepancies may simply be a matter of technique.

With the continuous-wave Doppler system, blood flow velocities are measured at all points along the pathway of the Doppler signal and our greatest concern about this technique is related to the difficulty of matching a corresponding section of aorta with the flow velocity waveform to calculate absolute volumetric flow. At our perinatal facility, we use suprasternal notch continuous-wave Doppler ultrasonography to obtain *relative* changes in stroke volume (for instance, before and during maternal exercise). We prefer to use the pulsed-wave Doppler technique to estimate *absolute* stroke volume because real-time imaging of the heart will allow measurement of the aortic annulus at the specific site of Doppler interrogation and associated angle correction factors can also be minimized. Furthermore, the pulsed-wave Doppler sample volume can be specifically placed at the corresponding aortic annulus, which is the limiting orifice that is associated with peak velocity, laminar blood flow, and a flat spatial velocity profile.[3]

Aside from these theoretic considerations, Dr. Easterling and colleagues have nicely demonstrated the application of a valuable technique to pregnancy. Pulsed- and continuous-wave Doppler ultrasonographic techniques should be jointly regarded as important but complementary adjuncts to other echocardiographic methods (e.g., two-dimensional, M-mode) that can be

used to noninvasively evaluate maternal hemodynamic function.

Response by Drs. Easterling and Benedetti. We agree with Drs. Lee and Rokey that Doppler technique is the best noninvasive method to measure cardiac output in pregnant patients. In our hands, continuous-wave Doppler has been demonstrated to correlate well with thermodilution. In Dr. Lee's hands, pulsed-wave Doppler has been demonstrated to work equally well. Neither Dr. Lee nor we use both methods extensively. Therefore, reasonable comparisons cannot be made. Each method with an experienced operator can be expected to accurately predict absolute cardiac output.

Maternal hematocrit and premature labor

To the Editors:

Contrary to Lieberman et al. (Lieberman E, Ryan KJ, Monson RR, Schoenbaum SC. Association of maternal hematocrit with premature labor. AM J OBSTET GYNECOL 1988;159:107-14), I believe that the association of maternal hematocrit with premature labor is simple. There is a physiologic anemia of pregnancy that is most severe in the second and early third trimesters when, by definition, cases of premature labor occur.[1] This decrease in hematocrit is documented by tables 1.3 and 1.5 in *The Physiology of Human Pregnancy* by Hytten and Leitch.[2] Lieberman et al. attempt to refute this simple explanation by reference to only a minimal change in maternal hematocrit. We need to know the hematocrit values of their patients with normal pregnancies in the second trimester and at term. I believe that it is almost a universal experience that maternal hematocrits in pregnant women rise at least 10% between the second trimester and term when they are given additional iron. What information do we have about the iron intake of their subjects?

While the authors did make reference to their very similar article in *The New England Journal of Medicine,* "Risk factors accounting for ratio differences in the rate of premature labor," is this not an example of "repetitive" publications[3]? Given the criticism the authors received by the multiple letters to the editor, as well as the editorial in *The New England Journal of Medicine,* I am surprised that they persisted in their repeat presentation, especially since Fig. 1 of their reply shows that increased hematocrit can be associated with increased percent of prematurity.[4] Is their argument only over the position of the nadir of the hematocrit curve versus percent prematurity?

To the Editors:

We are well aware the there are physiologic changes in hematocrit over the course of pregnancy, including a decrease in hematocrit early in pregnancy. Changes in hematocrit in later pregnancy, however, are less well documented. Although Dr. Goodlin believes that it is "... almost a universal experience that maternal hematocrits in pregnant women rise at least 10% between the second trimester and term ...," he cites no references to support this view. The literature shows that when hematocrits are measured serially in individual women, hematocrit values either stabilize by 24 weeks[3] or increase slightly (two percentage points or less) between 25 and 30 weeks and term.[4,5] We have previously shown that after adjusting for such small changes, the association of hematocrit with premature labor remains strong.[6] Dr. Goodlin further inappropriately draws conclusions that are based on a hypothetical model that appeared in our letter to *The New England Journal of Medicine.*[6] This model corrected for possible changes in hematocrit over the course of pregnancy and was constructed solely to demonstrate that the association of hematocrit and premature birth would remain even after adjusting for hematocrit changes that might occur late in pregnancy. Finally, we agree that serial examination of both second-trimester and term hematocrits in the same patients would be useful and we have been collecting such data.

We were puzzled by Dr. Goodlin's accusation of repetitive publication on our part. The two articles to which he referred (1,2) were both published in the literature in leading peer-reviewed journals and were cross-referenced. While both are related to preterm birth, they focus on completely different issues. The article in the JOURNAL[1] focused on hematocrit as a risk factor for preterm labor. The other article[2] considered

a wide variety of socioeconomic and medical variables (including hematocrit) as part of an examination of the increased risk of preterm labor in black women. Its aim was not to determine if variables themselves were risk factors for premature labor but rather to ascertain whether these specific risks accounted for racial differences in the occurrence of premature labor. The analyses of the two articles were conducted independently and the groups of women in the two studies were not identical. We suggest that Dr. Goodlin read both articles and reconsider his accusation.

Multiple gestation with intrauterine insemination and menotropin therapy

To the Editors:

Dodson et al. recently reported their experience with combined intrauterine insemination and menotropin therapy (Dodson WC, Hughes CL Jr, Haney AF. Multiple pregnancies conceived with intrauterine insemination during superovulation: an evaluation of clinical characteristics and monitored parameters of conception cycles. AM J OBSTET GYNECOL 1988;159:382-5). They concluded that "25% to 30% of the conceptions" will "unavoidably result in multiple pregnancy." (Actually, their data describe pregnancies past the first trimester rather than "conceptions.") We do not believe that their conclusion is warranted.

We had previously reported a similar experience with menotropin/intrauterine insemination therapy[1] but have now been able to reduce the multiple gestation rate substantially. In 1987, only 3 of 35 viable pregnancies in patients with combined menotropin/intrauterine insemination therapy resulted in multiple pregnancies (all twins), for a multiple gestation rate of $<10\%$.

We see three significant differences between our approach to menotropin/intrauterine insemination therapy and that used by Dodson et al., which may contribute to our lower multiple gestation rate: (1) Patient selection. Virtually all patients in our menotropin/intrauterine insemination program represent failures of clomiphene citrate/menotropin/intrauterine insemination therapy. The prior use of the clomiphene citrate/menotropin/intrauterine insemination protocol[2] may preselect patients with a lower fecundity for the menotropin/intrauterine insemination program resulting in lower pregnancy rate per cycle and a decreased number of multiple gestations. (2) Menotropin management. Dodson et al. stated that human chorionic gonadotropin is administered when "one follicle or more" measure >15 mm. Apparently more than one follicle >15 mm was quite common because they reported the mean number of such follicles to be 3.5 to 3.8. Similarly, the mean estradiol concentration at human chorionic gonadotropin administration was about 1000 pg/ml. By contrast, the corresponding numbers for our pregnant patients are as follows: mean follicle number ≥ 15 mm, 1.7; mean serum estradiol concentration, 419 pg/ml (menotropin/intrauterine insemination program, 1987). (3) Sperm preparation. Dodson et al. prepared sperm by simple centrifugation and inseminated the entire cellular component of the specimen, approximately 100 million motile sperm. On the other hand, we use a swim-up procedure and, since our initial experience,[1] deliberately limit the number of motile sperm in the inseminate to <20 million.

Since our initial experience with menotropin/intrauterine insemination was similar to that discussed by Dodson et al. and since reductions in sperm number per inseminate represent the major modification in our treatment protocol, the 1987 drop in our multiple gestation rate may reflect primarily the impact of limiting numbers of sperm in the inseminate.

Whereas we were able to reduce the multiple gestation rate, our menotropin/intrauterine insemination program also demonstrated a lower cycle fecundity (10%) than reported by Dodson et al. Whether the lower pregnancy rate can be attributed to patient selection, more conservative menotropin management, or sperm numbers cannot be ascertained from our data at this time, but it is likely that all three factors play a role.

It is our contention that the 25% to 30% multiple gestation rate with menotropin/intrauterine insemination can be reduced. It is possible that this increase

in safety is at the expense of a lower probability of pregnancy per treatment cycle.

Reply

To the Editors:

We appreciate the interest in our publication shown by Corsan et al. and are grateful for the opportunity to continue the dialogue.

We agree that factors potentially associated with an increased multiple gestation rate might include patient characteristics (such as age, diagnosis, parity), prior treatment experience, and sperm preparation techniques. However, at present no convincing evidence of such associations exists. After reviewing our patient population, we determined that these factors were not overrepresented in the couples with multiple gestations.

Management of superovulation may be different at Duke than at the University of Medicine and Dentistry of New Jersey, and there is no simple way to compare the two programs because Shelden et al. did not monitor the ovarian response to menotropin with pelvic ultrasonography.

Corsan et al. indicate that limiting the numbers of sperm inseminated may reduce the multiple gestation rate. They noticed a decrease in the multiple gestation rate in 1987, after limiting the sperm number per inseminate. Our experience does not confirm that such a relationship exists. In our retrospective report we found no association of the multiple gestation rate and the number of sperm inseminated. Additionally, in the past year we noted a 40% decrease in the multiple gestation rate—without limiting the number of sperm inseminated.

In summary, we still cannot identify any clinical features, monitored parameters, or sperm characteristics of a pregnancy cycle currently used in our program that would indicate which couples are more likely to conceive multiple pregnancies with intrauterine insemination and menotropin–induced superovulation. Furthermore, the currently available retrospective analyses that identify correlated factors need to be substantiated with prospective randomized trials.

Allergic vaginitis

To the Editors:

The report by Witkin et al. (Witkin SS, Jeremiahs J, Ledger WJ. Recurrent vaginitis as a result of sexual transmission of IgE antibodies. Am J Obstet Gynecol 1988;159:32-6) proposes that there are subsets of patients with vaginitis caused by immunoglobulin E–mediated reactions, transmitted both actively, through antigens that are present in seminal fluid and react with sensitized vaginal mucosa, and passively, through specific immunoglobulin in seminal fluid that reacts with antigens in the vaginal mucosa. These workers found that the use of a condom eliminates the reactions. The following may be an example of allergic vaginitis caused by atmospheric allergens and suggests an alternative method of treatment of this problem.

The patient, a 26-year-old, married graphic designer, was referred by her gynecologist because of vaginal symptoms that he susepcted might be allergic in nature. In the winter or early spring of 1983, she began to have vaginal itching and burning pain with coitus. The itching, but not the pain, was helped by vinegar douches. In January 1987, vaginal cultures and smears were negative, and she did not respond to empiric treatment with Flagyl. In mid-July she developed symptoms typical of allergic rhinitis, and in September she had increased coital pain. She consulted an ophthalmologist because of itching eyes; allergic conjunctivitis and dry eyes were confirmed by Schirmer's test, and eye symptoms were relieved by topical steroids and cromolyn sodium. By January the nasal, eye, and vaginal symptoms cleared completely, and she was well until mid-July 1988, when she had a recurrence of nasal, eye, and all vaginal symptoms. Examination revealed moderately congested, red, dry nasal membranes, dry, slightly injected conjunctivae, and a clear chest. Results of vaginal examination were unremarkable.

Intradermal tests to inhalant allergens showed significant positive reactions to weeds, grasses, molds, dust, and household environmental agents. Smears of nasal and vaginal secretions showed large numbers of leukocytes (half eosinophils and the rest neutrophils). Impression was allergic rhinitis, conjunctivitis, and possible vaginitis (dry eye syndrome).

For treatment, she was given Opticrom (cromolyn 4%), one drop in each eye, for the eye symptoms and Nasalcrom nasal solution, one puff in each nostril four times daily, for the nasal symptoms. She was instructed to obtain ampules of cromolyn sodium, containing 20 mg in 2 ml, and to inject it intravaginally with a rubber ear syringe four times daily. She returned for follow-up 2 weeks later on August 30, having gone through a menstrual cycle, and reported marked improvement in all symptoms. Specifically, the vaginal symptoms cleared completely, and she no longer had pain or discomfort on coitus.

A smear of nasal secretions was unchanged from the pre-

vious examination. A smear of vaginal secretions showed a moderate number of leukocytes (three fourths neutrophils and the rest eosinophils).

While one can never be certain in an unusual presentation of this kind, the history and response to medication suggest the possibility that this patient did have allergic vaginitis caused by pollen.

Cromolyn sodium acts by stabilizing mast cells, thereby reducing mediator release. Its site of action may involve effects on calcium channels[1] or regulation of phosphorylation of a protein that is essential for degranulation to occur.[2] It has proved useful in preventing allergic conjunctivitis, allergic rhinitis, and asthma caused by allergy, exercise, exposure to cold, and some irritants. Its efficacy in vaginitis remains to be proved by properly controlled studies, but since it is such an innocuous medication, it is reasonable to consider using it to treat vaginitis where allergic mechanisms are suspected.

Since submission of this letter, the patient has gone through the 1989 spring and fall pollen seasons with recurrence of allergic symptoms, including vaginal itching and burning. The vaginal symptoms were again completely controlled with the use of cromolyn instilled intravaginally.

Reply

To the Editors:

Dr. Steven Witkin asked me to comment on the letter from Dr. Dworetzky concerning the use of intravaginal cromolyn sodium for treatment of vaginal allergy.

For the past 18 months I have been prescribing intravaginal cromolyn sodium for patients with allergic vaginitis. Diagnosis of allergic vaginitis was based on the presence of immunoglobulin E by immunofluorescence testing of vaginal secretions. Fifteen patients so diagnosed all were advised to douche vaginally with ampules of cromolyn sodium containing 20 mg in 2 ml twice daily. Fifteen patients have reported results to me. Douching with cromolyn sodium has been beneficial in 35%, with the improvement in vaginal symptoms being modest, rated by the patients at a 30% to 50% improvement in symptoms of itching, burning, and discomfort.

Results of uterine activity studies in agreement, but methods differ

To the Editors:

I read with interest the article by Dr. Nageotte and his coworkers about the spontaneous contraction activity of the pregnant uterus (Nageotte MP, Dorchester W, Porto M, Keegan KA Jr., Freeman RK. Quantitation of uterine activity preceding preterm, term, and postterm labor. Am J Obstet Gynecol 1988;158:1254-9). We agree with the results of the authors but not with the method. The authors prospectively studied the maximum uterine contraction frequency during any 10-minute period in 2446 patients and found significantly higher activity in the premature group. However, the length of observation (i.e., the average number of measurements) also was the highest in the premature group (4.4 ± 1.8 in the preterm group versus 2.2 ± 1.6 in the postterm group). Obviously, anyone has a greater chance to find a 10-minute period with high-frequency activity if the length of the observation is longer. On the other hand, the increased contraction activity of the uterus may clearly appear in a large number of patients in the pathologic group, even with the authors' method, but not in each individual case because a 10-minute period does not represent the whole day's activity.

In a prospective clinical study performed in the past 2 years with a smaller group of pregnant women, we already have observed >600 hours of spontaneous uterine activity of pregnant women between 25 and 37 weeks' gestation.[1] According to our data the activity sometimes suddenly increases, then decreases without any regularity. The difference between "normal" and "abnormal" in some cases is only the number of high-frequency periods per day. So, high-frequency periods may and usually do appear in normal cases, too (e.g., after sexual intercourse or nipple stimulation, or because of a full bladder). Therefore with a 10-minute or even a 30-minute window the physician can and probably will miss most of the pathognomonic periods that appear in some cases one or more times a day, but in another case can register the only high-frequency period of the day.

In light of the above-mentioned facts, we prefer long-time continuous uterine activity monitoring of high-risk patients with portable uterine contraction monitors.[2-4] The predictive value and efficacy of preterm uterine activity monitoring can reach a significant level only by this method.

Reply.

To the Editors:

I would like to take this opportunity to clarify some misunderstandings. The article on uterine activity preceding preterm, term, and postterm delivery addressed the assessment of maximum uterine activity in any 10-minute period *before* uterine stimulation was begun in patients who underwent contraction stress tests. The length of time that preceded the start of uterine stimulation never exceeded 20 minutes according to protocol. Consequently, the maximum contraction rate during any 10 minutes of this 20-minute "window" is what constitutes the study period. It is not any 10-minute period as apparently was the understanding.

Certainly longer periods of monitoring uterine activity will give more information of contraction frequency for a given patient. We do not propose that simply looking at 10 to 20 minutes of uterine activity in a particular patient has any predictive value to time delivery. However, when evaluating a large number of patients it is interesting to note an apparent population-based difference in contraction frequency at a given gestational age for patients delivered of preterm, term, and postterm infants.

Effect of magnesium and preeclampsia on plasma cholinesterase activity

To the Editors:

In a recent report (Kambam JR, Perry SM, Entman S, Smith BE. Effect of magnesium on plasma cholinesterase activity. AM J OBSTET GYNECOL 1988;159:309-11), an approximately 30% reduction in plasma cholinesterase activity was demonstrated in women with preeclampsia as compared with healthy gravid women. There was no difference in plasma cholinesterase activity before and after the administration of magnesium sulfate. It was concluded that the low level of plasma cholinesterase is probably responsible for the prolonged action of succinylcholine in women with preeclampsia who are receiving magnesium sulfate. There are three reasons why this conclusion is questionable. First, the elimination of magnesium sulfate does not depend on plasma cholinesterase; magnesium is excreted primarily by the kidney. Second, there was no difference in the duration of action of succinylcholine between healthy gravid women undergoing cesarean section and women undergoing laparoscopic tubal ligation despite a 20% lower level of plasma cholinesterase in the pregnant women.[1] In healthy puerperal women 2 days post partum, when the plasma cholinesterase level is at its lowest (21% less than at the time of cesarean section),[1] the action of succinylcholine was only 200 seconds longer than in young gynecologic patients, a clinically insignificant prolongation.[2] Third, magnesium sulfate is a depressant of the neuromuscular junction and, as such, prolongs the action of all muscle relaxants, including the nondepolarizing agents, which are not degradated by plasma cholinesterase.[3, 4] Thus the prolongation of the action of succinylcholine in gravid women with preeclampsia can be amply explained by the characteristics of magnesium sulfate alone.

Reply

To the Editors:

Our plasma cholinesterase data show that there is a mean decrease of 60% (range 40% to 80%) and 30% (range 25% to 55%) in pregnant patients with preeclampsia when compared with healthy nonpregnant and pregnant patients, respectively. We hope to clarify the questions raised by Marx.

There are at least two good reasons why pregnant patients with preeclampsia are different from healthy pregnant patients in relation to the duration of action of succinylcholine: (1) The blood volume and consequently the distribution volume are increased for succinylcholine in healthy pregnant patients when compared with pregnant patients with preeclampsia in whom there is a decrease in blood volume; (2) the decrease in plasma cholinesterase activity in patients with preeclampsia is far greater than that seen in healthy

pregnant patients. To our knowledge, there are no published data to date on the correlation of plasma cholinesterase activity and duration of succinylcholine in patients with preeclampsia. A correlative study published by Viby-Mogensen[1] did show that when there is a decrease of >60% to 80% in mean plasma cholinesterase activity, the duration of apnea after succinylcholine (1 mg/kg intravenously) administration in nonpregnant patients lasts up to 22 minutes. This duration of apnea is approximately what we see clinically in patients with preeclampsia after a single dose of succinylcholine, 1 mg/kg intravenously. It is also possible that an occasional patient with preeclampsia and very low plasma cholinesterase activity may develop a desensitization block, in which case the action of succinylcholine may be prolonged several times the usual duration. We have recently shown such a desensitization block after a single injection of succinylcholine in a patient with approximately 20% of normal plasma cholinesterase activity.[2]

Regarding the comment on magnesium pharmacokinetics, we did not state in our article that the elimination of magnesium is influenced by plasma cholinesterase activity. Magnesium is known to decrease the release of acetylcholine at the neuromuscular junction. While a decrease in acetylcholine release at the neuromuscular junction explains the mechanism for prolongation of a nondepolarizing or curare type of block, this does not explain the reason for prolongation of a depolarizing or succinylcholine-induced block. Data of James et al.[3] clearly show that magnesium has no effect on the duration of action of succinylcholine when tested in healthy nonpregnant patients with presumably normal plasma cholinesterase activity levels. On the basis of the fact that there is a decrease in distribution volume, as well as a decrease in plasma cholinesterase activity in preeclampsia, and in the presence of evidence that magnesium does not prolong the action of succinylcholine in nonpregnant patients with normal level of plasma cholinesterase, we concluded that the low level of plasma cholinesterase activity is probably responsible for the prolonged action of succinylcholine in women with preeclampsia who receive magnesium sulfate.

Abe T (*see* Kyodo et al). 1989;161:94-6
Abitbol MM, Monheit AG, Rochelson BL, Stern W, Blyakher L, Saraf V. The use of an indwelling Doppler probe to study acute changes in umbilical artery waveforms in the fetal sheep. 1989;161:1324-31
Abraham A (*see* Kanwar et al). 1989;161:995-6
Abramowicz JS, Jaffe R, Warsof SL. Ultrasonographic measurement of fetal femur length in growth disturbances. 1989;161:1137-40
Abu-Fadil S (*see* Sacks et al). 1989;161:638-41
—— (*see* Sacks et al). 1989;161:642-5
Abulafia O (*see* Feinkind et al). 1989;161:765-70
Adam E (*see* Kaufman et al). 1989;161:1420 (Letter reply)
Adamson SL (*see* Morrow et al). 1989;161:1055-60
Adcock LL (*see* Borazjani et al). 1989;161:1253-7
Adelson M (*see* Baggish et al). 1989;161:60-8
Adler-Storthz K (*see* Kaufman et al). 1989;161:1420 (Letter reply)
Ahn MO (*see* Sarno et al). 1989;161:1508-14
—— (*see* Strong et al). 1989;161:29-32
Ahokas RA, Sibai BM, Anderson GD. Lack of evidence of a vasodepressor role for relaxin in spontaneously hypertensive and normotensive pregnant rats. 1989;161:618-22
Akino T (*see* Hallman et al). 1989;161:965-9
Albazzaz SJ (*see* Hadi and Albazzaz). 1989;161:318-21
Alberda AT (*see* Weyerman et al). 1989;161:1145-6
Alden ER (*see* Cohen et al). 1989;161:1013-4
Ali MM (*see* Hurt et al). 1989;161:530-1
Allen RD (*see* Spinnato et al). 1989;161:742-7
Alonso JG (*see* Valenzuela et al). 1989;161:1566-70
Alvarez RD, Grizzle WE, Smith LJ, Miller DM. Compensatory ovarian hypertrophy occurs by a mechanism distinct from compensatory growth in the regenerating liver. 1989;161:1653-7
Amon E (*see* Sadovsky et al). 1989;161:613-7
Ananth U, Queenan JT. Does midtrimester ΔOD_{450} of amniotic fluid reflect severity of Rh disease? 1989;161:47-9
Andersen HF (*see* Elkins et al). 1989;161:150-4
Anderson CF (*see* Reed et al). 1989;161:1532-5
Anderson DJ (*see* Hill and Anderson). 1989;161:861-4
Anderson GD (*see* Ahokas et al). 1989;161:618-22
—— (*see* Elkins et al). 1989;161:150-4
Anderson JV (*see* Panos et al). 1989;161:357-61
Anderson RE (*see* Sauer et al). 1989;161:1673-6
Andreu A, Genover E, Coira A, Farrán I. Antepartum infection as a result of *Streptococcus pneumoniae* and sepsis in neonate. 1989;161:1424-5 (Letter)
Andrews L (*see* Moore et al). 1989;161:849-55 (Clin. opinion)
Andrianakis P, Walker DW, Ralph MM, Thorburn GD. Effect of inhibiting prostaglandin synthesis in pregnant sheep with 4-aminoantipyrine under normothermic and hyperthermic conditions. 1989;161:241-7
Angel JL (*see* Morales et al). 1989;161:568-72
Ansbacher R. Race and gender factors omitted from results. 1989;161:502 (Letter)
Anyaegbunam A, Billett HH, Langer O, Brustman L, Berger C, Wyse L, Nagel RL, Merkatz IR. Maternal hemoglobin F levels may have an adverse effect on neonatal birth weight in pregnancies with sickle cell disease. 1989;161:654-6
—— (*see* Langer et al). 1989;161:593-9
—— (*see* Langer et al). 1989;161:646-53
Aono T (*see* Mori et al). 1989;161:207-11
Apostolides AY (*see* Cohen et al). 1989;161:1013-4
Appelbaum PC (*see* Pankuch et al). 1989;161:802-7
Appleton CP (*see* Reed et al). 1989;161:1532-5
Arcaini L (*see* Fedele et al). 1989;161:871-6
Archer DF, Hofmann G, Brzyski R, Ross B, Scott RT, Philput CB, Oehninger S, Ware JC. Effects of clomiphene citrate on episodic luteinizing hormone secretion throughout the menstrual cycle. 1989;161:581-92
Arieli S (*see* Pansky et al). 1989;161:393-6
Ariet M (*see* Resnick et al). 1989;161:184-7
Arjomaa P (*see* Hallman et al). 1989;161:965-9
Arnoletti E (*see* Sideri et al). 1989;161:38-42
Arora CP (*see* Castro et al). 1989;161:623-7
—— (*see* Castro et al) (1989;161:623-7). 1989;161:1238 (Correction)

Subject index*

A

Abdominal wall, pathology
Delivery of fetuses with gastroschisis (Weiner). 1989;161:1089 (Letter)

Abnormalities
Amniotic fluid acetylcholinesterase ratios in prenatal diagnosis of fetal abnormalities (Kelly et al). 1989;161:703-5
Comparison of six different ultrasonographic methods for predicting lethal fetal pulmonary hypoplasia (Vintzileos et al). 1989;161:606-12
Dandy-Walker syndrome: a review of fifteen cases evaluated by prenatal sonography (Russ et al). 1989;161:401-6
Delivery of fetuses with gastroschisis (Weiner). 1989;161:1089 (Letter)
The effects of maternal exercise on early pregnancy outcome (Clapp). 1989;161:1453-7
Enlarged cisterna magna in trisomy 18: prenatal ultrasonographic diagnosis (Thurmond et al). 1989;161:83-5
First-trimester midgut herniation: a high-frequency transvaginal sonographic study (Timor-Tritsch et al). 1989;161:831-3
Maternal phenylketonuria and hyperphenylalaninemia: implications for medical practice in the United States (Luder and Greene). 1989;161:1102-5 (Clin. opinion)
Multidisciplinary team counseling for fetal anomalies (Lorenz and Kuhn). 1989;161:263-6 (Clin. opinion)
Significant decrease in congenital malformations in newborn infants of an unselected population of diabetic women (Damm and Mølsted-Pedersen). 1989;161:1163-7

Abnormalities, drug-induced
Attempted suicide and pregnancy (Czeizel and Lendvay). 1989;161:497 (Letter)
Fetal and neonatal cardiovascular complications from β-sympathomimetic therapy for tocolysis (Katz and Seeds). 1989;161:1-9 (Clin. opinion)

Abortifacient agents
Progesterone antagonist lilopristone: a potent abortifacient in the common marmoset (Puri et al). 1989;161:248-53

Abortion
Analysis of fetal loss after transcervical chorionic villus sampling a review of 719 patients (Wade and Young). 1989;161:513-9
The effects of maternal exercise on early pregnancy outcome (Clapp). 1989;161:1453-7
Histologic and immunologic study of uterine biopsy tissue of women with incipient abortion (Michel et al). 1989;161:409-14
Placenta percreta induced uterine rupture and resulted in intraabdominal abortion (Nagy). 1989;161:1185-6
Successful treatment of two women with antiphospholipid antibodies and refractory pregnancy losses with intravenous immunoglobulin infusions (Wapner et al). 1989;161:1271-2

Abortion, induced
Cervical dilation: a comparison of Lamicel and Dilapan (Wells and Hulka). 1989;161:1124-6
The frequency and management of uterine perforations during first-trimester abortions (Kaali et al). 1989;161:406-8

Abortion, missed
Missed abortion: Still appropriate terminology? (Pridjian and Moawad). 1989;161:261-2 (Clin. opinion)

Acetylcholine
In vitro release of endothelium-derived relaxing factor by acetylcholine is increased during the guinea pig pregnancy (Weiner et al). 1989;161:1599-605

Acetylcholinesterase
Amniotic fluid acetylcholinesterase ratios in prenatal diagnosis of fetal abnormalities (Kelly et al). 1989;161:703-5

Acid-base equilibrium
Acid-base status at birth and neurodevelopmental outcome at four and one-half years (Dennis et al). 1989;161:213-20

Acidosis
Acid-base status at birth and neurodevelopmental outcome at four and one-half years (Dennis et al). 1989;161:213-20

Acoustic stimulation
The effect of vibroacoustic stimulation on the nonstress test at gestational ages of thirty-two weeks or less (Druzin et al). 1989;161:1476-8
Effects of low-frequency vibration on human term fetuses (Gagnon et al). 1989;161:1479-85
The effects of vibroacoustic stimulation on baseline heart rate, breathing activity, and body movements of normal term fetuses (Dévoe et al). 1989;161:524-9
Human fetal behavioral states after vibratory stimulation (Gagnon et al). 1989;161:1470-6
Preterm and term fetal cardiac and movement responses to vibratory acoustic stimulation (Thomas et al). 1989;161:141-5

Acquired immunodeficiency syndrome
Immunosuppression in pregnant women infected with human immunodeficiency virus (Biggar et al). 1989;161:1239-44
The impact of the acquired immunodeficiency syndrome epidemic on the philosophy of childbirth (Rotmensch et al). 1989;161:855-6 (Clin. opinion)

Adenocarcinoma
Determination of cellular oncogene rearrangement or amplification in ovarian adenocarcinomas (Smith et al). 1989;161:911-5

Adenosine monophosphate
Uncoupling of excitation from contraction in uterine

*July, 1-260; August, 261-504; September, 505-842; October, 843-1094; November, 1095-1430; December, part 1, 1431-1824; part 2, 1825-1868.

smooth muscle in near-term ewes (Reid et al). 1989;161:229-33

Adenyl cyclase
Up-regulation of guinea pig myometrial adenylate cyclase activity by intrauterine estradiol and progesterone pellets (Hatjis and Koritnik). 1989;161:1073-8

Adenylate cyclase; *see* **Adenyl cyclase**

Administration, rectal
Anal submucosal injection: a new route for drug administration in pelvic malignancies. IV. Submucosal anal injection in the treatment of cancer of uterine cervix preliminary study (Shafik). 1989;161:69-72

Adolescence
Seminoma in pubertal patient with androgen insensitivity syndrome (Hurt et al). 1989;161:530-1
Uterine development and endocrine relationships after menarche (Porcu et al). 1989;161:174-7

Adolescent pregnancy; *see* **Pregnancy in adolescence**

Adrenal cortex hormones
Depressive episodes in premenstrual syndrome (Mortola et al). 1989;161:1682-7

Adrenal glands
Effects of fetal sex and dexamethasone on preterm maternal serum concentrations of human chorionic gonadotropin, progesterone, estrone, estradiol, and estriol (Haning et al). 1989;161:1549-53

Aerobic exercise; *see* **Exercise**

Aged
A new surgical technique to treat refractory labial fusion in the elderly (Johnson et al). 1989;161:289-90

AIDS virus; *see* **HIV**

Albumin
Comparison of in vivo bioavailability of progestational agents into the rat uterus and liver and the effect of plasma protein binding (Van Voorhis et al). 1989;161:1698-703

Allergy; *see* **Hypersensitivity**

Alloimmunization; *see* **Fetal blood, immunology**

Allopurinol
In vivo administration of allopurinol affects ovulation and early embryonic development in rabbits (Miyazaki et al). 1989;161:1709-14

Alpha fetoproteins
Data sought to link adverse pregnancy outcome with maternal serum α-fetoprotein levels in black gravid women (Lenke) (Letter); (Macri et al) (Reply). 1989;161:254-5
Detection of fetal blood (Leiberman et al) (Letter); (Cardwell) (Reply). 1989;161:257-8
Effect of diagnostic and therapeutic cordocentesis on maternal serum α-fetoprotein concentration (Weiner et al). 1989;161:706-8
Predictive values, relative risks, and overall benefits of high and low maternal serum α-fetoprotein screening in singleton pregnancies: new epidemiologic data (Milunsky et al). 1989;161:291-7
The role of ultrasonography and amniocentesis in the evaluation of pregnancies at risk for neural tube defects (Hogge et al). 1989;161:520-4
Unexplained elevated maternal serum α-fetoprotein level associated with third-trimester problems (Stephens). 1989;161:500 (Letter)

Ambulatory care
Outpatient triplet management: a contemporary review (Newman et al). 1989;161:547-5

Amenorrhea
The patient's reaction to side effects of oral contraceptives (Hillard). 1989;161:1412-5 (Symposium)

The American Board of Obstetrics and Gynecology
Board status. 1989;161:1428

American Journal of Obstetrics and Gynecology
Consultants for the American Journal of Obstetrics and Gynecology. 1989;161:1431-8

Amino acids
Plasma amino acids in appropriate- and small-for-gestational-age fetuses (Economides et al). 1989;161:1219-27

Amniocentesis
Amniotic fluid acetylcholinesterase ratios in prenatal diagnosis of fetal abnormalities (Kelly et al). 1989;161:703-5
Amniotic fluid leukotaxis assay as an early indicator of chorioamnionitis (Pankuch et al). 1989;161:802-7
Candida warrants concern (Elliott) (Letter); (Smith) (Reply). 1989;161:503
Ceramide lactoside in amniotic fluid: high concentration in chorioamnionitis and in preterm labor (Hallman et al). 1989;161:313-8
Does midtrimester ΔOD_{450} of amniotic fluid reflect severity of Rh disease? (Ananth and Queenan). 1989;161:47-9
Esterase activity in second- and third-trimester amniotic fluid: an indicator of chorioamnionitis (Hoskins et al). 1989;161:1543-5
5-Hydroxyeicosatetraenoic acid, leukotriene C_4, and prostaglandin $F_{2\alpha}$ in amniotic fluid before and during term and preterm labor (Walsh). 1989;161:1352-60
The incidence of positive amniotic fluid cultures in patients in preterm labor with intact membranes (Skoll et al). 1989;161:813-6
Infection and labor. V. Prevalence, microbiology, and clinical significance of intraamniotic infection in women with preterm labor and intact membranes (Romero et al). 1989;161:817-24
Integration of the transabdominal technique into an ongoing chorionic villus sampling program (Copeland et al). 1989;161:1289-94
The role of ultrasonography and amniocentesis in the evaluation of pregnancies at risk for neural tube defects (Hogge et al). 1989;161:520-4
Surfactant proteins in the diagnosis of fetal lung maturity. II. The 35 kd protein and phospholipids in complicated pregnancy (Hallman et al). 1989;161:965-9
Uselessness of the phosphatidylglycerol assay for prediction of lung maturity (Egberts and Wijnands) (Letter); (Fadel) (Reply). 1989;161:1417-8

Amnion
CA 125 in the epithelium closely related to the embryonic ectoderm: the periderm and the amnion (Nanbu et al). 1989;161:462-7
Ultrasonographic criteria for the prenatal diagnosis of placental chorionicity in twin gestations (Winn et al). 1989;161:1540-2

Amniotic fluid
Antepartum infection as a result of *Streptococcus pneumoniae* and sepsis in neonate (Andreu et al). 1989;161:1424-5 (Letter)
Duplex Doppler ultrasonographic evaluation of the fetal renal artery in normal and abnormal fetuses (Veille and Kanaan). 1989;161:1502-7

Amniotic fluid—cont'd
Evidence relating bacterial vaginosis to intraamniotic infection (Silver et al). 1989;161:808-12
Fetal blood volume, urine flow, swallowing, and amniotic fluid volume responses to long-term intravascular infusions of saline (Brace). 1989;161:1049-54
Impact of residual amniotic fluid volume in patients receiving parenteral tocolysis after premature rupture of the membranes (Silver et al). 1989;161:784-7
Infection and labor. IV. Cachectin–tumor necrosis factor in the amniotic fluid of women with intraamniotic infection and preterm labor (Romero et al). 1989;161:336-41
Intrapartum Doppler velocimetry, amniotic fluid volume, and fetal heart rate as predictors of subsequent fetal distress. I. An initial report (Sarno et al). 1989;161:1508-14
Low amniotic pressure in oligohydramnios Is this the cause of pulmonary hypoplasia? (Nicolini et al). 1989;161:1098-101 (Clin. opinion)
Normal amniotic fluid volume changes throughout pregnancy (Brace and Wolf). 1989;161:382-8
Normal values for human umbilical venous and amniotic fluid pressures and their alteration by fetal disease (Weiner et al). 1989;161:714-7
Saline solution amnioinfusion for oligohydramnios after premature rupture of the membranes (Imanaka et al). 1989;161:102-6
Amniotic fluid, microbiology
Evidence relating bacterial vaginosis to intraamniotic infection (Silver et al). 1989;161:808-12
The incidence of positive amniotic fluid cultures in patients in preterm labor with intact membranes (Skoll et al). 1989;161:813-6
Infection and labor. V. Prevalence, microbiology, and clinical significance of intraamniotic infection in women with preterm labor and intact membranes (Romero et al). 1989;161:817-24
Amoxicillin
Randomized treatment of mucopurulent cervicitis with doxycycline or amoxicillin (Paavonen et al). 1989;161:128-35
Anal drug administration; *see* **Administration, rectal**
Anal sphincter; *see* **Anus**
Analgesia
Fentanyl citrate analgesia during labor (Rayburn et al). 1989;161:202-6
Analgesia, epidural
The effect of continuous epidural analgesia on cesarean section for dystocia in nulliparous women (Thorp et al). 1989;161:670-5
Androgen insensitivity; *see* **Receptors, androgen, deficiency**
Androgens
Androgen sulfate and glucuronide conjugates in nonhirsute and hirsute women with polycystic ovarian syndrome (Matteri et al). 1989;161:1704-9
Androstenedione
Effect of a 48-hour Δ^4-androstenedione infusion on the pregnant rhesus monkey in the last third of gestation: changes in maternal plasma estradiol concentrations and myometrial contractility (Figueroa et al). 1989;161:481-6
Androsterone
Androgen sulfate and glucuronide conjugates in nonhirsute and hirsute women with polycystic ovarian syndrome (Matteri et al). 1989;161:1704-9
Anemia
Does furosemide alter the hemodynamic response to rapid intravascular transfusion of the anemic fetal lamb (Chestnut et al). 1989;161:1571-5
Effect of acute intravascular volume expansion on human fetal prostaglandin concentrations (Weiner and Robillard). 1989;161:1494-7
The effect of intravascular transfusion on umbilical venous pressure in anemic fetuses with and without hydrops (Weiner et al). 1989;161:1498-501
Anemia, fetal; *see* **Fetal hemoglobin**
Anemia, hypochromic
Role of ferritin supported in diagnosis of anemias of pregnancy (Goodlin) (Letter); (Schifman) (Reply). 1989;161:258-9
Anemia, sickle cell
Maternal hemoglobin F levels may have an adverse effect on neonatal birth weight in pregnancies with sickle cell disease (Anyaegbunam et al). 1989;161:654-6
Anencephaly
Fetal hyperinsulinism in anencephaly (Hubinont et al). 1989;161:306-7
Anesthesia, conduction
Pulmonary artery catheterization in severe eclampsia (Gibbs). 1989;161:1089 (Letter)
Anesthesia, obstetrical
Anesthetic management of labor in a patient with dextrocardia, congenitally corrected transposition, Wolff-Parkinson-White syndrome, and congestive heart failure (Sellers et al). 1989;161:1001-3
Reproductive outcome after anesthesia and operation during pregnancy: registry study of 5405 cases (Mazze and Källén). 1989;161:1178-85
Angiomyxoma; *see* **Pelvic neoplasms**
Angiotensin II
Human α- and β-calcitonin gene-related peptides are vasodilators in human chorionic plate vasculature (Firth and Pipkin). 1989;161:1318-9
Lack of evidence of a vasodepressor role for relaxin in spontaneously hypertensive and normotensive pregnant rats (Ahokas et al). 1989;161:618-22
Lymph flow rate response to angiotensin II is decreased in pregnant sheep (Valenzuela and Longo). 1989;161:1615-9
The renin-angiotensin system during pregnancy in chronically instrumented, conscious rats (Conrad et al). 1989;161:1065-72
Angiotensins
Effects of cephalic hypotension, hypertension, and barbiturates on fetal cerebral blood flow and metabolism (Hohimer and Bissonnette). 1989;161:1344-51
Announcements
Board status. 1989;161:1428
Anoxemia
Fetal heart rate patterns in red blood cell isoimmunized pregnancies (Nicolaides et al). 1989;161:351-6
Anoxemia, animal
Effect of prolonged hypoxemia on fetal heart rate accelerations and decelerations in sheep (Bocking et al). 1989;161:722-7
Intrauterine growth retardation and the circulatory responses to acute hypoxemia in fetal sheep (Block et al). 1989;161:1576-9
Umbilical artery flow velocity waveforms during acute hypoxemia and the relationship with hemodynamic changes in the fetal lamb (van Huisseling et al). 1989;161:1061-4

Antibiotics
Antibiotics for postcesarean endometritis (Duff). 1989;161:1087 (Letter)
Short course of antibiotic therapy in treatment of postpartum endomyometritis (Morales et al). 1989;161:568-72
Antibodies
Presence of autoantibodies in women with unexplained infertility (Taylor et al). 1989;161:377-9
The prevalence and biologic significance of lupus anticoagulant and anticardiolipin antibodies in a general obstetric population (Lockwood et al). 1989;161:369-73
Relationship between circulating antisperm antibodies in women and autoantibodies on the ejaculated sperm of their partners (Witkin and Chaudhry). 1989;161:900-3
Sperm antibodies and infertility (Shulman) (Letter); (Witkin) (Reply). 1989;161:497-9
Successful treatment of two women with antiphospholipid antibodies and refractory pregnancy losses with intravenous immunoglobulin infusions (Wapner et al). 1989;161:1271-2
Antibodies, monoclonal
The influence of human antimurine antibody on CA 125 levels in patients with ovarian cancer undergoing radioimmunotherapy or immunoscintigraphy with murine monoclonal antibody OC 125 (Muto et al). 1989;161:1206-12
A monoclonal antibody (MSN-1) against a newly established uterine endometrial cancer cell line (SNG-II) and its application to immunohistochemistry and flow cytometry (Nozawa et al). 1989;161:1079-86
Antibodies, neoplasm
CA 125 in the epithelium closely related to the embryonic ectoderm: the periderm and the amnion (Nanbu et al). 1989;161:462-7
Anticoagulants
Thrombosis prophylaxis in pregnancy with use of subcutaneous heparin adjusted by monitoring heparin concentration in plasma (Dahlman et al). 1989;161:420-5
Antigens
Isoimmunization to Cromer antigen in pregnancy (Sacks and Garratty). 1989;161:928-9
Antigens, neoplasm
Immunohistochemical expression of TAG-72 in normal and malignant endometrium: correlation of antigen expression with estrogen receptor and progesterone receptor levels (Soisson et al). 1989;161:1258-63
Antigens, tumor-associated, carbohydrate
CA 125 in the epithelium closely related to the embryonic ectoderm: the periderm and the amnion (Nanbu et al). 1989;161:462-7
CA 125 as an independent prognostic factor for survival in patients with epithelial ovarian cancer (Sevelda et al). 1989;161:1213-6
The influence of human antimurine antibody on CA 125 levels in patients with ovarian cancer undergoing radioimmunotherapy or immunoscintigraphy with murine monoclonal antibody OC 125 (Muto et al). 1989;161:1206-12
Other routes charted after description of adventurous journey of CA 125 (Fuith) (Letter); (Quirk and O'Brien) (Reply). 1989;161:1747-8
Antihypertensive agents, antagonists
Antagonism of antihypertensive drug therapy in pregnancy by indomethacin? (Schoenfeld et al). 1989;161:1204-5
Antineoplastic agents
Local methotrexate injection: a nonsurgical treatment of ectopic pregnancy (Pansky et al). 1989;161:393-6
Antineoplastic agents, combined
Phase II trial of ifosfamide and mesna in mixed mesodermal tumors of the uterus (A Gynecologic Oncology Group Study) (Sutton et al). 1989;161:309-12
Antiphospholipid antibodies; *see* **Antibodies**
Antispermatogenic agents
Relationship between circulating antisperm antibodies in women and autoantibodies on the ejaculated sperm of their partners (Witkin and Chaudhry). 1989;161:900-3
Anus
Anal and perianal abnormalities in prepubertal victims of sexual abuse (Muram). 1989;161:278-81
Aorta, descending, animal; *see* **Aorta, thoracic, animal**
Aorta, thoracic, animal
Evaluation of pulsed Doppler echocardiography for measurement of aortic blood flow in the fetal lamb (Veille et al). 1989;161:1610-4
Apgar score
Acid-base status at birth and neurodevelopmental outcome at four and one-half years (Dennis et al). 1989;161:213-20
Diagnosis of birth asphyxia on the basis of fetal pH, Apgar score, and newborn cerebral dysfunction (Gilstrap et al). 1989;161:825-30
Arachidonic acids
Effects of chronic fetal hyperinsulinemia on plasma arachidonic acid and prostaglandin concentrations (Stonestreet et al). 1989;161:894-9
Prolonged hyperinsulinemia reduces plasma fatty acid levels in the major lipid groups in fetal sheep (Ogburn et al). 1989;161:728-32
Arginine
Vasopressin receptors in human pregnant myometrium and decidua: interactions with oxytocin and vasopressin agonists and antagonists (Ivanisevic et al). 1989;161:1637-43
Aromatase
Aromatase in human fetal tissues (Doody and Carr). 1989;161:1694-7
Arrhenoblastoma
Steroid biosynthesis in the Sertoli-Leydig cell tumor: effects of insulin and luteinizing hormone (Nagamani et al). 1989;161:1738-43
Arterial lines; *see* **Catheters, indwelling**
Arterial occlusive diseases
Pregnancy after aortofemoral bypass grafting in a diabetic patient (Bradley-Watson). 1989;161:200-1
Artificial intelligence
Heuristic determination of relevant diagnostic procedures in a medical expert system for gynecology (Small and Muechler). 1989;161:17-24 (Clin. opinion)
Ascites
Leiomyoma of the ovary with ascites and hydrothorax (Nicoll and Cox). 1989;161:177-8
Asphyxia neonatorum
Acid-base status at birth and neurodevelopmental outcome at four and one-half years (Dennis et al). 1989;161:213-20
Diagnosis of birth asphyxia on the basis of fetal pH, Apgar score, and newborn cerebral dysfunction (Gilstrap et al). 1989;161:825-30
Aspirin
Aspirin differentially affects thromboxane and prostacyclin production by trophoblast and villous core compartments

Aspirin—cont'd
of human placental villi (Nelson and Walsh). 1989;161:1593-8
Atrial natriuretic peptides; *see* **Natriuretic peptides, atrial**
Autoantibodies
Presence of autoantibodies in women with unexplained infertility (Taylor et al). 1989;161:377-9
Relationship between circulating antisperm antibodies in women and autoantibodies on the ejaculated sperm of their partners (Witkin and Chaudhry). 1989;161:900-3
Autoimmune diseases
Relapsing polychondritis in pregnancy: a case report and review (Gimovsky and Nishiyama). 1989;161:332-4
Azidothymidine
Pharmacokinetics of azidothymidine during late pregnancy in Long-Evans rats (Little et al). 1989;161:732-4

B

Bacteriological techniques
Haemophilus influenzae culture (Winn and Egley). 1989;161:1419 (Letter)
Bed rest
Controlled trial of hydration and bed rest versus bed rest alone in the evaluation of preterm uterine contractions (Pircon et al). 1989;161:775-9
Beta-adrenergic receptors, animals; *see* **Receptors, adrenergic, beta, animal**
Bicycle ergometry test; *see* **Exercise test**
Binding sites
Isolation and sequencing of a complementary deoxyribonucleic acid clone encoding human placental 17β-estradiol dehydrogenase: identification of the putative cofactor binding site (Gast et al). 1989;161:1726-31
Localization of gonadotropin binding sites in human ovarian neoplasms (Nakano et al). 1989;161:905-10
Biophysics
The effect of magnesium sulfate tocolysis on the fetal biophysical profile (Peaceman et al). 1989;161:771-4
Biopsy
Double endometrial aspirative biopsy (Quilez et al). 1989;161:1426-7 (Letter)
Histologic and immunologic study of uterine biopsy tissue of women with incipient abortion (Michel et al). 1989;161:409-14
Birth defects; *see* **Abnormalities**
Birth weight
Birth weight prediction from remote ultrasonographic examination (Spinnato et al). 1989;161:742-7
Effect of birth weight, race, and sex on survival of low-birth-weight infants in neonatal intensive care (Resnick et al). 1989;161:184-7
Intrauterine growth retardation: standards for diagnosis (Goldenberg et al). 1989;161:271-7 (Clin. opinion)
Macrosomia in the postdate pregnancy: Is routine ultrasonographic screening indicated? (Chervenak et al). 1989;161:753-6
Maternal hemoglobin F levels may have an adverse effect on neonatal birth weight in pregnancies with sickle cell disease (Anyaegbunam et al). 1989;161:654-6
Neonatal mortality in normal birth weight babies: Does the level of hospital care make a difference? (Berg et al). 1989;161:86-91
Role of ferritin supported in diagnosis of anemias of pregnancy (Goodlin) (Letter); (Schifman) (Reply). 1989;161:258-9
Bladder
Empty bladder recommended in initial ultrasonographic examinations (Stephens). 1989;161:1088-9 (Letter)
Measurement of fetal urine production in normal pregnancy by real-time ultrasonography (Rabinowitz et al). 1989;161:1264-6
Blood circulation, animal
Intrauterine growth retardation and the circulatory responses to acute hypoxemia in fetal sheep (Block et al). 1989;161:1576-9
Blood flow velocity
Clinical management of the fetus with markedly diminished umbilical artery end-diastolic flow (Divon et al). 1989;161:1523-7
Doppler assessment of the fetal and uteroplacental circulation during nifedipine therapy for preterm labor (Mari et al). 1989;161:1514-8
Doppler assessment of the pulsatility index of the middle cerebral artery during constriction of the fetal ductus arteriosus after indomethacin therapy (Mari et al). 1989;161:1528-31
Duplex Doppler ultrasonographic evaluation of the fetal renal artery in normal and abnormal fetuses (Veille and Kanaan). 1989;161:1502-7
Effect of placental embolization on the umbilical arterial velocity waveform in fetal sheep (Morrow et al). 1989;161:1055-60
Effect of placental laterality on uterine artery resistance and development of preeclampsia and intrauterine growth retardation (Kofinas et al). 1989;161:1536-9
Human fetal tricuspid and mitral deceleration time: changes with normal pregnancy and intrauterine growth retardation (Reed et al). 1989;161:1532-5
Intrapartum Doppler velocimetry, amniotic fluid volume, and fetal heart rate as predictors of subsequent fetal distress. I. An initial report (Sarno et al). 1989;161:1508-14
Maternal and fetal blood flow velocity waveforms in patients with preterm labor: relationship to outcome (Brar et al). 1989;161:1519-22
Umbilical artery flow velocity waveforms during acute hypoxemia and the relationship with hemodynamic changes in the fetal lamb (van Huisseling et al). 1989;161:1061-4
Blood gas analysis
Blood gases, pH, and lactate in appropriate- and small-for-gestational-age fetuses (Nicolaides et al). 1989;161:996-1001
Fetal blood gas analysis from cordocentesis for abnormal fetal heart rate patterns (Shah and Boehm). 1989;161:374-6
Routine umbilical cord blood gas determinations? (Thorp et al). 1989;161:600-5
Blood glucose
Does insulin affect placental glucose metabolism and transfer? (Urbach et al). 1989;161:953-9
The effect of elevated blood glucose on the electroencephalogram and cerebral metabolism during short-term brain ischemia in fetal sheep (Chao et al). 1989;161:221-8
High glucose level decreases proliferation of cultured human fetal cells from placenta (Nelson and Curran). 1989;161:1553-8
Maternal-fetal glucose gradient in normal pregnancies and in pregnancies complicated by alloimmunization and fetal growth retardation (Nicolini et al). 1989;161:924-7
Randomized trial of diet versus diet plus cardiovascular con-

ditioning on glucose levels in gestational diabetes (Jovanovic-Peterson et al). 1989;161:415-9

Blood platelets
Can platelet volume predict progressive hypertensive disease in pregnancy? (Walker et al). 1989;161:676-9
Effect of magnesium on cocaine-induced, catecholamine-mediated platelet and vascular response in term pregnant ewes (Weaver et al). 1989;161:1331-7

Blood pressure
Lack of evidence of a vasodepressor role for relaxin in spontaneously hypertensive and normotensive pregnant rats (Ahokas et al). 1989;161:618-22
The measuring of blood pressure during pregnancy (Villar et al). 1989;161:1019-24
Systolic/diastolic ratios and waveform shapes (Bewley) (Letter); (Schulman) (Reply). 1989;161:1420-1

Blood pressure, high; *see* **Hypertension**

Blood transfusion, intrauterine
Does furosemide alter the hemodynamic response to rapid intravascular transfusion of the anemic fetal lamb (Chestnut et al). 1989;161:1571-5
Does midtrimester ΔOD_{450} of amniotic fluid reflect severity of Rh disease? (Ananth and Queenan). 1989;161:47-9
Effect of acute intravascular volume expansion on human fetal prostaglandin concentrations (Weiner and Robillard). 1989;161:1494-7
The effect of intravascular transfusion on umbilical venous pressure in anemic fetuses with and without hydrops (Weiner et al). 1989;161:1498-501
Fetal cardiac output in the isoimmunized pregnancy: a pulsed Doppler-echocardiographic study of patients undergoing intravascular intrauterine transfusion (Copel et al). 1989;161:361-5
Fetal liver length in normal and isoimmunized pregnancies (Roberts et al). 1989;161:42-6
Frequency and timing of intravascular intrauterine transfusions reconsidered (Voto and Margulies) (Letter); (Socol et al) (Reply). 1989;161:255-6
Ovine fetal cardiovascular responses to packed red blood cell transfusions (Brace). 1989;161:1367-74
Plasma atrial natriuretic peptide in human fetus: response to intravascular blood transfusion (Panos et al). 1989;161:357-61
Prediction of hematocrit decline after intravascular fetal transfusion (MacGregor et al). 1989;161:1491-3
Pulsed Doppler flow-velocity waveforms in the prediction of fetal hematocrit of the severely isoimmunized pregnancy (Copel et al). 1989;161:341-4
Two hundred intrauterine exchange transfusions in severe blood incompatibilities (Poissonnier et al). 1989;161:709-13

Blood volume
Atrial natriuretic factor: the effects of pregnancy and a high-salt diet on atrial levels (Castro et al). 1989;161:1620-3
Fetal blood volume, urine flow, swallowing, and amniotic fluid volume responses to long-term intravascular infusions of saline (Brace). 1989;161:1049-54
Ovine fetal cardiovascular responses to packed red blood cell transfusions (Brace). 1989;161:1367-74
Plasma atrial natriuretic peptide in human fetus: response to intravascular blood transfusion (Panos et al). 1989;161:357-61

Bone development
Long bone growth in fetuses with Down syndrome (Fitz-Simmons et al). 1989;161:1174-7

Books
Books received. 1989; 161:841, 1093, 1429

Brain, blood supply, animal
The effect of elevated blood glucose on the electroencephalogram and cerebral metabolism during short-term brain ischemia in fetal sheep (Chao et al). 1989;161:221-8
Effects of cephalic hypotension, hypertension, and barbiturates on fetal cerebral blood flow and metabolism (Hohimer and Bissonnette). 1989;161:1344-51

Breast diseases
Breast disease programs in obstetrics and gynecology: a plea for training in mammography (Gleicher). 1989;161:267-70 (Clin. opinion)

Breast feeding
Methicillin-resistant staphylococcal mastitis (Kalstone). 1989;161:120

Breast neoplasms
Breast disease programs in obstetrics and gynecology: a plea for training in mammography (Gleicher). 1989;161:267-70 (Clin. opinion)
A case-control study of epithelial ovarian cancer (Hartge et al). 1989;161:10-6 (Clin. opinion)

Breast neoplasms, epidemiology
The cancer question: an overview of recent epidemiologic and retrospective data (Henderson). 1989;161:1859-64 (Symposium)

Breech presentation
Breech presentation after cesarean section: always a section (Ophir et al). 1989;161:25-8
Management of the nonvertex second twin: primary cesarean section, external version, or primary breech extraction (Gocke et al). 1989;161:111-4

Buserelin
Buserelin versus danazol in the treatment of endometriosis-associated infertility (Fedele et al). 1989;161:371-6

C

CA 125; *see* **Antigens, tumor-associated, carbohydrate**

Cadmium poisoning
Zinc, cadmium, and hypertension in parturient women (Lazebnik et al). 1989;161:437-40

Calcitonin
Human α- and β-calcitonin gene-related peptides are vasodilators in human chorionic plate vasculature (Firth and Pipkin). 1989;161:1318-9

Calcium
Calcium intake and pregnancy-induced hypertension (Semchyshyn) (Letter); (Belizán and Villar) (Reply). 1989;161:834-5
Erythrocyte cation metabolism in preeclampsia (Sowers et al). 1989;161:441-5

Calcium channel blockers
Doppler assessment of the fetal and uteroplacental circulation during nifedipine therapy for preterm labor (Mari et al). 1989;161:1514-8
Fetal vascular responses to maternal nicardipine administration in the hypertensive ewe (Parisi et al). 1989;161:1035-9
Nifedipine pharmacokinetics during preterm labor tocolysis (Ferguson et al). 1989;161:1485-90

Calcium channel blockers—cont'd
Ovine fetal cardiorespiratory response to nicardipine (Holbrook et al). 1989;161:718-21
Placental vascular responses to nicardipine in the hypertensive ewe (Parisi et al). 1989;161:1039-43
Calcium entry blockers; *see* **Calcium channel blockers**
Callithricidae
Progesterone antagonist lilopristone: a potent abortifacient in the common marmoset (Puri et al). 1989;161:248-53
Cancer; *see* **Neoplasms**
Cancer syndromes, hereditary
Cervical cancer in Jewish women (Glezerman et al). 1989;161:1186-90
Candida albicans
Candida albicans: cellular immune system interactions during different stages of menstrual cycle (Kalo-Klein and Witkin). 1989;161:1132-6
Candida warrants concern (Elliott) (Letter); (Smith) (Reply). 1989;161:503
Carbohydrates
Effect of nutrient intake on premenstrual depression (Wurtman et al). 1989;161:1228-34
Carbohydrates, metabolism
Carbohydrate metabolism in the course of intrahepatic cholestasis in pregnancy (Wójcicka-Jagodzińska et al). 1989;161:959-64
Triphasic Randomized Clinical Trial: comparison of effects on carbohydrate metabolism (Bowes et al). 1989;161:1402-7 (Symposium)
Cardiac output
Cardiovascular changes in early pregnancy (Capeless and Clapp). 1989;161:1449-53
Measurement of cardiac output in pregnancy by thoracic electrical bioimpedance and thermodilution (Masaki et al). 1989;161:680-4
Cardiography, impedance
Measurement of cardiac output in pregnancy by thoracic electrical bioimpedance and thermodilution (Masaki et al). 1989;161:680-4
Cardiolipin antibodies; *see* **Antibodies**
Cardiopulmonary bypass
Subsequent fertility in women who undergo cardiac surgery (Nunley et al). 1989;161:573-6
Cardiovascular diseases
Estrogen replacement and cardiovascular disease: serum lipids and blood pressure effects (Hazzard). 1989;161:1847-53 (Symposium)
Cardiovascular system
Cardiovascular changes in early pregnancy (Capeless and Clapp). 1989;161:1449-53
Carotene
Decreased β-carotene tissue levels in uterine leiomyomas and cancers of reproductive and nonreproductive organs (Palan et al). 1989;161:1649-52
Effects of smoking and oral contraception on plasma β-carotene levels in healthy women (Palan et al). 1989;161:881-5
Carotenoids
Risk factors for vulvar lichen sclerosus (Sideri et al). 1989;161:38-42
Carotid arteries, animal
Effect of pregnancy on uterine and carotid artery response to norepinephrine, epinephrine, and phenylephrine in vessels with documented functional endothelium (Weiner et al). 1989;161:1605-10
In vitro release of endothelium-derived relaxing factor by acetylcholine is increased during the guinea pig pregnancy (Weiner et al). 1989;161:1599-605
Catecholamines
Effect of magnesium on cocaine-induced, catecholamine-mediated platelet and vascular response in term pregnant ewes (Weaver et al). 1989;161:1331-7
Effect of pregnancy on uterine and carotid artery response to norepinephrine, epinephrine, and phenylephrine in vessels with documented functional endothelium (Weiner et al). 1989;161:1605-10
Catheterization, central venous
Central hemodynamic assessment of normal term pregnancy (Clark et al). 1989;161:1439-42
The central hemodynamics of severe preeclampsia (Mabie et al). 1989;161:1443-8
Is central venous pressure monitoring "contraindicated" in patients with severe preeclampsia? (Woodward and Romanoff) (Letter); (Clark and Cotton) (Reply). 1989;161:837-9
Pulmonary artery catheterization in severe eclampsia (Gibbs). 1989;161:1089 (Letter)
Ultrasonographic guidance for central venous access during pregnancy (Lee et al). 1989;161:1012-3
Catheterization, Swan-Ganz; *see also* **Pulmonary artery**
The central hemodynamics of severe preeclampsia (Mabie et al). 1989;161:1443-8
Catheters, indwelling
Central hemodynamic assessment of normal term pregnancy (Clark et al). 1989;161:1439-42
Caucasoid race
Fetal radius length: a critical evaluation of race as a factor in gestational age assessment (Hill et al). 1989;161:193-9
Cell membrane permeability
Is a decrease in plasma oncotic pressure enough to explain the edema of pregnancy? (Valenzuela). 1989;161:1624-7
Cells, cultured
High glucose level decreases proliferation of cultured human fetal cells from placenta (Nelson and Curran). 1989;161:1553-8
Human uterus-derived growth substances for rat bone cells and fibroblasts (Koutsilieris). 1989;161:1313-7
Central nervous system
Dandy-Walker syndrome: a review of fifteen cases evaluated by prenatal sonography (Russ et al). 1989;161:401-6
Central venous pressure
Central hemodynamic assessment of normal term pregnancy (Clark et al). 1989;161:1439-42
The central hemodynamics of severe preeclampsia (Mabie et al). 1989;161:1443-8
Is central venous pressure monitoring "contraindicated" in patients with severe preeclampsia? (Woodward and Romanoff) (Letter); (Clark and Cotton) (Reply). 1989;161:837-9
Pulmonary artery catheterization in severe eclampsia (Gibbs). 1989;161:1089 (Letter)
Ultrasonographic guidance for central venous access during pregnancy (Lee et al). 1989;161:1012-3
Ceramide lactoside
Ceramide lactoside in amniotic fluid: high concentration in chorioamnionitis and in preterm labor (Hallman et al). 1989;161:313-8
Cerebellum
Enlarged cisterna magna in trisomy 18: prenatal ultrasonographic diagnosis (Thurmond et al). 1989;161:83-5

Cerebral arteries
Doppler assessment of the pulsatility index of the middle cerebral artery during constriction of the fetal ductus arteriosus after indomethacin therapy (Mari et al). 1989;161:1528-31
Cerebral ischemia, animal
The effect of elevated blood glucose on the electroencephalogram and cerebral metabolism during short-term brain ischemia in fetal sheep (Chao et al). 1989;161:221-8
Effects of cephalic hypotension, hypertension, and barbiturates on fetal cerebral blood flow and metabolism (Hohimer and Bissonnette). 1989;161:1344-51
Cervicitis
Randomized treatment of mucopurulent cervicitis with doxycycline or amoxicillin (Paavonen et al). 1989;161:128-35
Cervicovaginal lavage; *see* **Cervix uteri, cytology**
Cervix diseases
Comparison of Cytobrush and cervicovaginal lavage sampling methods for the detection of genital human papillomavirus (Goldberg et al). 1989;161:1669-72
Mechanism for human papillomavirus transmission at birth (Sedlacek et al). 1989;161:55-9
Cervix dysplasia
Colposcopic findings and intraepithelial neoplasia in diethylstilbestrol-exposed offspring (Helmerhorst et al). 1989;161:1191-4
A ten-year experience treating cervical intraepithelial neoplasia with the CO_2 laser (Baggish et al). 1989;161:60-8
Cervix neoplasms
Anal submucosal injection: a new route for drug administration in pelvic malignancies. IV. Submucosal anal injection in the treatment of cancer of uterine cervix—preliminary study (Shafik). 1989;161:69-72
Cervical cancer in Jewish women (Glezerman et al). 1989;161:1186-90
Pelvic and paraaortic lymphocysts after radical surgery because of cervical and ovarian cancer (Petru et al). 1989;161:937-41
A ten-year experience treating cervical intraepithelial neoplasia with the CO_2 laser (Baggish et al). 1989;161:60-8
Cervix uteri, cytology
Comparison of Cytobrush and cervicovaginal lavage sampling methods for the detection of genital human papillomavirus (Goldberg et al). 1989;161:1669-72
Cesarean section
Antibiotics for postcesarean endometritis (Duff). 1989;161:1087 (Letter)
Basic reference gambles recommended for utility assessment (Thornton and Lilford) (Letter); (Silver and Minogue) (Reply). 1989;161:256-7
Breech presentation after cesarean section: always a section (Ophir et al). 1989;161:25-8
Court-ordered cesarean section: an analysis of ethical concerns in compelling cases (Elkins et al). 1989;161:150-4
The effect of continuous epidural analgesia on cesarean section for dystocia in nulliparous women (Thorp et al). 1989;161:670-5
Effect of physician characteristics on the cesarean birth rate (Berkowitz et al). 1989;161:146-9
Evaluation of surgical staples in cesarean section (Burkett et al). 1989;161:540-7
Management of the nonvertex second twin: primary cesarean section, external version, or primary breech extraction (Gocke et al). 1989;161:111-4
Neonatal seizures and cesarean section (Boylan) (Letter); (Spellacy) (Reply). 1989;161:836-7
Usefulness of continuous fetal heart rate monitoring during cesarean section (Petrikovsky et al). 1989;161:36-7
Vaginal birth after cesarean delivery in the twin gestation (Strong et al). 1989;161:29-32
Vaginal birth after cesarean section: a reappraisal of risk (Yetman and Nolan). 1989;161:1119-23
Chemotaxis, leukocyte
Amniotic fluid leukotaxis assay as an early indicator of chorioamnionitis (Pankuch et al). 1989;161:802-7
Child abuse, sexual
Anal and perianal abnormalities in prepubertal victims of sexual abuse (Muram). 1989;161:278-81
Chlamydia trachomatis
Fetal death from chlamydial infection across intact amniotic membranes (Thorp et al). 1989;161:1245-6
Randomized treatment of mucopurulent cervicitis with doxycycline or amoxicillin (Paavonen et al). 1989;161:128-35
Cholestasis, intrahepatic
Carbohydrate metabolism in the course of intrahepatic cholestasis in pregnancy (Wójcicka-Jagodzińska et al). 1989;161:959-64
Cholesterol
The effect of triphasic oral contraceptives on plasma lipids and lipoproteins (Patsch et al). 1989;161:1396-401 (Symposium)
Cholinesterases
Effect of magnesium and preeclampsia on plasma cholinesterase activity (Marx) (Letter); (Kambam et al) (Reply). 1989;161:1754-5
Chorioamnionitis
Amniotic fluid leukotaxis assay as an early indicator of chorioamnionitis (Pankuch et al). 1989;161:802-7
Candida warrants concern (Elliott) (Letter); (Smith) (Reply). 1989;161:503
Ceramide lactoside in amniotic fluid: high concentration in chorioamnionitis and in preterm labor (Hallman et al). 1989;161:313-8
Esterase activity in second- and third-trimester amniotic fluid: an indicator of chorioamnionitis (Hoskins et al). 1989;161:1543-5
Haemophilus influenzae culture (Winn and Egley). 1989;161:1419 (Letter)
Choriocarcinoma
Gestational trophoblastic disease and use of oral contraceptives (Rosenberg et al). 1989;161:1087-8 (Letter)
Chorion
Human α- and β-calcitonin gene-related peptides are vasodilators in human chorionic plate vasculature (Firth and Pipkin). 1989;161:1318-9
Ultrasonographic criteria for the prenatal diagnosis of placental chorionicity in twin gestations (Winn et al). 1989;161:1540-2
Chorionic gonadotropins; *see* **Gonadotropins, chorionic**
Chorionic villi
Analysis of fetal loss after transcervical chorionic villus sampling a review of 719 patients (Wade and Young). 1989;161:513-9
Aspirin differentially affects thromboxane and prostacyclin production by trophoblast and villous core compartments of human placental villi (Nelson and Walsh). 1989;161:1593-8
Chorionic villi sampling
Integration of the transabdominal technique into an on-

Chorionic villi sampling—cont'd
going chorionic villus sampling program (Copeland et al). 1989;161:1289-94
Pregnancy loss in a small chorionic villus sampling series (Clark et al). 1989;161:301-2
Chromosome abnormalities
Rapid chromosome analysis with spontaneously dividing cells derived from umbilical cord blood (fetal and neonatal) (Tipton et al). 1989;161:1546-8
Chromosomes, analysis
Rapid chromosome analysis with spontaneously dividing cells derived from umbilical cord blood (fetal and neonatal) (Tipton et al). 1989;161:1546-8
Chung Chong
In vitro uterine response to tetramethylpyrazine, the active constituent of *Chung Chong* (a traditional Chinese medicine) (Tuttle et al). 1989;161:1319-23
Chylomicrons
Absorption of oral progesterone is influenced by vehicle and particle size (Hargrove et al). 1989;161:948-51
Cisterna magna
Enlarged cisterna magna in trisomy 18: prenatal ultrasonographic diagnosis (Thurmond et al). 1989;161:83-5
Cleavage stage, ovum
Semen predictors of in vitro fertilization and embryo cleavage (Daya et al). 1989;161:1284-9
Clindamycin
Short course of antibiotic therapy in treatment of postpartum endomyometritis (Morales et al). 1989;161:568-72
Clinical opinion
Clinical opinion. 1989;161:1-24, 261-77, 843-60, 1095-1105
Clinical protocols
Clinical management of the fetus with markedly diminished umbilical artery end-diastolic flow (Divon et al). 1989;161:1523-7
Clinical trials
Controlled trial of hydration and bed rest versus bed rest alone in the evaluation of preterm uterine contractions (Pircon et al). 1989;161:775-9
Gestational trophoblastic disease: a case-control study from the People's Republic of China (Brinton et al). 1989;161:121-7
Magnesium supplementation during pregnancy: a double-blind randomized controlled clinical trial (Sibai et al). 1989;161:115-9
Removing a retained placenta by oxytocin a controlled study (Wilken-Jensen et al). 1989;161:155-6
Clitoris
A new surgical technique to treat refractory labial fusion in the elderly (Johnson et al). 1989;161:289-90
Clomiphene
Effects of clomiphene citrate on episodic luteinizing hormone secretion throughout the menstrual cycle (Archer et al). 1989;161:581-92
Peri-implantation phase endometrial estrogen and progesterone receptors: effect of ovulation induction with clomiphene citrate (Hecht et al). 1989;161:1688-93
Clone cells
Isolation and sequencing of a complementary deoxyribonucleic acid clone encoding human placental 17β-estradiol dehydrogenase: identification of the putative cofactor binding site (Gast et al). 1989;161:1726-31
Clostridium
Maternal deaths associated with *Clostridium sordellii* infection (McGregor et al). 1989;161:987-95
Cocaine
Cocaine abuse during pregnancy: peripartum prevalence and perinatal outcome (Neerhof et al). 1989;161:633-8
Effect of magnesium on cocaine-induced, catecholamine-mediated platelet and vascular response in term pregnant ewes (Weaver et al). 1989;161:1331-7
In utero cocaine exposure: observations of fetal behavioral state may predict neonatal outcome (Hume et al). 1989;161:685-90
Colposcopy
Colposcopic findings and intraepithelial neoplasia in diethylstilbestrol-exposed offspring (Helmerhorst et al). 1989;161:1191-4
Combination drug therapy; *see* **Drug therapy, combination**
Compliance
Compliance considerations with estrogen replacement: withdrawal bleeding and other factors (Hahn). 1989;161:1854-8 (Symposium)
The patient's reaction to side effects of oral contraceptives (Hillard). 1989;161:1412-5 (Symposium)
Computer assisted diagnosis; *see* **Diagnosis, computer assisted**
Congenital abnormality; *see* **Abnormalities**
Congenital defects; *see* **Abnormalities**
Consultants
Consultants for the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY. 1989;161:1431-8
Contraceptive devices, female
The importance of ultrasonography in infertile women with "forgotten" intrauterine contraceptive devices (Ron-El et al). 1989;161:211-2
Contraceptives, oral
A case-control study of epithelial ovarian cancer (Hartge et al). 1989;161:10-6 (Clin. opinion)
Correcting misconceptions about oral contraceptives (Mishell). 1989;161:1385-9 (Symposium)
The effect of triphasic oral contraceptives on plasma lipids and lipoproteins (Patsch et al). 1989;161:1396-401 (Symposium)
Effects of smoking and oral contraception on plasma β-carotene levels in healthy women (Palan et al). 1989;161:881-5
Evaluating triphasic oral contraceptives: the rationale for a randomized trial (Grimes). 1989;161:1390-2 (Symposium)
Longitudinal ultrasonographic study of the ovarian suppressive activity of a low-dose triphasic oral contraceptive during correct and incorrect pill intake (Hamilton and Hoogland). 1989;161:1159-62
Study design for the Triphasic Randomized Comparative Trial (Dickerson). 1989;161:1392-6 (Symposium)
Triphasic Randomized Clinical Trial: comparative frequency of intermenstrual bleeding (Droegemueller et al). 1989;161:1407-11 (Symposium)
Triphasic Randomized Clinical Trial: comparison of effects on carbohydrate metabolism (Bowes et al). 1989;161:1402-7 (Symposium)
Contraceptives, oral, adverse effects
Correcting misconceptions about oral contraceptives (Mishell). 1989;161:1385-9 (Symposium)
Gestational trophoblastic disease: a case-control study from the People's Republic of China (Brinton et al). 1989;161:121-7
Gestational trophoblastic disease and use of oral contraceptives (Rosenberg et al). 1989;161:1087-8 (Letter)

The patient's reaction to side effects of oral contraceptives (Hillard). 1989;161:1412-5 (Symposium)
Triphasic Randomized Clinical Trial: comparative frequency of intermenstrual bleeding (Droegemueller et al). 1989;161:1407-11 (Symposium)
Cordocentesis; *see* **Fetal blood**
Coronary disease
Cardiac isoenzymes and electrocardiographic changes during ritodrine tocolysis (Hadi and Albazzaz). 1989;161:318-21
Decreased in vitro production of 6-keto-prostaglandin $F_{1\alpha}$ by uterine arteries from postmenopausal women (Steinleitner et al). 1989;161:1677-81
Estrogen replacement and cardiovascular disease: serum lipids and blood pressure effects (Hazzard). 1989;161:1847-53 (Symposium)
Coronary heart disease; *see* **Coronary disease**
Corpus luteum maintenance
Effects of systemic administration of indomethacin on ovulation, luteinization, and steroidogenesis in the rabbit ovary (Katz et al). 1989;161:1361-6
Corrections
Effects of regular and decaffeinated coffee on fetal breathing and heart rate (Salvador HS, Koos BJ) (1989;160:1043-7). 1989;161:669
Identification of a deoxyribonucleic acid allelic variant for β1-4 galactosyltransferase expression associated with male sperm binding/penetration infertility (Humphreys-Beher MG, Blackwell RE) (1989;160:1160-5). 1989;161:816
Metabolic changes during medical treatment of endometriosis: Nafarelin acetate versus danazol (Burry et al) (1989;160:1454-61). 1989;161:1755
Perinatal factors influencing atrial natriuretic peptide levels in umbilical arterial plasma at the time of delivery (Castro et al). (1989;161:623-7). 1989;161:1238
Correspondence
Letters. 1989;161:254-9, 497-503, 834-40, 1087-92, 1416-27, 1744-54
Cortisol; *see* **Adrenal cortex hormones**
Counseling
Multidisciplinary team counseling for fetal anomalies (Lorenz and Kuhn). 1989;161:263-6 (Clin. opinion)
Crisis intervention
Court-ordered cesarean section: an analysis of ethical concerns in compelling cases (Elkins et al). 1989;161:150-4
Critical care
Central hemodynamic assessment of normal term pregnancy (Clark et al). 1989;161:1439-42
Cromer antigen
Isoimmunization to Cromer antigen in pregnancy (Sacks and Garratty). 1989;161:928-9
Cultured human fetal cells; *see* **Cells, cultured**
Current development
Current development. 1989;161:1025-34, 1375-84
Current investigation
Current investigation. 1989;161:1297-304
Cystic hygroma; *see* **Lymphangioma**
Cysts
Pelvic and paraaortic lymphocysts after radical surgery because of cervical and ovarian cancer (Petru et al). 1989;161:937-41
Cytobrush; *see* **Cervix uteri, cytology**
Cytochrome P-450
Aromatase in human fetal tissues (Doody and Carr). 1989;161:1694-7
Cytogenetics
Rapid chromosome analysis with spontaneously dividing cells derived from umbilical cord blood (fetal and neonatal) (Tipton et al). 1989;161:1546-8

D

Danazol
Buserelin versus danazol in the treatment of endometriosis-associated infertility (Fedele et al). 1989;161:871-6
Elevated serum levels of endometrial secretory protein PP14 in patients with advanced endometriosis: suppression by treatment with danazol and high-dose medroxyprogesterone acetate (Telimaa et al). 1989;161:866-71
Dandy-Walker syndrome
Dandy-Walker syndrome: a review of fifteen cases evaluated by prenatal sonography (Russ et al). 1989;161:401-6
Death rate, maternal; *see* **Maternal mortality**
Decidua
Vasopressin receptors in human pregnant myometrium and decidua: interactions with oxytocin and vasopressin agonists and antagonists (Ivanisevic et al). 1989;161:1637-43
Deglutition
Stimuli for fetal swallowing: systemic factors (Ross et al). 1989;161:1559-65
Deglutition, animal
Fetal blood volume, urine flow, swallowing, and amniotic fluid volume responses to long-term intravascular infusions of saline (Brace). 1989;161:1049-54
Delivery
Comparison of predelivery versus postdelivery Kleihauer–Betke stains in cases of fetal death (Owen et al). 1989;161:663-6
Increased myometrial responsiveness to oxytocin during term and preterm labor (Garfield and Beier). 1989;161:454-61
Management of the nonvertex second twin: primary cesarean section, external version, or primary breech extraction (Gocke et al). 1989;161:111-4
Perinatal factors influencing atrial natriuretic peptide levels in umbilical arterial plasma at the time of delivery (Castro et al). 1989;161:623-7
Perinatal factors influencing atrial natriuretic peptide levels in umbilical arterial plasma at the time of delivery (Castro et al). (1989;161:623-7). 1989;161:1238 (Correction)
Relaxin in paired samples of serum and milk from women after term and preterm delivery (Eddie et al). 1989;161:970-3
Vaginal birth after cesarean section: a reappraisal of risk (Yetman and Nolan). 1989;161:1119-23
Densitometry
Monitoring skeletal response to estrogen (Mazess et al). 1989;161:843-8 (Clin opinion)
Deoxyribonucleic acid; *see* **DNA**
Deoxyribonucleic acid probes; *see* **DNA probes**
Depression
Depressive episodes in premenstrual syndrome (Mortola et al). 1989;161:1682-7
Effect of nutrient intake on premenstrual depression (Wurtman et al). 1989;161:1228-34
Dexamethasone
Effects of fetal sex and dexamethasone on preterm maternal

Dexamethasone—cont'd
serum concentrations of human chorionic gonadotropin, progesterone, estrone, estradiol, and estriol (Haning et al). 1989;161:1549-53
Impact of antenatal dexamethasone administration on respiratory distress syndrome in surfactant-treated infants (Farrell et al). 1989;161:628-33
Dextrocardia
Anesthetic management of labor in a patient with dextrocardia, congenitally corrected transposition, Wolff-Parkinson-White syndrome, and congestive heart failure (Sellers et al). 1989;161:1001-3
Diabetes mellitus, animal
Gestational diabetes in the BHE rat: influence of dietary fat (Bue et al). 1989;161:234-40
Diabetes mellitus in pregnancy; *see* **Pregnancy in diabetes**
Diagnosis, computer-assisted
Fetal heart rate patterns in the small-for-gestational-age human fetus (Gagnon et al). 1989;161:779-84
Heuristic determination of relevant diagnostic procedures in a medical expert system for gynecology (Small and Muechler). 1989;161:17-24 (Clin. opinion)
Diagnosis, differential
Intrauterine growth retardation: standards for diagnosis (Goldenberg et al). 1989;161:271-7 (Clin. opinion)
Serial human chorionic gonadotropin determinations by fluoroimmunoassay for differentiation between intrauterine and ectopic gestation (Lindblom et al). 1989;161:397-400
Diagnostic services
Heuristic determination of relevant diagnostic procedures in a medical expert system for gynecology (Small and Muechler). 1989;161:17-24 (Clin. opinion)
Diet therapy
Randomized trial of diet versus diet plus cardiovascular conditioning on glucose levels in gestational diabetes (Jovanovic-Peterson et al). 1989;161:415-9
Dietary fats
Gestational diabetes in the BHE rat: influence of dietary fat (Bue et al). 1989;161:234-40
Dietary habits; *see* **Food habits**
Diethylstilbestrol
Colposcopic findings and intraepithelial neoplasia in diethylstilbestrol-exposed offspring (Helmerhorst et al). 1989;161:1191-4
Dilapan
Cervical dilation: a comparison of Lamicel and Dilapan (Wells and Hulka). 1989;161:1124-6
Dilatation and curettage
Cervical dilation: a comparison of Lamicel and Dilapan (Wells and Hulka). 1989;161:1124-6
DNA
Flow cytometry of normal, hyperplastic, and malignant human endometrium (Thornton et al). 1989;161:487-92
Increased frequency of detection of human papillomavirus deoxyribonucleic acid in exfoliated cervical cells during pregnancy (Rando et al). 1989;161:50-5
Mechanism for human papillomavirus transmission at birth (Sedlacek et al). 1989;161:55-9
Rapid determination of fetal sex by deoxyribonucleic acid amplification of Y chromosome–specific sequences (Pinckert et al). 1989;161:693-8
DNA, neoplasm
Flow cytometry of normal, hyperplastic, and malignant human endometrium (Thornton et al). 1989;161:487-92
DNA probes
Isolation and sequencing of a complementary deoxyribonucleic acid clone encoding human placental 17β-estradiol dehydrogenase: identification of the putative cofactor binding site (Gast et al). 1989;161:1726-31
Molecular scanning of Yq11 (interval 6) in men with Sertoli-cell-only syndrome (Johnson et al). 1989;161:1732-7
DNA probes, HPV
Increased frequency of detection of human papillomavirus deoxyribonucleic acid in exfoliated cervical cells during pregnancy (Rando et al). 1989;161:50-5
Presence of human papillomavirus deoxyribonucleic acid (Beckmann et al) (Letter); (Kaufman et al) (Reply). 1989;161:1419-20
Doppler echocardiography; *see* **Echocardiography, Doppler**
Doppler ultrasound; *see* **Ultrasonic diagnosis**
Doppler velocimetry; *see* **Flowmeters**
Down's syndrome
The efficacy of fetal sonographic biometry in Down syndrome screening (Peters et al). 1989;161:297-300
Long bone growth in fetuses with Down syndrome (Fitz-Simmons et al). 1989;161:1174-7
Predictive values, relative risks, and overall benefits of high and low maternal serum α-fetoprotein screening in singleton pregnancies: new epidemiologic data (Milunsky et al). 1989;161:291-7
Prenatal screening for Down syndrome with maternal serum human chorionic gonadotropin levels (Petrocik et al). 1989;161:1168-73
Doxycycline
Randomized treatment of mucopurulent cervicitis with doxycycline or amoxicillin (Paavonen et al). 1989;161:128-35
Drug antagonism
Antagonism of antihypertensive drug therapy in pregnancy by indomethacin? (Schoenfeld et al). 1989;161:1204-5
Drug induced abnormalities; *see* **Abnormalities, drug induced**
Drug interactions
Neuromuscular blockade with magnesium sulfate and nifedipine (Snyder and Cardwell). 1989;161:35-6
Drug resistance, microbial
Vancomycin during pregnancy: Does it cause hearing loss or nephrotoxicity in the infant? (Reyes et al). 1989;161:977-81
Drug therapy, combination
Number clarification requested (Hatjis) (Letter); (Wilkins and Lynch) (Reply). 1989;161:1746
Ductus arteriosus
Doppler assessment of the pulsatility index of the middle cerebral artery during constriction of the fetal ductus arteriosus after indomethacin therapy (Mari et al). 1989;161:1528-31
Dysgerminoma
Seminoma in pubertal patient with androgen insensitivity syndrome (Hurt et al). 1989;161:530-1
Dyspareunia
A new surgical technique to treat refractory labial fusion in the elderly (Johnson et al). 1989;161:289-90
Dysplasia, cervix; *see* **Cervix dysplasia**
Dystocia
The effect of continuous epidural analgesia on cesarean

section for dystocia in nulliparous women (Thorp et al). 1989;161:670-5

E

Echocardiography
Cardiovascular changes in early pregnancy (Capeless and Clapp). 1989;161:1449-53
Hemodynamic changes during twin pregnancy: a Doppler and M-mode echocardiographic study (Robson et al). 1989;161:1273-8

Echocardiography, Doppler
Evaluation of pulsed Doppler echocardiography for measurement of aortic blood flow in the fetal lamb (Veille et al). 1989;161:1610-4
Hemodynamic changes during twin pregnancy: a Doppler and M-mode echocardiographic study (Robson et al). 1989;161:1273-8
Human fetal tricuspid and mitral deceleration time: changes with normal pregnancy and intrauterine growth retardation (Reed et al). 1989;161:1532-5
Maternal hemodynamic effects of uterine contractions by M-mode and pulsed-Doppler echocardiography (Lee et al). 1989;161:974-7
Right ventricular dysfunction in human fetal compromise (Räsänen et al). 1989;161:136-40

Eclampsia
Pulmonary artery catheterization in severe eclampsia (Gibbs). 1989;161:1089 (Letter)

Ectoderm
CA 125 in the epithelium closely related to the embryonic ectoderm: the periderm and the amnion (Nanbu et al). 1989;161:462-7

Ectopic pregnancy; *see* **Pregnancy, ectopic**

Edema
Is a decrease in plasma oncotic pressure enough to explain the edema of pregnancy? (Valenzuela). 1989;161:1624-7

Education, medical
Breast disease programs in obstetrics and gynecology: a plea for training in mammography (Gleicher). 1989;161:267-70 (Clin. opinion)

Elderly; *see* **Aged**

Electrocardiography
Cardiac isoenzymes and electrocardiographic changes during ritodrine tocolysis (Hadi and Albazzaz). 1989;161:318-21

Electroencephalography
The effect of elevated blood glucose on the electroencephalogram and cerebral metabolism during short-term brain ischemia in fetal sheep (Chao et al). 1989;161:221-8

Electromyography
Power spectrum analysis of myometrial electromyogram and intrauterine pressure changes in the pregnant rhesus monkey in late gestation (Hsu et al). 1989;161:467-73

ELISA; *see* **Enzyme-linked immunosorbent assay**

Embolism
Death caused by air embolism associated with neodymium:yttrium-aluminum-garnet laser surgery and artificial sapphire tips (Baggish and Daniell). 1989;161:877-8

Embolism, amniotic fluid, animal
Effect of placental embolization on the umbilical arterial velocity waveform in fetal sheep (Morrow et al). 1989;161:1055-60

Embryo
CA 125 in the epithelium closely related to the embryonic ectoderm: the periderm and the amnion (Nanbu et al). 1989;161:462-7
First-trimester midgut herniation: a high-frequency transvaginal sonographic study (Timor-Tritsch et al). 1989;161:831-3
Semen predictors of in vitro fertilization and embryo cleavage (Daya et al). 1989;161:1284-9

Embryo development; *see* **Fetal development**

Embryo transfer
Cervical pregnancy after in vitro fertilization and embryo transfer (Weyerman et al). 1989;161:1145-6
Successful twin pregnancy after embryo donation to a patient with XY gonadal dysgenesis (Sauer et al). 1989;161:380-1

Endometrial hyperplasia
Flow cytometry of normal, hyperplastic, and malignant human endometrium (Thornton et al). 1989;161:487-92

Endometriosis
Buserelin versus danazol in the treatment of endometriosis-associated infertility (Fedele et al). 1989;161:871-6
Elevated serum levels of endometrial secretory protein PP14 in patients with advanced endometriosis: suppression by treatment with danazol and high-dose medroxyprogesterone acetate (Telimaa et al). 1989;161:866-71
Lymphocyte activity in the presence of peritoneal fluid from fertile women and infertile women with and without endometriosis (Hill and Anderson). 1989;161:861-4
Peritoneal blood painting: an aid in the diagnosis of endometriosis (Redwine). 1989;161:865-6

Endometritis
Antibiotics for postcesarean endometritis (Duff). 1989;161:1087 (Letter)

Endometrium
The cancer question: an overview of recent epidemiologic and retrospective data (Henderson). 1989;161:1859-64 (Symposium)
Epidermal growth factor receptor expression in normal and malignant endometrium (Berchuck et al). 1989;161:1247-52
Flow cytometry of normal, hyperplastic, and malignant human endometrium (Thornton et al). 1989;161:487-92
Immunocytochemical study of *ras* and *myc* proto-oncogene polypeptide expression in the human menstrual cycle (Odom et al). 1989;161:1663-8
Immunohistochemical expression of TAG-72 in normal and malignant endometrium: correlation of antigen expression with estrogen receptor and progesterone receptor levels (Soisson et al). 1989;161:1258-63
Peri-implantation phase endometrial estrogen and progesterone receptors: effect of ovulation induction with clomiphene citrate (Hecht et al). 1989;161:1688-93
Prognostic significance of steroid receptors measured in primary metastatic and recurrent endometrial carcinoma (Borazjani et al). 1989;161:1253-7

Endometrium, cytology
Double endometrial aspirative biopsy (Quilez et al). 1989;161:1426-7 (Letter)

Endomyometritis; *see* **Myometrium, microbiology**

Endorphins
Fetal intermediate lobe is stimulated by parturition (Facchinetti et al). 1989;161:1267-70

Endothelium, vascular
Lipid peroxidation in pregnancy: new perspectives on preeclampsia (Hubel et al). 1989;161:1025-34 (Curr. dev.)

Endothelium, vascular—cont'd
Preeclampsia: an endothelial cell disorder (Roberts et al). 1989;161:1200-4
Endothelium, vascular, animal
Effect of pregnancy on uterine and carotid artery response to norepinephrine, epinephrine, and phenylephrine in vessels with documented functional endothelium (Weiner et al). 1989;161:1605-10
In vitro release of endothelium-derived relaxing factor by acetylcholine is increased during the guinea pig pregnancy (Weiner et al). 1989;161:1599-605
Endothelium-derived relaxing factor
In vitro release of endothelium-derived relaxing factor by acetylcholine is increased during the guinea pig pregnancy (Weiner et al). 1989;161:1599-605
Enzyme-linked immunosorbent assay
Sperm antibodies and infertility (Shulman) (Letter); (Witkin) (Reply). 1989;161:497-9
Epidemiology
Gestational trophoblastic disease: a case-control study from the People's Republic of China (Brinton et al). 1989;161:121-7
Epidermal growth factor receptors; *see* **Receptors, epidermal growth factor-urogastrone**
Epidermal growth factor-urogastrone
Assessment of epidermal growth factor in the healing process of clean full-thickness skin wounds (Jijon et al). 1989;161:1658-62
Human uterus-derived growth substances for rat bone cells and fibroblasts (Koutsilieris). 1989;161:1313-7
Epidermal growth factors; *see* **Growth substances**
Epidural analgesia; *see* **Analgesia, epidural**
Epinephrine
Effect of pregnancy on uterine and carotid artery response to norepinephrine, epinephrine, and phenylephrine in vessels with documented functional endothelium (Weiner et al). 1989;161:1605-10
Erythroblastosis, fetal; *see also* **Rh isoimmunization**
Frequency and timing of intravascular intrauterine transfusions reconsidered (Voto and Margulies) (Letter); (Socol et al) (Reply). 1989;161:255-6
Isoimmunization to Cromer antigen in pregnancy (Sacks and Garratty). 1989;161:928-9
Pulsed Doppler flow-velocity waveforms in the prediction of fetal hematocrit of the severely isoimmunized pregnancy (Copel et al). 1989;161:341-4
Erythropoiesis
Cordocentesis in the investigation of fetal erythropoiesis (Nicolaides et al). 1989;161:1197-200
Esterases
Esterase activity in second- and third-trimester amniotic fluid: an indicator of chorioamnionitis (Hoskins et al). 1989;161:1543-5
Estradiol
Effect of a 48-hour Δ^4-androstenedione infusion on the pregnant rhesus monkey in the last third of gestation: changes in maternal plasma estradiol concentrations and myometrial contractility (Figueroa et al). 1989;161:481-6
Effects of fetal sex and dexamethasone on preterm maternal serum concentrations of human chorionic gonadotropin, progesterone, estrone, estradiol, and estriol (Haning et al). 1989;161:1549-53
Mechanisms that subserve estradiol's induction of increased prolactin concentrations: evidence of amplitude modulation of spontaneous prolactin secretory bursts (Veldhuis et al). 1989;161:1149-58
Treatment of oophorectomized guinea pigs with intrauterine 17β-estradiol pellets may modulate myometrial β-adrenergic receptor binding properties (Hatjis et al). 1989;161:1628-32
Up-regulation of guinea pig myometrial adenylate cyclase activity by intrauterine estradiol and progesterone pellets (Hatjis and Koritnik). 1989;161:1073-8
Estradiol dehydrogenase
Isolation and sequencing of a complementary deoxyribonucleic acid clone encoding human placental 17β-estradiol dehydrogenase: identification of the putative cofactor binding site (Gast et al). 1989;161:1726-31
Estradiol valerate
Pattern of human chorionic gonadotropin binding in the polycystic ovary (Brawer et al). 1989;161:474-80
Estriol
Effects of fetal sex and dexamethasone on preterm maternal serum concentrations of human chorionic gonadotropin, progesterone, estrone, estradiol, and estriol (Haning et al). 1989;161:1549-53
Estrogens
Effect of a 48-hour Δ^4-androstenedione infusion on the pregnant rhesus monkey in the last third of gestation: changes in maternal plasma estradiol concentrations and myometrial contractility (Figueroa et al). 1989;161:481-6
Estrogens, biosynthesis
Biosynthesis and physiologic effects of estrogen and pathophysiologic effects of estrogen deficiency: a review (Utian). 1989;161:1828-31 (Symposium)
Estrogens, deficiency
Biosynthesis and physiologic effects of estrogen and pathophysiologic effects of estrogen deficiency: a review (Utian). 1989;161:1828-31 (Symposium)
Decreased in vitro production of 6-keto-prostaglandin $F_{1\alpha}$ by uterine arteries from postmenopausal women (Steinleitner et al). 1989;161:1677-81
Estrogen replacement therapy: an overview (Mishell). 1989;161:1825-7 (Symposium)
Estrogens, physiology
Biosynthesis and physiologic effects of estrogen and pathophysiologic effects of estrogen deficiency: a review (Utian). 1989;161:1828-31 (Symposium)
Estrogens, therapeutic use
Biosynthesis and physiologic effects of estrogen and pathophysiologic effects of estrogen deficiency: a review (Utian). 1989;161:1828-31 (Symposium)
The cancer question: an overview of recent epidemiologic and retrospective data (Henderson). 1989;161:1859-64 (Symposium)
Compliance considerations with estrogen replacement: withdrawal bleeding and other factors (Hahn). 1989;161:1854-8 (Symposium)
Estrogen replacement and cardiovascular disease: serum lipids and blood pressure effects (Hazzard). 1989;161:1847-53 (Symposium)
Estrogen replacement therapy: indications, contraindications, and agent selection (Notelovitz). 1989;161:1832-41 (Symposium)
Estrogen replacement therapy: an overview (Mishell). 1989;161:1825-7 (Symposium)
Estrogen replacement therapy: what the future holds (Hammond). 1989;161:1864-8 (Symposium)

Estrogens in the prevention of osteoporosis in postmenopausal women (Genant et al). 1989;161:1842-6 (Symposium)
Monitoring skeletal response to estrogen (Mazess et al). 1989;161:843-8 (Clin opinion)
Twin pregnancy in premature ovarian failure after estrogen treatment: a case report (Tang and Sawers). 1989;161:172-3

Estrone
Effects of fetal sex and dexamethasone on preterm maternal serum concentrations of human chorionic gonadotropin, progesterone, estrone, estradiol, and estriol (Haning et al). 1989;161:1549-53

Ethics, medical
Basic reference gambles recommended for utility assessment (Thornton and Lilford) (Letter); (Silver and Minogue) (Reply). 1989;161:256-7
The challenge of change revisited (Greiss). 1989;161:505-9 (Pres. address)
Court-ordered cesarean section: an analysis of ethical concerns in compelling cases (Elkins et al). 1989;161:150-4

Ethnic groups
Cervical cancer in Jewish women (Glezerman et al). 1989;161:1186-90

Exercise
The effects of maternal exercise on early pregnancy outcome (Clapp). 1989;161:1453-7
Exercise prescription in pregnancy: weight-bearing versus non-weight-bearing exercise (Artal et al). 1989;161:1464-9

Exercise test
Exercise prescription in pregnancy: weight-bearing versus non-weight-bearing exercise (Artal et al). 1989;161:1464-9
Oxygen consumption during treadmill exercise before, during, and after pregnancy (Clapp). 1989;161:1458-64
Predicting maximal oxygen uptake from treadmill testing in trained and untrained women (Martin et al). 1989;161:1127-32

Exercise therapy
Randomized trial of diet versus diet plus cardiovascular conditioning on glucose levels in gestational diabetes (Jovanovic-Peterson et al). 1989;161:415-9

Experimental design; *see* **Research design**

F

False positive reactions
Specifics of specificity and sensitivity (Kadar) (Letter); (Kolins) (Reply). 1989;161:1416-7

Fatty acids
Absorption of oral progesterone is influenced by vehicle and particle size (Hargrove et al). 1989;161:948-51
Prolonged hyperinsulinemia reduces plasma fatty acid levels in the major lipid groups in fetal sheep (Ogburn et al). 1989;161:728-32

Fatty liver
Elevated liver enzymes and thrombocytopenia in the third trimester of pregnancy: an unusual case report and a review of the literature (Hannah et al). 1989;161:322-3

Femur
The efficacy of fetal sonographic biometry in Down syndrome screening (Peters et al). 1989;161:297-300
Race and gender factors omitted from results (Ansbacher) (Letter); (Goldstein) (Reply). 1989;161:502-3

Fenestration
Recurrence of functional ovarian cysts after laparoscopic fenestration (De Wilde). 1989;161:839 (Letter)

Fentanyl
Fentanyl citrate analgesia during labor (Rayburn et al). 1989;161:202-6

Ferritin
Role of ferritin supported in diagnosis of anemias of pregnancy (Goodlin) (Letter); (Schifman) (Reply). 1989;161:258-9

Fertility
Fertility after ectopic pregnancy (Mitchell et al). 1989;161:576-80
Gestational diabetes in the BHE rat: influence of dietary fat (Bue et al). 1989;161:234-40
Lymphocyte activity in the presence of peritoneal fluid from fertile women and infertile women with and without endometriosis (Hill and Anderson). 1989;161:861-4
Subsequent fertility in women who undergo cardiac surgery (Nunley et al). 1989;161:573-6

Fertilization
Significance of D-mannose as a sperm receptor site on the zona pellucida in human fertilization (Mori et al). 1989;161:207-11

Fertilization in vitro
Cervical pregnancy after in vitro fertilization and embryo transfer (Weyerman et al). 1989;161:1145-6
Effects of platelet activating factor on mouse oocyte fertilization in vitro (Minhas et al). 1989;161:1714-7
Ovarian hyperstimulation presenting as acute hydrothorax after in vitro fertilization (Kingsland et al). 1989;161:381-2
Semen predictors of in vitro fertilization and embryo cleavage (Daya et al). 1989;161:1284-9

Fetal anemia; *see* **Fetal hemoglobin**

Fetal anoxia
Renal artery flow-velocity waveforms in normal and hypoxemic fetuses (Vyas et al). 1989;161:168-72

Fetal anoxia, animal
Effects of cephalic hypotension, hypertension, and barbiturates on fetal cerebral blood flow and metabolism (Hohimer and Bissonnette). 1989;161:1344-51

Fetal blood
Blood gases, pH, and lactate in appropriate- and small-for-gestational-age fetuses (Nicolaides et al). 1989;161:996-1001
Clinical management of the fetus with markedly diminished umbilical artery end-diastolic flow (Divon et al). 1989;161:1523-7
Cordocentesis in the diagnosis of intrauterine starvation (Economides et al). 1989;161:1004-8
Cordocentesis in the investigation of fetal erythropoiesis (Nicolaides et al). 1989;161:1197-200
Detection of fetal blood (Leiberman et al) (Letter); (Cardwell) (Reply). 1989;161:257-8
Doppler assessment of the fetal and uteroplacental circulation during nifedipine therapy for preterm labor (Mari et al). 1989;161:1514-8
Doppler assessment of the pulsatility index of the middle cerebral artery during constriction of the fetal ductus arteriosus after indomethacin therapy (Mari et al). 1989;161:1528-31
Duplex Doppler ultrasonographic evaluation of the fetal renal artery in normal and abnormal fetuses (Veille and Kanaan). 1989;161:1502-7

Fetal blood—cont'd
Effect of acute intravascular volume expansion on human fetal prostaglandin concentrations (Weiner and Robillard). 1989;161:1494-7
Effect of diagnostic and therapeutic cordocentesis on maternal serum α-fetoprotein concentration (Weiner et al). 1989;161:706-8
The effect of intravascular transfusion on umbilical venous pressure in anemic fetuses with and without hydrops (Weiner et al). 1989;161:1498-501
Fetal blood gas analysis from cordocentesis for abnormal fetal heart rate patterns (Shah and Boehm). 1989;161:374-6
Fetal hyperinsulinism in anencephaly (Hubinont et al). 1989;161:306-7
Fetal intermediate lobe is stimulated by parturition (Facchinetti et al). 1989;161:1267-70
Human fetal tricuspid and mitral deceleration time: changes with normal pregnancy and intrauterine growth retardation (Reed et al). 1989;161:1532-5
Maternal and fetal blood flow velocity waveforms in patients with preterm labor: relationship to outcome (Brar et al). 1989;161:1519-22
Normal values for human umbilical venous and amniotic fluid pressures and their alteration by fetal disease (Weiner et al). 1989;161:714-7
Plasma atrial natriuretic peptide in human fetus: response to intravascular blood transfusion (Panos et al). 1989;161:357-61
Prediction of hematocrit decline after intravascular fetal transfusion (MacGregor et al). 1989;161:1491-3
Prolactin levels in umbilical cord blood of human infants: relation to gestational age, maternal complications, and neonatal lung function (Parker et al). 1989;161:795-802
Rapid chromosome analysis with spontaneously dividing cells derived from umbilical cord blood (fetal and neonatal) (Tipton et al). 1989;161:1546-8
Routine umbilical cord blood gas determinations? (Thorp et al). 1989;161:600-5
Techniques differ in use of Doppler ultrasonography (Easterling and Benedetti) (Letter); (Lee and Rokey) (Reply). 1989;161:1748-50
Thrombocytopenia and cordocentesis clarifications requested (Weiner). 1989;161:1091-2 (Letter)
Transfer of prostaglandins to the fetus after prostaglandin E_2 vaginal pessary administration (MacKenzie et al). 1989;161:920-3

Fetal blood, animal
Evaluation of pulsed Doppler echocardiography for measurement of aortic blood flow in the fetal lamb (Veille et al). 1989;161:1610-4
Fetal blood volume, urine flow, swallowing, and amniotic fluid volume responses to long-term intravascular infusions of saline (Brace). 1989;161:1049-54
Intrauterine growth retardation and the circulatory responses to acute hypoxemia in fetal sheep (Block et al). 1989;161:1576-9
Ovine fetal cardiovascular responses to packed red blood cell transfusions (Brace). 1989;161:1367-74

Fetal blood, immunology
Fetal cardiac output in the isoimmunized pregnancy: a pulsed Doppler-echocardiographic study of patients undergoing intravascular intrauterine transfusion (Copel et al). 1989;161:361-5
Fetal heart rate patterns in red blood cell isoimmunized pregnancies (Nicolaides et al). 1989;161:351-6
Maternal-fetal glucose gradient in normal pregnancies and in pregnancies complicated by alloimmunization and fetal growth retardation (Nicolini et al). 1989;161:924-7
Pulsed Doppler flow-velocity waveforms in the prediction of fetal hematocrit of the severely isoimmunized pregnancy (Copel et al). 1989;161:341-4

Fetal death
Analysis of fetal loss after transcervical chorionic villus sampling a review of 719 patients (Wade and Young). 1989;161:513-9
Comparison of predelivery versus postdelivery Kleihauer–Betke stains in cases of fetal death (Owen et al). 1989;161:663-6
Does midtrimester ΔOD_{450} of amniotic fluid reflect severity of Rh disease? (Ananth and Queenan). 1989;161:47-9
Fetal death: diagnosis and management (Merlob). 1989;161:254 (Letter)
Fetal death from chlamydial infection across intact amniotic membranes (Thorp et al). 1989;161:1245-6
Fetomaternal hemorrhage possible cause of fetal distress and death (Cardwell and Snyder) (Letter); (Biddinger et al) (Reply). 1989;161:1744
Missed abortion: Still appropriate terminology? (Pridjian and Moawad). 1989;161:261-2 (Clin. opinion)
Perinatal death as a result of social factors (Fribourg) (Letter); (Delke and Minkoff) (Reply). 1989;161:1748
Predictive value of increased plasma levels of fibronectin in gestational hypertension (Ballegeer et al). 1989;161:432-6
Predictive values, relative risks, and overall benefits of high and low maternal serum α-fetoprotein screening in singleton pregnancies: new epidemiologic data (Milunsky et al). 1989;161:291-7
Pregnancy loss in a small chorionic villus sampling series (Clark et al). 1989;161:301-2
The prevalence and biologic significance of lupus anticoagulant and anticardiolipin antibodies in a general obstetric population (Lockwood et al). 1989;161:369-73
Twin-to-twin transfusion syndrome: What are appropriate diagnostic criteria? (Danskin and Neilson). 1989;161:365-9

Fetal death, animal
Effect of inhibiting prostaglandin synthesis in pregnant sheep with 4-aminoantipyrine under normothermic and hyperthermic conditions (Andrianakis et al). 1989;161:241-7

Fetal development
Concurrence of mouthing movement and rapid eye movement/non–rapid eye movement phases with advance in gestation of the human fetus (Horimoto et al). 1989;161:344-51
Dating the early pregnancy by sequential appearance of embryonic structures (Warren et al). 1989;161:747-53
Estimating gestational age in the term pregnancy with a model based on multiple indices of fetal maturity (Goldstein et al). 1989;161:1235-8
Fetal and neonatal cardiovascular complications from β-sympathomimetic therapy for tocolysis (Katz and Seeds). 1989;161:1-9 (Clin. opinion)
Fetal radius length: a critical evaluation of race as a factor in gestational age assessment (Hill et al). 1989;161:193-9
Individual growth curve standards in twins: prediction of

third-trimester growth and birth characteristics (Stefos et al). 1989;161:179-83
Long bone growth in fetuses with Down syndrome (Fitz-Simmons et al). 1989;161:1174-7
A longitudinal study of the relationship between placental and fetal growth as measured by ultrasonography (Wolf et al). 1989;161:1140-5
Low amniotic pressure in oligohydramnios Is this the cause of pulmonary hypoplasia? (Nicolini et al). 1989;161:1098-101 (Clin. opinion)
Normal amniotic fluid volume changes throughout pregnancy (Brace and Wolf). 1989;161:382-8
Plasma amino acids in appropriate- and small-for-gestational-age fetuses (Economides et al). 1989;161:1219-27
The predictive value of fetal breathing movement and Bishop score in the diagnosis of "true" preterm labor (Schreyer et al). 1989;161:886-9
Stimuli for fetal swallowing: systemic factors (Ross et al). 1989;161:1559-65
Ultrasonographic measurement of fetal femur length in growth disturbances (Abramowicz et al). 1989;161:1137-40

Fetal development, animal

In vivo administration of allopurinol affects ovulation and early embryonic development in rabbits (Miyazaki et al). 1989;161:1709-14

Fetal development, epidemiology

Fetal radius length: a critical evaluation of race as a factor in gestational age assessment (Hill et al). 1989;161:193-9

Fetal diseases; *see also* **Abnormalities**

Abscess of allantoic duct remnant (Baill et al). 1989;161:334-6
Amniotic fluid acetylcholinesterase ratios in prenatal diagnosis of fetal abnormalities (Kelly et al). 1989;161:703-5
Antenatal ultrasonographic diagnosis of fetal seizure activity (Landy et al). 1989;161:308
Candida warrants concern (Elliott) (Letter); (Smith) (Reply). 1989;161:503
First-trimester and early second-trimester diagnosis of nuchal cystic hygroma by transvaginal sonography: diverse prognosis of the septated from the nonseptated lesion (Bronshtein et al). 1989;161:78-82
First-trimester midgut herniation: a high-frequency transvaginal sonographic study (Timor-Tritsch et al). 1989;161:831-3
In utero cocaine exposure: observations of fetal behavioral state may predict neonatal outcome (Hume et al). 1989;161:685-90
Isolation of human immunodeficiency virus from the placenta or from maternal blood contaminating the placenta? (Greenspoon and Settlage) (Letter); (Hill et al) (Reply). 1989;161:501-2
Noninvasive management of isolated bilateral fetal hydrothorax (Pijpers et al). 1989;161:330-2
Normal values for human umbilical venous and amniotic fluid pressures and their alteration by fetal disease (Weiner et al). 1989;161:714-7

Fetal distress

Acid-base status at birth and neurodevelopmental outcome at four and one-half years (Dennis et al). 1989;161:213-20
Effects of maternal hyperoxia on the biophysical assessment of fetuses with suspected intrauterine growth retardation (Ruedrich et al). 1989;161:188-92
Fetal blood gas analysis from cordocentesis for abnormal fetal heart rate patterns (Shah and Boehm). 1989;161:374-6
Fetomaternal hemorrhage possible cause of fetal distress and death (Cardwell and Snyder) (Letter); (Biddinger et al) (Reply). 1989;161:1744
Intrapartum Doppler velocimetry, amniotic fluid volume, and fetal heart rate as predictors of subsequent fetal distress. I. An initial report (Sarno et al). 1989;161:1508-14
Perinatal factors influencing atrial natriuretic peptide levels in umbilical arterial plasma at the time of delivery (Castro et al). 1989;161:623-7
Perinatal factors influencing atrial natriuretic peptide levels in umbilical arterial plasma at the time of delivery (Castro et al). (1989;161:623-7). 1989;161:1238 (Correction)
Right ventricular dysfunction in human fetal compromise (Räsänen et al). 1989;161:136-40
Usefulness of continuous fetal heart rate monitoring during cesarean section (Petrikovsky et al). 1989;161:36-7

Fetal distress, animal

Effects of cephalic hypotension, hypertension, and barbiturates on fetal cerebral blood flow and metabolism (Hohimer and Bissonnette). 1989;161:1344-51
The use of an indwelling Doppler probe to study acute changes in umbilical artery waveforms in the fetal sheep (Abitbol et al). 1989;161:1324-31

Fetal growth retardation

Blood gases, pH, and lactate in appropriate- and small-for-gestational-age fetuses (Nicolaides et al). 1989;161:996-1001
Doppler velocimetry and placental disease (Bracero et al). 1989;161:388-93
Duplex Doppler ultrasonographic evaluation of the fetal renal artery in normal and abnormal fetuses (Veille and Kanaan). 1989;161:1502-7
Effect of placental laterality on uterine artery resistance and development of preeclampsia and intrauterine growth retardation (Kofinas et al). 1989;161:1536-9
Effects of maternal hyperoxia on the biophysical assessment of fetuses with suspected intrauterine growth retardation (Ruedrich et al). 1989;161:188-92
Fetal heart rate patterns in the small-for-gestational-age human fetus (Gagnon et al). 1989;161:779-84
Glycemic control in gestational diabetes mellitus How tight is tight enough: Small for gestational age versus large for gestational age? (Langer et al). 1989;161:646-53
Human fetal tricuspid and mitral deceleration time: changes with normal pregnancy and intrauterine growth retardation (Reed et al). 1989;161:1532-5
Intrauterine growth retardation: standards for diagnosis (Goldenberg et al). 1989;161:271-7 (Clin. opinion)
Maternal-fetal glucose gradient in normal pregnancies and in pregnancies complicated by alloimmunization and fetal growth retardation (Nicolini et al). 1989;161:924-7
Plasma amino acids in appropriate- and small-for-gestational-age fetuses (Economides et al). 1989;161:1219-27
Ultrasonographic measurement of fetal femur length in growth disturbances (Abramowicz et al). 1989;161:1137-40
Which is better, being small or thin? (Nikliński) (Letter); (Patterson) (Reply). 1989;161:1089-90

Fetal growth retardation, animal

Effect of placental embolization on the umbilical arterial velocity waveform in fetal sheep (Morrow et al). 1989;161:1055-60

Fetal growth retardation, animal—cont'd
Intrauterine growth retardation and the circulatory responses to acute hypoxemia in fetal sheep (Block et al). 1989;161:1576-9
Pulmonary β-adrenergic receptors and response do not mature precociously in growth-retarded rabbit fetuses (Lee et al). 1989;161:1044-9
Fetal heart
Fetal and neonatal cardiovascular complications from β-sympathomimetic therapy for tocolysis (Katz and Seeds). 1989;161:1-9 (Clin. opinion)
Fetal cardiac output in the isoimmunized pregnancy: a pulsed Doppler-echocardiographic study of patients undergoing intravascular intrauterine transfusion (Copel et al). 1989;161:361-5
Fetal heart rate patterns in red blood cell isoimmunized pregnancies (Nicolaides et al). 1989;161:351-6
Right ventricular dysfunction in human fetal compromise (Räsänen et al). 1989;161:136-40
Fetal heart rate; *see* **Heart rate, fetal**
Fetal hemoglobin
Detection of fetal blood (Leiberman et al) (Letter); (Cardwell) (Reply). 1989;161:257-8
Does midtrimester ΔOD_{450} of amniotic fluid reflect severity of Rh disease? (Ananth and Queenan). 1989;161:47-9
Fetal liver length in normal and isoimmunized pregnancies (Roberts et al). 1989;161:42-6
Fetal hydrops; *see* **Hydrops fetalis**
Fetal hydrothorax; *see* **Hydrothorax**
Fetal macrosomia
Glycemic control in gestational diabetes mellitus How tight is tight enough: Small for gestational age versus large for gestational age? (Langer et al). 1989;161:646-53
Macrosomia in the postdate pregnancy: Is routine ultrasonographic screening indicated? (Chervenak et al). 1989;161:753-6
Fetal maturity, chronologic; *see* **Gestational age**
Fetal membranes
Abscess of allantoic duct remnant (Baill et al). 1989;161:334-6
Fetal death from chlamydial infection across intact amniotic membranes (Thorp et al). 1989;161:1245-6
Prostaglandin E_2 metabolism in the human fetal membranes (Cheung and Challis). 1989;161:1580-5
Fetal membranes, premature rupture
Impact of residual amniotic fluid volume in patients receiving parenteral tocolysis after premature rupture of the membranes (Silver et al). 1989;161:784-7
Prolongation of pregnancy and survival of twin B after loss of twin A at 21 weeks' gestation (Feichtinger et al). 1989;161:891-3
Risk factors for intraamniotic infection: a prospective epidemiologic study (Soper et al). 1989;161:562-8
Saline solution amnioinfusion for oligohydramnios after premature rupture of the membranes (Imanaka et al). 1989;161:102-6
Fetal monitoring
Continuous fetal monitoring with a pulse oximeter: a case of cord compression (Johnson and Johnson). 1989;161:1295-6
Continuous tissue pH monitoring in the term fetus (Small et al). 1989;161:323-9
Effects of maternal hyperoxia on the biophysical assessment of fetuses with suspected intrauterine growth retardation (Ruedrich et al). 1989;161:188-92
Fetal blood gas analysis from cordocentesis for abnormal fetal heart rate patterns (Shah and Boehm). 1989;161:374-6
Fetal heart rate patterns in red blood cell isoimmunized pregnancies (Nicolaides et al). 1989;161:351-6
Postdate fetal surveillance: Is 41 weeks too early? (Guidetti et al). 1989;161:91-3
Preterm and term fetal cardiac and movement responses to vibratory acoustic stimulation (Thomas et al). 1989;161:141-5
Renal artery flow-velocity waveforms in normal and hypoxemic fetuses (Vyas et al). 1989;161:168-72
Risk factors for intraamniotic infection: a prospective epidemiologic study (Soper et al). 1989;161:562-8
Usefulness of continuous fetal heart rate monitoring during cesarean section (Petrikovsky et al). 1989;161:36-7
Fetal movement
Concurrence of mouthing movement and rapid eye movement/non–rapid eye movement phases with advance in gestation of the human fetus (Horimoto et al). 1989;161:344-51
The effect of vibroacoustic stimulation on the nonstress test at gestational ages of thirty-two weeks or less (Druzin et al). 1989;161:1476-8
Effects of low-frequency vibration on human term fetuses (Gagnon et al). 1989;161:1479-85
The effects of vibroacoustic stimulation on baseline heart rate, breathing activity, and body movements of normal term fetuses (Devoe et al). 1989;161:524-9
Human fetal behavioral states after vibratory stimulation (Gagnon et al). 1989;161:1470-6
Preterm and term fetal cardiac and movement responses to vibratory acoustic stimulation (Thomas et al). 1989;161:141-5
Fetal organ maturity
Measurement of fetal urine production in normal pregnancy by real-time ultrasonography (Rabinowitz et al). 1989;161:1264-6
Ovine fetal lung fluid response to atrial natriuretic factor (Castro et al). 1989;161:1337-43
Pulmonary β-adrenergic receptors and response do not mature precociously in growth-retarded rabbit fetuses (Lee et al). 1989;161:1044-9
Surfactant proteins in the diagnosis of fetal lung maturity. II. The 35 kd protein and phospholipids in complicated pregnancy (Hallman et al). 1989;161:965-9
Uselessness of the phosphatidylglycerol assay for prediction of lung maturity (Egberts and Wijnands) (Letter); (Fadel) (Reply). 1989;161:1417-8
Fetal presentation, breech; *see* **Breech presentation**
Fetal proteins
Immunoregulatory activity in supernatants from cultures of normal human trophoblast cells of the first trimester (Sanyal et al). 1989;161:446-53
Fetal scalp monitoring; *see* **Fetal monitoring**
Fetal transfusion; *see* **Blood transfusion, intrauterine**
Fetal viability
Renal artery flow-velocity waveforms in normal and hypoxemic fetuses (Vyas et al). 1989;161:168-72
Fetofetal transfusion
Perinatal outcome in very preterm births with twin-twin transfusion syndrome (Shan and Chaffin). 1989;161:1111-3
Twin-to-twin transfusion syndrome: What are appropriate

diagnostic criteria? (Danskin and Neilson). 1989;161:365-9

Fetomaternal transfusion
Comparison of predelivery versus postdelivery Kleihauer–Betke stains in cases of fetal death (Owen et al). 1989;161:663-6
Fetomaternal hemorrhage possible cause of fetal distress and death (Cardwell and Snyder) (Letter); (Biddinger et al) (Reply). 1989;161:1744

α-Fetoproteins; *see* **Alpha fetoproteins**

Fetus
Effects of fetal sex and dexamethasone on preterm maternal serum concentrations of human chorionic gonadotropin, progesterone, estrone, estradiol, and estriol (Haning et al). 1989;161:1549-53
Effects of maternal hyperoxia on the biophysical assessment of fetuses with suspected intrauterine growth retardation (Ruedrich et al). 1989;161:188-92
The efficacy of fetal sonographic biometry in Down syndrome screening (Peters et al). 1989;161:297-300
Fetal liver length in normal and isoimmunized pregnancies (Roberts et al). 1989;161:42-5

Fetus, abnormalities
Comparison of six different ultrasonographic methods for predicting lethal fetal pulmonary hypoplasia (Vintzileos et al). 1989;161:606-12
Early pregnancy glycosylated hemoglobin, severity of diabetes, and fetal malformations (Lucas et al). 1989;161:426-31
Fetal hyperinsulinism in anencephaly (Hubinont et al). 1989;161:306-7
Multidisciplinary team counseling for fetal anomalies (Lorenz and Kuhn). 1989;161:263-6 (Clin. opinion)

Fetus, animal
Does furosemide alter the hemodynamic response to rapid intravascular transfusion of the anemic fetal lamb (Chestnut et al). 1989;161:1571-5
The effect of elevated blood glucose on the electroencephalogram and cerebral metabolism during short-term brain ischemia in fetal sheep (Chao et al). 1989;161:221-8
Effect of prolonged hypoxemia on fetal heart rate accelerations and decelerations in sheep (Bocking et al). 1989;161:722-7
Effects of cephalic hypotension, hypertension, and barbiturates on fetal cerebral blood flow and metabolism (Hohimer and Bissonnette). 1989;161:1344-51
Fetal vascular responses to maternal nicardipine administration in the hypertensive ewe (Parisi et al). 1989;161:1035-9
Ovine fetal cardiorespiratory response to nicardipine (Holbrook et al). 1989;161:718-21
Prolonged hyperinsulinemia reduces plasma fatty acid levels in the major lipid groups in fetal sheep (Ogburn et al). 1989;161:728-32

Fetus, cytology
Aromatase in human fetal tissues (Doody and Carr). 1989;161:1694-7
High glucose level decreases proliferation of cultured human fetal cells from placenta (Nelson and Curran). 1989;161:1553-8

Fever
Effect of inhibiting prostaglandin synthesis in pregnant sheep with 4-aminoantipyrine under normothermic and hyperthermic conditions (Andrianakis et al). 1989;161:241-7

Fibroblasts
Human uterus-derived growth substances for rat bone cells and fibroblasts (Koutsilieris). 1989;161:1313-7

Fibronectins
Predictive value of increased plasma levels of fibronectin in gestational hypertension (Ballegeer et al). 1989;161:432-6

First trimester pregnancy; *see* **Pregnancy trimester, first**

Flow cytometry
Flow cytometry of normal, hyperplastic, and malignant human endometrium (Thornton et al). 1989;161:487-92
A monoclonal antibody (MSN-1) against a newly established uterine endometrial cancer cell line (SNG-II) and its application to immunohistochemistry and flow cytometry (Nozawa et al). 1989;161:1079-86

Flowmeters
Clinical management of the fetus with markedly diminished umbilical artery end-diastolic flow (Divon et al). 1989;161:1523-7
Discordant twins a prospective study of the diagnostic value of real-time ultrasonography combined with umbilical artery velocimetry (Divon et al). 1989;161:757-60
Doppler assessment of the fetal and uteroplacental circulation during nifedipine therapy for preterm labor (Mari et al). 1989;161:1514-8
Doppler assessment of the pulsatility index of the middle cerebral artery during constriction of the fetal ductus arteriosus after indomethacin therapy (Mari et al). 1989;161:1528-31
Doppler umbilical artery waveform indices normal values from fourteen to forty-two weeks (Hendricks et al). 1989;161:761-5
Duplex Doppler ultrasonographic evaluation of the fetal renal artery in normal and abnormal fetuses (Veille and Kanaan). 1989;161:1502-7
Evaluation of pulsed Doppler echocardiography for measurement of aortic blood flow in the fetal lamb (Veille et al). 1989;161:1610-4
Intrapartum Doppler velocimetry, amniotic fluid volume, and fetal heart rate as predictors of subsequent fetal distress. I. An initial report (Sarno et al). 1989;161:1508-14
Maternal and fetal blood flow velocity waveforms in patients with preterm labor: relationship to outcome (Brar et al). 1989;161:1519-22
Renal artery flow-velocity waveforms in normal and hypoxemic fetuses (Vyas et al). 1989;161:168-72
Screening with Doppler velocimetry in labor (Feinkind et al). 1989;161:765-70
Systolic/diastolic ratios and waveform shapes (Bewley) (Letter); (Schulman) (Reply). 1989;161:1420-1
Techniques differ in use of Doppler ultrasonography (Easterling and Benedetti) (Letter); (Lee and Rokey) (Reply). 1989;161:1748-50
The use of an indwelling Doppler probe to study acute changes in umbilical artery waveforms in the fetal sheep (Abitbol et al). 1989;161:1324-31
The use of color Doppler imaging for prenatal diagnosis of umbilical cord anomalies: report of three cases (Jauniaux et al). 1989;161:1195-7

Fluid balance; *see* **Water-electrolyte balance**

Fluid therapy
Controlled trial of hydration and bed rest versus bed rest alone in the evaluation of preterm uterine contractions (Pircon et al). 1989;161:775-9

Fluoroimmunoassay
Serial human chorionic gonadotropin determinations by fluoroimmunoassay for differentiation between intrauterine and ectopic gestation (Lindblom et al). 1989;161:397-400
Follicular cyst
Pattern of human chorionic gonadotropin binding in the polycystic ovary (Brawer et al). 1989;161:474-80
Food habits
Risk factors for vulvar lichen sclerosus (Sideri et al). 1989;161:38-42
Forceps; *see* Obstetrical forceps
Forskolin
Uncoupling of excitation from contraction in uterine smooth muscle in near-term ewes (Reid et al). 1989;161:229-33
Free radicals
In vivo administration of allopurinol affects ovulation and early embryonic development in rabbits (Miyazaki et al). 1989;161:1709-14
Frontal bone, growth
In utero diagnosis of benign fetal macrocephaly (DeRosa et al). 1989;161:690-2
Funicitis; *see* Umbilical cord
Furosemide
Does furosemide alter the hemodynamic response to rapid intravascular transfusion of the anemic fetal lamb (Chestnut et al). 1989;161:1571-5

G

Gene amplification
Determination of cellular oncogene rearrangement or amplification in ovarian adenocarcinomas (Smith et al). 1989;161:911-5
Gene rearrangement
Determination of cellular oncogene rearrangement or amplification in ovarian adenocarcinomas (Smith et al). 1989;161:911-5
Genetic counseling
Multidisciplinary team counseling for fetal anomalies (Lorenz and Kuhn). 1989;161:263-6 (Clin. opinion)
Genetic screening
Prenatal screening for Down syndrome with maternal serum human chorionic gonadotropin levels (Petrocik et al). 1989;161:1168-73
Screening for gestational diabetes (Hunter) (Letter); (Weiner) (Reply). 1989;161:1423-4
Genital diseases, female
Phosphorus 31 nuclear magnetic resonance examination of female reproductive tissues (Noyszewski et al). 1989;161:282-8
Gestational age
Concurrence of mouthing movement and rapid eye movement/non–rapid eye movement phases with advance in gestation of the human fetus (Horimoto et al). 1989;161:344-51
Dating the early pregnancy by sequential appearance of embryonic structures (Warren et al). 1989;161:747-53
Doppler umbilical artery waveform indices normal values from fourteen to forty-two weeks (Hendricks et al). 1989;161:761-5
Estimating gestational age in the term pregnancy with a model based on multiple indices of fetal maturity (Goldstein et al). 1989;161:1235-8
Fetal radius length: a critical evaluation of race as a factor in gestational age assessment (Hill et al). 1989;161:193-9
Intrauterine growth retardation: standards for diagnosis (Goldenberg et al). 1989;161:271-7 (Clin. opinion)
Normal amniotic fluid volume changes throughout pregnancy (Brace and Wolf). 1989;161:382-8
Prolactin levels in umbilical cord blood of human infants: relation to gestational age, maternal complications, and neonatal lung function (Parker et al). 1989;161:795-802
Race and gender factors omitted from results (Ansbacher) (Letter); (Goldstein) (Reply). 1989;161:502-3
Gestational trophoblastic tumors; *see* Trophoblastic tumor
Glucose, blood; *see* Blood glucose
Glucose tolerance test
Carbohydrate metabolism in the course of intrahepatic cholestasis in pregnancy (Wójcicka-Jagodzińska et al). 1989;161:959-64
Do the current standards for glucose tolerance testing in pregnancy represent a valid conversion of O'Sullivan's original criteria? (Sacks et al). 1989;161:638-41
Gestational diabetes in the BHE rat: influence of dietary fat (Bue et al). 1989;161:234-40
How reliable is the fifty-gram, one-hour glucose screening test? (Sacks et al). 1989;161:642-5
Management of women with one abnormal oral glucose tolerance test value reduces adverse outcome in pregnancy (Langer et al). 1989;161:593-9
Screening for gestational diabetes (Hunter) (Letter); (Weiner) (Reply). 1989;161:1423-4
Glucuronates
Androgen sulfate and glucuronide conjugates in nonhirsute and hirsute women with polycystic ovarian syndrome (Matteri et al). 1989;161:1704-9
Glycolipids
Ceramide lactoside in amniotic fluid: high concentration in chorioamnionitis and in preterm labor (Hallman et al). 1989;161:313-8
Glycoproteins
Comparison of in vivo bioavailability of progestational agents into the rat uterus and liver and the effect of plasma protein binding (Van Voorhis et al). 1989;161:1698-703
Glycosylated hemoglobin; *see* Hemoglobin A, glycosylated
Gonadal dysgenesis, 46,XY
Successful twin pregnancy after embryo donation to a patient with XY gonadal dysgenesis (Sauer et al). 1989;161:380-1
Gonadotropin-releasing hormone, analogs; *see* Pituitary hormone releasing hormone, analogs
Gonadotropins
Localization of gonadotropin binding sites in human ovarian neoplasms (Nakano et al). 1989;161:905-10
Gonadotropins, chorionic
Effects of fetal sex and dexamethasone on preterm maternal serum concentrations of human chorionic gonadotropin, progesterone, estrone, estradiol, and estriol (Haning et al). 1989;161:1549-53
Effects of systemic administration of indomethacin on ovulation, luteinization, and steroidogenesis in the rabbit ovary (Katz et al). 1989;161:1361-6
Localization of gonadotropin binding sites in human ovarian neoplasms (Nakano et al). 1989;161:905-10
Pattern of human chorionic gonadotropin binding in the polycystic ovary (Brawer et al). 1989;161:474-80
Prenatal screening for Down syndrome with maternal se-

rum human chorionic gonadotropin levels (Petrocik et al). 1989;161:1168-73
Serial human chorionic gonadotropin determinations by fluoroimmunoassay for differentiation between intrauterine and ectopic gestation (Lindblom et al). 1989;161:397-400
Spontaneously resorbing ectopic pregnancy: preservation of human chorionic gonadotropin bioactivity despite declining steroid hormone levels (Sauer et al). 1989;161:1673-6

Graft rejection
A new surgical technique to treat refractory labial fusion in the elderly (Johnson et al). 1989;161:289-90

Grief
Multidisciplinary team counseling for fetal anomalies (Lorenz and Kuhn). 1989;161:263-6 (Clin. opinion)

Growth retardation, intrauterine; *see* **Fetal growth retardation**

Growth substances
Human uterus-derived growth substances for rat bone cells and fibroblasts (Koutsilieris). 1989;161:1313-7

Gynecologic diseases; *see* **Genital diseases, female**

Gynecology
Breast disease programs in obstetrics and gynecology: a plea for training in mammography (Gleicher). 1989;161:267-70 (Clin. opinion)

H

Haemophilus influenzae
Haemophilus influenzae culture (Winn and Egley). 1989;161:1419 (Letter)

HCG; *see* **Gonadotropins, chorionic**

Hearing loss, sensorineural
Vancomycin during pregnancy: Does it cause hearing loss or nephrotoxicity in the infant? (Reyes et al). 1989;161:977-81

Heart defects, congenital
Fetal and neonatal cardiovascular complications from β-sympathomimetic therapy for tocolysis (Katz and Seeds). 1989;161:1-9 (Clin. opinion)

Heart failure, congestive
Anesthetic management of labor in a patient with dextrocardia, congenitally corrected transposition, Wolff-Parkinson-White syndrome, and congestive heart failure (Sellers et al). 1989;161:1001-3

Heart rate, fetal
The effects of vibroacoustic stimulation on baseline heart rate, breathing activity, and body movements of normal term fetuses (Devoe et al). 1989;161:524-9
Fetal and neonatal cardiovascular complications from β-sympathomimetic therapy for tocolysis (Katz and Seeds). 1989;161:1-9 (Clin. opinion)
Fetal blood gas analysis from cordocentesis for abnormal fetal heart rate patterns (Shah and Boehm). 1989;161:374-6
Fetal heart rate patterns in red blood cell isoimmunized pregnancies (Nicolaides et al). 1989;161:351-6
Fetal heart rate patterns in the small-for-gestational-age human fetus (Gagnon et al). 1989;161:779-84
Human fetal behavioral states after vibratory stimulation (Gagnon et al). 1989;161:1470-6
Human fetal tricuspid and mitral deceleration time: changes with normal pregnancy and intrauterine growth retardation (Reed et al). 1989;161:1532-5
Intrapartum Doppler velocimetry, amniotic fluid volume, and fetal heart rate as predictors of subsequent fetal distress. I. An initial report (Sarno et al). 1989;161:1508-14
Preterm and term fetal cardiac and movement responses to vibratory acoustic stimulation (Thomas et al). 1989;161:141-5
Umbilical artery flow velocity waveforms during acute hypoxemia and the relationship with hemodynamic changes in the fetal lamb (van Huisseling et al). 1989;161:1061-4
Usefulness of continuous fetal heart rate monitoring during cesarean section (Petrikovsky et al). 1989;161:36-7

Heart rate, fetal, animal
Effect of prolonged hypoxemia on fetal heart rate accelerations and decelerations in sheep (Bocking et al). 1989;161:722-7
Effects of terbutaline sulfate on fetal cardiac function (Petersen et al). 1989;161:509-12
Ovine fetal cardiorespiratory response to nicardipine (Holbrook et al). 1989;161:718-21
Ovine fetal cardiovascular responses to packed red blood cell transfusions (Brace). 1989;161:1367-74

Heart surgery
Subsequent fertility in women who undergo cardiac surgery (Nunley et al). 1989;161:573-6

Hematocrit
Maternal hematocrit and premature labor (Goodlin) (Letter); (Lieberman et al) (Reply). 1989;161:1750-1
Ovine fetal cardiovascular responses to packed red blood cell transfusions (Brace). 1989;161:1367-74
Prediction of hematocrit decline after intravascular fetal transfusion (MacGregor et al). 1989;161:1491-3
Pulsed Doppler flow-velocity waveforms in the prediction of fetal hematocrit of the severely isoimmunized pregnancy (Copel et al). 1989;161:341-4

Hemodynamics
Cardiovascular changes in early pregnancy (Capeless and Clapp). 1989;161:1449-53
Central hemodynamic assessment of normal term pregnancy (Clark et al). 1989;161:1439-42
The central hemodynamics of severe preeclampsia (Mabie et al). 1989;161:1443-8
Does furosemide alter the hemodynamic response to rapid intravascular transfusion of the anemic fetal lamb (Chestnut et al). 1989;161:1571-5
Hemodynamic changes during twin pregnancy: a Doppler and M-mode echocardiographic study (Robson et al). 1989;161:1273-8
Maternal hemodynamic effects of uterine contractions by M-mode and pulsed-Doppler echocardiography (Lee et al). 1989;161:974-7

Hemoglobin A, glycosylated
Early pregnancy glycosylated hemoglobin, severity of diabetes, and fetal malformations (Lucas et al). 1989;161:426-31

Hemoglobin F; *see* **Fetal hemoglobin**
Maternal hemoglobin F levels may have an adverse effect on neonatal birth weight in pregnancies with sickle cell disease (Anyaegbunam et al). 1989;161:654-6

Hemolytic disease of newborn; *see* **Erythroblastosis, fetal**

Hemorrhage, fetomaternal; *see* **Fetomaternal transfusion**

Heparin
Thrombosis prophylaxis in pregnancy with use of subcutaneous heparin adjusted by monitoring heparin concentration in plasma (Dahlman et al). 1989;161:420-5

Hepatitis B
High hepatitis B carrier rate among non-Oriental patients with acute salpingitis (Smith et al). 1989;161:879-80
Hernia, ventral
First-trimester midgut herniation: a high-frequency transvaginal sonographic study (Timor-Tritsch et al). 1989;161:831-3
Hexoprenaline
Introduction of hexoprenaline into the treatment of preterm labor (Lechner). 1989;161:1090-1 (Letter)
Hirsutism
Androgen sulfate and glucuronide conjugates in nonhirsute and hirsute women with polycystic ovarian syndrome (Matteri et al). 1989;161:1704-9
Histocompatibility antigens
Differences between white and Chinese populations in human leukocyte antigen sharing and gestational trophoblastic tumors (Ho et al). 1989;161:942-8
HIV
Immunosuppression in pregnant women infected with human immunodeficiency virus (Biggar et al). 1989;161:1239-44
Pharmacokinetics of azidothymidine during late pregnancy in Long-Evans rats (Little et al). 1989;161:732-4
HIV seropositivity
Isolation of human immunodeficiency virus from the placenta or from maternal blood contaminating the placenta? (Greenspoon and Settlage) (Letter); (Hill et al) (Reply). 1989;161:501-2
Homeostasis
Effects of thromboxane synthetase inhibition on maternal-fetal homeostasis in gravid ewes with ovine pregnancy-induced hypertension (Keith et al). 1989;161:1305-13
Hospitals, community
Neonatal resuscitation in community hospitals: a regional-based, team-oriented training program coordinated by the tertiary center (Moore et al). 1989;161:849-55 (Clin. opinion)
Human chorionic gonadotropin; *see* **Gonadotropins, chorionic**
Human immunodeficiency viruses; *see* **HIV**
Human leukocyte antigens; *see* **Histocompatibility antigens**
Human papillomavirus DNA probes; *see* **DNA probes, HPV**
Hyaline membrane disease; *see also* **Respiratory distress syndrome**
Prolactin levels in umbilical cord blood of human infants: relation to gestational age, maternal complications, and neonatal lung function (Parker et al). 1989;161:795-802
Hybridization
Increased frequency of detection of human papillomavirus deoxyribonucleic acid in exfoliated cervical cells during pregnancy (Rando et al). 1989;161:50-5
Mechanism for human papillomavirus transmission at birth (Sedlacek et al). 1989;161:55-9
Hydatidiform mole
Gestational trophoblastic disease: a case-control study from the People's Republic of China (Brinton et al). 1989;161:121-7
Gestational trophoblastic disease and use of oral contraceptives (Rosenberg et al). 1989;161:1087-8 (Letter)
Hydramnios
Noninvasive management of isolated bilateral fetal hydrothorax (Pijpers et al). 1989;161:330-2
Saline solution amnioinfusion for oligohydramnios after premature rupture of the membranes (Imanaka et al). 1989;161:102-6
Hydration; *see* **Fluid therapy**
Hydrogen-ion concentration
Blood gases, pH, and lactate in appropriate- and small-for-gestational-age fetuses (Nicolaides et al). 1989;161:996-1001
Continuous tissue pH monitoring in the term fetus (Small et al). 1989;161:323-9
Diagnosis of birth asphyxia on the basis of fetal pH, Apgar score, and newborn cerebral dysfunction (Gilstrap et al). 1989;161:825-30
Effect of whole-body pH changes on thoracic duct lymph flow in anesthetized sheep (Valenzuela et al). 1989;161:1566-70
Routine umbilical cord blood gas determinations? (Thorp et al). 1989;161:600-5
Hydrops fetalis
The effect of intravascular transfusion on umbilical venous pressure in anemic fetuses with and without hydrops (Weiner et al). 1989;161:1498-501
Fetal cardiac output in the isoimmunized pregnancy: a pulsed Doppler-echocardiographic study of patients undergoing intravascular intrauterine transfusion (Copel et al). 1989;161:361-5
Frequency and timing of intravascular intrauterine transfusions reconsidered (Voto and Margulies) (Letter); (Socol et al) (Reply). 1989;161:255-6
Normal values for human umbilical venous and amniotic fluid pressures and their alteration by fetal disease (Weiner et al). 1989;161:714-7
Two hundred intrauterine exchange transfusions in severe blood incompatibilities (Poissonnier et al). 1989;161:709-13
Hydrostatic pressure
Is a decrease in plasma oncotic pressure enough to explain the edema of pregnancy? (Valenzuela). 1989;161:1624-7
Hydrothorax
Leiomyoma of the ovary with ascites and hydrothorax (Nicoll and Cox). 1989;161:177-8
Noninvasive management of isolated bilateral fetal hydrothorax (Pijpers et al). 1989;161:330-2
Ovarian hyperstimulation presenting as acute hydrothorax after in vitro fertilization (Kingsland et al). 1989;161:381-2
Hydroxyeicosatetraenoic acids
5-Hydroxyeicosatetraenoic acid, leukotriene C_4, and prostaglandin $F_{2\alpha}$ in amniotic fluid before and during term and preterm labor (Walsh). 1989;161:1352-60
Hydroxyurea
Standard administration of hydroxyurea recommended (Piver) (Letter); (Stehman and Bundy) (Reply). 1989;161:1425-6
Hyperglycemia
Glycemic control in gestational diabetes mellitus How tight is tight enough: Small for gestational age versus large for gestational age? (Langer et al). 1989;161:646-53
Hyperinsulinism
The central role of obesity (hyperinsulinemia) in the pathogenesis of the polycystic ovary syndrome (Nestler et al). 1989;161:1095-7 (Clin. opinion)
Effects of chronic fetal hyperinsulinemia on plasma arachidonic acid and prostaglandin concentrations (Stonestreet et al). 1989;161:894-9

Hyperinsulinism, animal
Prolonged hyperinsulinemia reduces plasma fatty acid levels in the major lipid groups in fetal sheep (Ogburn et al). 1989;161:728-32
Hyperphenylalaninemia; *see* **Phenylalanine**
Hypersensitivity
Allergic vaginitis (Dworetzky) (Letter); (Galland) (Reply). 1989;161:1752-3
Hypersensitivity to magnesium sulfate (Thorp et al). 1989;161:889-90
Hypertension
Calcium intake and pregnancy-induced hypertension (Semchyshyn) (Letter); (Belizán and Villar) (Reply). 1989;161:834-5
Can platelet volume predict progressive hypertensive disease in pregnancy? (Walker et al). 1989;161:676-9
Estrogen replacement and cardiovascular disease: serum lipids and blood pressure effects (Hazzard). 1989;161:1847-53 (Symposium)
Predictive value of increased plasma levels of fibronectin in gestational hypertension (Ballegeer et al). 1989;161:432-6
Zinc, cadmium, and hypertension in parturient women (Lazebnik et al). 1989;161:437-40
Hypertension, animal
Effect of magnesium on cocaine-induced, catecholamine-mediated platelet and vascular response in term pregnant ewes (Weaver et al). 1989;161:1331-7
Effects of cephalic hypotension, hypertension, and barbiturates on fetal cerebral blood flow and metabolism (Hohimer and Bissonnette). 1989;161:1344-51
Effects of thromboxane synthetase inhibition on maternal-fetal homeostasis in gravid ewes with ovine pregnancy-induced hypertension (Keith et al). 1989;161:1305-13
Fetal vascular responses to maternal nicardipine administration in the hypertensive ewe (Parisi et al). 1989;161:1035-9
Lack of evidence of a vasodepressor role for relaxin in spontaneously hypertensive and normotensive pregnant rats (Ahokas et al). 1989;161:618-22
Placental vascular responses to nicardipine in the hypertensive ewe (Parisi et al). 1989;161:1039-43
Hypertension, classification
Semantic changes suggested in hypertensive disorders (Reamy) (Letter); (Davey and MacGillivray) (Reply). 1989;161:1422-3
Hyperthermia; *see* **Fever**
Hypotension, animal
Effects of cephalic hypotension, hypertension, and barbiturates on fetal cerebral blood flow and metabolism (Hohimer and Bissonnette). 1989;161:1344-51
Hypoxemia; *see* **Anoxemia**
Hysterectomy
Basic reference gambles recommended for utility assessment (Thornton and Lilford) (Letter); (Silver and Minogue) (Reply). 1989;161:255-7
Hysterosalpingography
Fertility after ectopic pregnancy (Mitchell et al). 1989;161:576-80

I

Ifosfamide
Phase II trial of ifosfamide and mesna in mixed mesodermal tumors of the uterus (A Gynecologic Oncology Group Study) (Sutton et al). 1989;161:309-12
IgE
Allergic vaginitis (Dworetzky) (Letter); (Galland) (Reply). 1989;161:1752-3
IgG
Presence of autoantibodies in women with unexplained infertility (Taylor et al). 1989;161:377-9
The prevalence and biologic significance of lupus anticoagulant and anticardiolipin antibodies in a general obstetric population (Lockwood et al). 1989;161:369-73
IgM
Presence of autoantibodies in women with unexplained infertility (Taylor et al). 1989;161:377-9
The prevalence and biologic significance of lupus anticoagulant and anticardiolipin antibodies in a general obstetric population (Lockwood et al). 1989;161:369-73
Immunity, cellular
Candida albicans: cellular immune system interactions during different stages of menstrual cycle (Kalo-Klein and Witkin). 1989;161:1132-6
Immunization, passive
Successful treatment of two women with antiphospholipid antibodies and refractory pregnancy losses with intravenous immunoglobulin infusions (Wapner et al). 1989;161:1271-2
Immunocytochemistry; *see* **Immunohistochemistry**
Immunoglobulins
Successful treatment of two women with antiphospholipid antibodies and refractory pregnancy losses with intravenous immunoglobulin infusions (Wapner et al). 1989;161:1271-2
Immunohistochemistry
CA 125 in the epithelium closely related to the embryonic ectoderm: the periderm and the amnion (Nanbu et al). 1989;161:462-7
Immunocytochemical study of *ras* and *myc* proto-oncogene polypeptide expression in the human menstrual cycle (Odom et al). 1989;161:1663-8
Immunohistochemical expression of TAG-72 in normal and malignant endometrium: correlation of antigen expression with estrogen receptor and progesterone receptor levels (Soisson et al). 1989;161:1258-63
A monoclonal antibody (MSN-1) against a newly established uterine endometrial cancer cell line (SNG-II) and its application to immunohistochemistry and flow cytometry (Nozawa et al). 1989;161:1079-86
Immunologic suppression; *see* **Immunosuppression**
Immunosuppression
Histologic and immunologic study of uterine biopsy tissue of women with incipient abortion (Michel et al). 1989;161:409-14
Immunoregulatory activity in supernatants from cultures of normal human trophoblast cells of the first trimester (Sanyal et al). 1989;161:446-53
Immunosuppression in pregnant women infected with human immunodeficiency virus (Biggar et al). 1989;161:1239-44
Indomethacin, adverse effects
Antagonism of antihypertensive drug therapy in pregnancy by indomethacin? (Schoenfeld et al). 1989;161:1204-5
Doppler assessment of the pulsatility index of the middle cerebral artery during constriction of the fetal ductus arteriosus after indomethacin therapy (Mari et al). 1989;161:1528-31

Indomethacin, adverse effects—cont'd
Effects of systemic administration of indomethacin on ovulation, luteinization, and steroidogenesis in the rabbit ovary (Katz et al). 1989;161:1361-6
Infant, low birth weight
Data sought to link adverse pregnancy outcome with maternal serum α-fetoprotein levels in black gravid women (Lenke) (Letter); (Macri et al) (Reply). 1989;161:254-5
Effect of birth weight, race, and sex on survival of low-birth-weight infants in neonatal intensive care (Resnick et al). 1989;161:184-7
Intrauterine growth retardation: standards for diagnosis (Goldenberg et al). 1989;161:271-7 (Clin. opinion)
Maternity shelter care for adolescents: its effect on incidence of low birth weight (LaGuardia et al). 1989;161:303-6
Pregnancy in obstetrics residents (Milet). 1989;161:1422 (Letter)
Infant, newborn
Acid-base status at birth and neurodevelopmental outcome at four and one-half years (Dennis et al). 1989;161:213-20
Fetal and neonatal cardiovascular complications from β-sympathomimetic therapy for tocolysis (Katz and Seeds). 1989;161:1-9 (Clin. opinion)
In utero cocaine exposure: observations of fetal behavioral state may predict neonatal outcome (Hume et al). 1989;161:685-90
Neonatal resuscitation in community hospitals: a regional-based, team-oriented training program coordinated by the tertiary center (Moore et al). 1989;161:849-55 (Clin. opinion)
Routine umbilical cord blood gas determinations? (Thorp et al). 1989;161:600-5
Significant decrease in congenital malformations in newborn infants of an unselected population of diabetic women (Damm and Mølsted-Pedersen). 1989;161:1163-7
Infant, newborn, diseases
Antepartum infection as a result of *Streptococcus pneumoniae* and sepsis in neonate (Andreu et al). 1989;161:1424-5 (Letter)
Diagnosis of birth asphyxia on the basis of fetal pH, Apgar score, and newborn cerebral dysfunction (Gilstrap et al). 1989;161:825-30
Meconium aspiration syndrome: intrapartum and neonatal attributes (Rossi et al). 1989;161:1106-10
Neonatal seizures and cesarean section (Boylan) (Letter); (Spellacy) (Reply). 1989;161:836-7
Vancomycin during pregnancy: Does it cause hearing loss or nephrotoxicity in the infant? (Reyes et al). 1989;161:977-81
Infant, postmature; *see also* **Pregnancy, prolonged**
Postdate fetal surveillance: Is 41 weeks too early? (Guidetti et al). 1989;161:91-3
Infant, premature
Changing outcome of extremely premature infants (≤26 weeks' gestation and ≤750 gm): survival and follow-up at a tertiary center (Ferrara et al). 1989;161:1114-8
Effect of birth weight, race, and sex on survival of low-birth-weight infants in neonatal intensive care (Resnick et al). 1989;161:184-7
The effect of vibroacoustic stimulation on the nonstress test at gestational ages of thirty-two weeks or less (Druzin et al). 1989;161:1476-8
Perinatal outcome in very preterm births with twin-twin transfusion syndrome (Shan and Chaffin). 1989;161:1111-3
Prematurity among insulin-requiring diabetic gravid women (Greene et al). 1989;161:106-11
Infant, small for gestational age
Glycemic control in gestational diabetes mellitus How tight is tight enough: Small for gestational age versus large for gestational age? (Langer et al). 1989;161:646-53
Intrauterine growth retardation: standards for diagnosis (Goldenberg et al). 1989;161:271-7 (Clin. opinion)
Infant mortality
Effect of birth weight, race, and sex on survival of low-birth-weight infants in neonatal intensive care (Resnick et al). 1989;161:184-7
Neonatal mortality in normal birth weight babies: Does the level of hospital care make a difference? (Berg et al). 1989;161:86-91
Infection, intraamniotic; *see* **Amniotic fluid**
Infertility, female
Buserelin versus danazol in the treatment of endometriosis-associated infertility (Fedele et al). 1989;161:871-6
A case-control study of epithelial ovarian cancer (Hartge et al). 1989;161:10-6 (Clin. opinion)
Gestational trophoblastic disease: a case-control study from the People's Republic of China (Brinton et al). 1989;161:121-7
The importance of ultrasonography in infertile women with "forgotten" intrauterine contraceptive devices (Ron-El et al). 1989;161:211-2
Lymphocyte activity in the presence of peritoneal fluid from fertile women and infertile women with and without endometriosis (Hill and Anderson). 1989;161:861-4
Presence of autoantibodies in women with unexplained infertility (Taylor et al). 1989;161:377-9
Relationship between circulating antisperm antibodies in women and autoantibodies on the ejaculated sperm of their partners (Witkin and Chaudhry). 1989;161:900-3
Subsequent fertility in women who undergo cardiac surgery (Nunley et al). 1989;161:573-6
Infertility, male
Relationship between circulating antisperm antibodies in women and autoantibodies on the ejaculated sperm of their partners (Witkin and Chaudhry). 1989;161:900-3
Sperm antibodies and infertility (Shulman) (Letter); (Witkin) (Reply). 1989;161:497-9
Informed consent
Pelvic examinations by medical students (Cohen et al). 1989;161:1013-4
Prenatal informed consent for sonogram: an indication for obstetric ultrasonography (Chervenak et al). 1989;161:857-60 (Clin. opinion)
Infusions, intravenous
Fetal blood volume, urine flow, swallowing, and amniotic fluid volume responses to long-term intravascular infusions of saline (Brace). 1989;161:1049-54
Insemination, artificial
Multiple gestation with intrauterine insemination and menotropin therapy (Corsan et al) (Letter); (Dodson et al) (Reply). 1989;161:1751-2
Insulin
Does insulin affect placental glucose metabolism and transfer? (Urbach et al). 1989;161:953-9

Fetal hyperinsulinism in anencephaly (Hubinont et al). 1989;161:306-7
Prolonged hyperinsulinemia reduces plasma fatty acid levels in the major lipid groups in fetal sheep (Ogburn et al). 1989;161:728-32
Triphasic Randomized Clinical Trial: comparison of effects on carbohydrate metabolism (Bowes et al). 1989;161: 1402-7 (Symposium)
Insulin receptors; *see* **Receptors, insulin**
Intensive care units, neonatal
Effect of birth weight, race, and sex on survival of low-birth-weight infants in neonatal intensive care (Resnick et al). 1989;161:184-7
Interleukin 1
Infection and labor. IV. Cachectin–tumor necrosis factor in the amniotic fluid of women with intraamniotic infection and preterm labor (Romero et al). 1989;161: 336-41
Intermenstrual bleeding; *see* **Menstruation, drug effects**
Internship and residency
Pregnancy in obstetrics residents (Milet). 1989;161:1422 (Letter)
Intraamniotic infection; *see* **Amniotic fluid**
Intraepithelial neoplasia; *see* **Cervix dysplasia**
Intraoperative complications
Does terbutaline cause uterine atony and increase intraoperative blood loss? (Brown) (Letter); (Patriarco) (Reply). 1989;161:259
Intrauterine blood transfusion; *see* **Blood transfusion, intrauterine**
Intrauterine devices
Candida warrants concern (Elliott) (Letter); (Smith) (Reply). 1989;161:503
The importance of ultrasonography in infertile women with "forgotten" intrauterine contraceptive devices (Ron-El et al). 1989;161:211-2
Uterine rupture: Are intrauterine pressure catheters useful in the diagnosis? (Rodriguez et al). 1989;161: 666-9
Intrauterine growth retardation; *see* **Fetal growth retardation**
Iron deficiency anemia; *see* **Anemia, hypochromic**
Ischemic heart disease; *see* **Coronary disease**
Isoenzymes
Cardiac isoenzymes and electrocardiographic changes during ritodrine tocolysis (Hadi and Albazzaz). 1989;161: 318-21
Isoimmunization; *see* **Rh isoimmunization**
Isoproterenol
Pregnancy-induced changes in the interaction of guinea pig myometrial β-adrenergic receptors with *l*-isoproterenol (Hatjis and Grogan). 1989;161:1633-6
Items
Items. 1989;161:260, 504, 842, 1094, 1430, 1756

K

Karyotyping
Rapid chromosome analysis with spontaneously dividing cells derived from umbilical cord blood (fetal and neonatal) (Tipton et al). 1989;161:1546-8
Kidney diseases
Vancomycin during pregnancy: Does it cause hearing loss or nephrotoxicity in the infant? (Reyes et al). 1989;161:977-81
Kleihauer-Betke stains; *see* **Stains and staining**
Kwashiorkor
Cordocentesis in the diagnosis of intrauterine starvation (Economides et al). 1989;161:1004-8

L

Labor
Fentanyl citrate analgesia during labor (Rayburn et al). 1989;161:202-6
Fetal intermediate lobe is stimulated by parturition (Facchinetti et al). 1989;161:1267-70
Oxytocin may explain neonatal seizures (Goodlin). 1989;161:259 (Letter)
Prostaglandin E_2 metabolism in the human fetal membranes (Cheung and Challis). 1989;161:1580-5
Screening with Doppler velocimetry in labor (Feinkind et al). 1989;161:765-70
Labor, animal
The antagonistic effect of oxytocin and relaxin on rat uterine segment contractility (Goldsmith et al). 1989;161:1644-9
5-Hydroxyeicosatetraenoic acid, leukotriene C_4, and prostaglandin $F_{2\alpha}$ in amniotic fluid before and during term and preterm labor (Walsh). 1989;161:1352-60
Increased myometrial responsiveness to oxytocin during term and preterm labor (Garfield and Beier). 1989;161:454-61
Labor, premature
Cardiac isoenzymes and electrocardiographic changes during ritodrine tocolysis (Hadi and Albazzaz). 1989;161:318-21
Cardiovascular and metabolic effects associated with nifedipine and ritodrine tocolysis (Ferguson et al). 1989;161:788-95
Ceramide lactoside in amniotic fluid: high concentration in chorioamnionitis and in preterm labor (Hallman et al). 1989;161:313-8
Controlled trial of hydration and bed rest versus bed rest alone in the evaluation of preterm uterine contractions (Pircon et al). 1989;161:775-9
Doppler assessment of the fetal and uteroplacental circulation during nifedipine therapy for preterm labor (Mari et al). 1989;161:1514-8
The effect of magnesium sulfate tocolysis on the fetal biophysical profile (Peaceman et al). 1989;161:771-4
The incidence of positive amniotic fluid cultures in patients in preterm labor with intact membranes (Skoll et al). 1989;161:813-6
Infection and labor. IV. Cachectin–tumor necrosis factor in the amniotic fluid of women with intraamniotic infection and preterm labor (Romero et al). 1989;161: 336-41
Infection and labor. V. Prevalence, microbiology, and clinical significance of intraamniotic infection in women with preterm labor and intact membranes (Romero et al). 1989;161:817-24
Introduction of hexoprenaline into the treatment of preterm labor (Lechner). 1989;161:1090-1 (Letter)
Maternal and fetal blood flow velocity waveforms in patients with preterm labor: relationship to outcome (Brar et al). 1989;161:1519-22
Maternal hematocrit and premature labor (Goodlin) (Letter); (Lieberman et al) (Reply). 1989;161:1750-1
Nifedipine pharmacokinetics during preterm labor tocolysis (Ferguson et al). 1989;161:1485-90
Pneumonia during pregnancy: Has modern technology im-

Labor, premature—cont'd
proved maternal and fetal outcome? (Madinger et al). 1989;161:657-62
The predictive value of fetal breathing movement and Bishop score in the diagnosis of "true" preterm labor (Schreyer et al). 1989;161:886-9
Relaxin in paired samples of serum and milk from women after term and preterm delivery (Eddie et al). 1989;161:970-3
Unexplained elevated maternal serum α-fetoprotein level associated with third-trimester problems (Stephens). 1989;161:500 (Letter)

Labor, premature, animal
5-Hydroxyeicosatetraenoic acid, leukotriene C_4, and prostaglandin $F_{2\alpha}$ in amniotic fluid before and during term and preterm labor (Walsh). 1989;161:1352-60
Increased myometrial responsiveness to oxytocin during term and preterm labor (Garfield and Beier). 1989;161:454-61
Ovine fetal cardiorespiratory response to nicardipine (Holbrook et al). 1989;161:718-21

Labor complications; *see also* **Amniotic fluid**
Defining "primiparas" (Gooden) (Letter); (Thomson) (Reply). 1989;161:1417
The effect of continuous epidural analgesia on cesarean section for dystocia in nulliparous women (Thorp et al). 1989;161:670-5
Neonatal mortality in normal birth weight babies: Does the level of hospital care make a difference? (Berg et al). 1989;161:86-91
Prophylactic amnioinfusion during labor complicated by meconium: a preliminary report (Sadovsky et al). 1989;161:613-7
Risk factors for intraamniotic infection: a prospective epidemiologic study (Soper et al). 1989;161:562-8

Lactates
Blood gases, pH, and lactate in appropriate- and small-for-gestational-age fetuses (Nicolaides et al). 1989;161:996-1001

Lamicel
Cervical dilation: a comparison of Lamicel and Dilapan (Wells and Hulka). 1989;161:1124-6

Laparoscopy; *see* **Peritoneoscopy**

Laparotomy
Nerve entrapment after Pfannenstiel incision (Piura) (Letter); (Sippo) (Reply). 1989;161:499-500

Laser surgery
Death caused by air embolism associated with neodymium:yttrium-aluminum-garnet laser surgery and artificial sapphire tips (Baggish and Daniell). 1989;161:877-8
A ten-year experience treating cervical intraepithelial neoplasia with the CO_2 laser (Baggish et al). 1989;161:60-8

Leiomyoma
Decreased β-carotene tissue levels in uterine leiomyomas and cancers of reproductive and nonreproductive organs (Palan et al). 1989;161:1649-52
Leiomyoma of the ovary with ascites and hydrothorax (Nicoll and Cox). 1989;161:177-8

Leiomyosarcoma; *see* **Sarcoma**

Letters
Letters. 1989;161:254-9, 497-503, 834-40, 1087-92, 1416-27, 1744-54

Leukocytes
Esterase activity in second- and third-trimester amniotic fluid: an indicator of chorioamnionitis (Hoskins et al). 1989;161:1543-5

Leukotaxis; *see* **Chemotaxis, leukocyte**

Leukotrienes
5-Hydroxyeicosatetraenoic acid, leukotriene C_4, and prostaglandin $F_{2\alpha}$ in amniotic fluid before and during term and preterm labor (Walsh). 1989;161:1352-60

Leydig cell tumor
Steroid biosynthesis in the Sertoli-Leydig cell tumor: effects of insulin and luteinizing hormone (Nagamani et al). 1989;161:1738-43

LH
Effects of clomiphene citrate on episodic luteinizing hormone secretion throughout the menstrual cycle (Archer et al). 1989;161:581-92
Pattern of human chorionic gonadotropin binding in the polycystic ovary (Brawer et al). 1989;161:474-80

Light
Vitamin D (soltriol), light, and reproduction (Stumpf and Denny). 1989;161:1375-84 (Curr. dev.)

Lilopristone; *see* **Abortifacient agents**

***Limulus* test**
Infection and labor. V. Prevalence, microbiology, and clinical significance of intraamniotic infection in women with preterm labor and intact membranes (Romero et al). 1989;161:817-24

Lipid peroxidation
Lipid peroxidation in pregnancy: new perspectives on preeclampsia (Hubel et al). 1989;161:1025-34 (Curr. dev.)

Lipids
Estrogen replacement and cardiovascular disease: serum lipids and blood pressure effects (Hazzard). 1989;161:1847-53 (Symposium)
Prolonged hyperinsulinemia reduces plasma fatty acid levels in the major lipid groups in fetal sheep (Ogburn et al). 1989;161:728-32

Lipopolysaccharides
Infection and labor. V. Prevalence, microbiology, and clinical significance of intraamniotic infection in women with preterm labor and intact membranes (Romero et al). 1989;161:817-24

Lipoproteins
The effect of triphasic oral contraceptives on plasma lipids and lipoproteins (Patsch et al). 1989;161:1396-401 (Symposium)

Liver
Elevated liver enzymes and thrombocytopenia in the third trimester of pregnancy: an unusual case report and a review of the literature (Hannah et al). 1989;161:322-3
Fetal liver length in normal and isoimmunized pregnancies (Roberts et al). 1989;161:42-6

Liver, animal
Comparison of in vivo bioavailability of progestational agents into the rat uterus and liver and the effect of plasma protein binding (Van Voorhis et al). 1989;161:1698-703
Compensatory ovarian hypertrophy occurs by a mechanism distinct from compensatory growth in the regenerating liver (Alvarez et al). 1989;161:1653-7

Liver, transplantation
Successful pregnancy after a liver transplant (Sims et al). 1989;161:532-3

Liver regeneration
Compensatory ovarian hypertrophy occurs by a mechanism distinct from compensatory growth in the regenerating liver (Alvarez et al). 1989;161:1653-7
Longitudinal studies
A longitudinal study of the relationship between placental and fetal growth as measured by ultrasonography (Wolf et al). 1989;161:1140-5
Longitudinal ultrasonographic study of the ovarian suppressive activity of a low-dose triphasic oral contraceptive during correct and incorrect pill intake (Hamilton and Hoogland). 1989;161:1159-62
Low birth weight; *see* **Infant, low birth weight**
Lung
Surfactant proteins in the diagnosis of fetal lung maturity. II. The 35 kd protein and phospholipids in complicated pregnancy (Hallman et al). 1989;161:965-9
Uselessness of the phosphatidylglycerol assay for prediction of lung maturity (Egberts and Wijnands) (Letter); (Fadel) (Reply). 1989;161:1417-8
Lung, abnormalities
Comparison of six different ultrasonographic methods for predicting lethal fetal pulmonary hypoplasia (Vintzileos et al). 1989;161:606-12
Low amniotic pressure in oligohydramnios Is this the cause of pulmonary hypoplasia? (Nicolini et al). 1989;161:1098-101 (Clin. opinion)
Lung, embryology
Low amniotic pressure in oligohydramnios Is this the cause of pulmonary hypoplasia? (Nicolini et al). 1989;161:1098-101 (Clin. opinion)
Lung, secretions, animal
Ovine fetal lung fluid response to atrial natriuretic factor (Castro et al). 1989;161:1337-43
Luteal phase
Optimal time in the menstrual cycle for serum progesterone measurement to diagnose luteal phase defects (Daya). 1989;161:1009-11
Luteinizing hormone; *see* **LH**
Lymph
Effect of whole-body pH changes on thoracic duct lymph flow in anesthetized sheep (Valenzuela et al). 1989;161:1566-70
Lymph flow rate response to angiotensin II is decreased in pregnant sheep (Valenzuela and Longo). 1989;161:1615-9
Lymphangioma
First-trimester and early second-trimester diagnosis of nuchal cystic hygroma by transvaginal sonography: diverse prognosis of the septated from the nonseptated lesion (Bronshtein et al). 1989;161:78-82
Lymphatic diseases
Pelvic and paraaortic lymphocysts after radical surgery because of cervical and ovarian cancer (Petru et al). 1989;161:937-41
Lymphatic system, animal
Effect of whole-body pH changes on thoracic duct lymph flow in anesthetized sheep (Valenzuela et al). 1989;161:1566-70
Lymph flow rate response to angiotensin II is decreased in pregnant sheep (Valenzuela and Longo). 1989;161:1615-9
Lymphocysts; *see* **Lymphatic diseases**
Lymphocytes
Lymphocyte activity in the presence of peritoneal fluid from fertile women and infertile women with and without endometriosis (Hill and Anderson). 1989;161:861-4

M

M-mode echocardiography; *see* **Echocardiography**
Macrocephaly; *see* **Skull, growth**
Macrophages
Release of tumor necrosis factor-α by human peritoneal macrophages in vivo and in vitro (Halme). 1989;161:1718-25
Macrosomia; *see* **Fetal macrosomia**
Magnesium
Effect of magnesium on cocaine-induced, catecholamine-mediated platelet and vascular response in term pregnant ewes (Weaver et al). 1989;161:1331-7
Effect of magnesium and preeclampsia on plasma cholinesterase activity (Marx) (Letter); (Kambam et al) (Reply). 1989;161:1754-5
Magnesium supplementation during pregnancy: a double-blind randomized controlled clinical trial (Sibai et al). 1989;161:115-9
Magnesium sulfate
The effect of magnesium sulfate tocolysis on the fetal biophysical profile (Peaceman et al). 1989;161:771-4
Hypersensitivity to magnesium sulfate (Thorp et al). 1989;161:889-90
Neuromuscular blockade with magnesium sulfate and nifedipine (Snyder and Cardwell). 1989;161:35-6
Number clarification requested (Hatjis) (Letter); (Wilkins and Lynch) (Reply). 1989;161:1746
Mammography
Breast disease programs in obstetrics and gynecology: a plea for training in mammography (Gleicher). 1989;161:267-70 (Clin. opinion)
Mannose
Significance of D-mannose as a sperm receptor site on the zona pellucida in human fertilization (Mori et al). 1989;161:207-11
Marmosets; *see* **Callithricidae**
Mastitis
Methicillin-resistant staphylococcal mastitis (Kalstone). 1989;161:120
Maternal-fetal exchange; *see also* **Tocolytic agents**
Candida warrants concern (Elliott) (Letter); (Smith) (Reply). 1989;161:503
Effects of thromboxane synthetase inhibition on maternal-fetal homeostasis in gravid ewes with ovine pregnancy-induced hypertension (Keith et al). 1989;161:1305-13
Isolation of human immunodeficiency virus from the placenta or from maternal blood contaminating the placenta? (Greenspoon and Settlage) (Letter); (Hill et al) (Reply). 1989;161:501-2
Maternal-fetal glucose gradient in normal pregnancies and in pregnancies complicated by alloimmunization and fetal growth retardation (Nicolini et al). 1989;161:924-7
Maternal health services
Maternity shelter care for adolescents: its effect on incidence of low birth weight (LaGuardia et al). 1989;161:303-6
Maternal mortality
Basic reference gambles recommended for utility assessment (Thornton and Lilford) (Letter); (Silver and Minogue) (Reply). 1989;161:256-7

Maternal mortality—cont'd
Maternal deaths associated with *Clostridium sordellii* infection (McGregor et al). 1989;161:987-95
Maternal mortality in North Carolina: a forty-year experience (May and Greiss). 1989;161:555-61
Pneumonia during pregnancy: Has modern technology improved maternal and fetal outcome? (Madinger et al). 1989;161:657-62
Maternal welfare
Maternity shelter care for adolescents: its effect on incidence of low birth weight (LaGuardia et al). 1989;161:303-6
Maximal oxygen uptake; *see* **Oxygen consumption**
Mayer-Rokitansky syndrome; *see* **Vagina, abnormalities**
Meconium
Prophylactic amnioinfusion during labor complicated by meconium: a preliminary report (Sadovsky et al). 1989;161:613-7
Meconium aspiration
Meconium aspiration syndrome: intrapartum and neonatal attributes (Rossi et al). 1989;161:1106-10
Prophylactic amnioinfusion during labor complicated by meconium: a preliminary report (Sadovsky et al). 1989;161:613-7
Medroxyprogesterone
Elevated serum levels of endometrial secretory protein PP14 in patients with advanced endometriosis: suppression by treatment with danazol and high-dose medroxyprogesterone acetate (Telimaa et al). 1989;161:866-71
Melanocyte stimulating hormone; *see* **MSH**
Menarche
Uterine development and endocrine relationships after menarche (Porcu et al). 1989;161:174-7
Menopause; *see also* **Estrogens, therapeutic use**
Biosynthesis and physiologic effects of estrogen and pathophysiologic effects of estrogen deficiency: a review (Utian). 1989;161:1828-31 (Symposium)
Decreased in vitro production of 6-keto-prostaglandin $F_{1\alpha}$ by uterine arteries from postmenopausal women (Steinleitner et al). 1989;161:1677-81
Estrogen replacement therapy: indications, contraindications, and agent selection (Notelovitz). 1989;161:1832-41 (Symposium)
Estrogen replacement therapy: an overview (Mishell). 1989;161:1825-7 (Symposium)
Estrogen replacement therapy: what the future holds (Hammond). 1989;161:1842-6 (Symposium)
Estrogens in the prevention of osteoporosis in postmenopausal women (Genant et al). 1989;161:1842-6 (Symposium)
A new surgical technique to treat refractory labial fusion in the elderly (Johnson et al). 1989;161:289-90
Menotropins
Multiple gestation with intrauterine insemination and menotropin therapy (Corsan et al) (Letter); (Dodson et al) (Reply). 1989;161:1751-2
Menstrual cycle
Atrial natriuretic peptide during the menstrual cycle (Jensen et al). 1989;161:951-2
Candida albicans: cellular immune system interactions during different stages of menstrual cycle (Kalo-Klein and Witkin). 1989;161:1132-6
Effects of clomiphene citrate on episodic luteinizing hormone secretion throughout the menstrual cycle (Archer et al). 1989;161:581-92
Immunocytochemical study of *ras* and *myc* proto-oncogene polypeptide expression in the human menstrual cycle (Odom et al). 1989;161:1663-8
Optimal time in the menstrual cycle for serum progesterone measurement to diagnose luteal phase defects (Daya). 1989;161:1009-11
Menstruation, drug effects
Compliance considerations with estrogen replacement: withdrawal bleeding and other factors (Hahn). 1989;161:1854-8 (Symposium)
The patient's reaction to side effects of oral contraceptives (Hillard). 1989;161:1412-5 (Symposium)
Triphasic Randomized Clinical Trial: comparative frequency of intermenstrual bleeding (Droegemueller et al). 1989;161:1407-11 (Symposium)
2-Mercaptoethanesulfonate
Phase II trial of ifosfamide and mesna in mixed mesodermal tumors of the uterus (A Gynecologic Oncology Group Study) (Sutton et al). 1989;161:309-12
Metastasis; *see* **Neoplasm metastasis**
Methicillin
Methicillin-resistant staphylococcal mastitis (Kalstone). 1989;161:120
Methodology; *see* **Research design**
Methotrexate
Anal submucosal injection: a new route for drug administration in pelvic malignancies. IV. Submucosal anal injection in the treatment of cancer of uterine cervix preliminary study (Shafik). 1989;161:69-72
Local methotrexate injection: a nonsurgical treatment of ectopic pregnancy (Pansky et al). 1989;161:393-6
Successful treatment of a viable cervical pregnancy with methotrexate (Palti et al). 1989;161:1147-8
Methylprednisolone
Dosage and duration differences lead to diverse conclusions (Shulman) (Letter); (Hammond) (Reply). 1989;161:1744-6
Microspheres
Intrauterine growth retardation and the circulatory responses to acute hypoxemia in fetal sheep (Block et al). 1989;161:1576-9
Midtrimester; *see* **Pregnancy trimester, second**
Milk, human
Relaxin in paired samples of serum and milk from women after term and preterm delivery (Eddie et al). 1989;161:970-3
Miscarriage; *see* **Abortion**
Missed abortion; *see* **Abortion, missed**
Mitral valve
Human fetal tricuspid and mitral deceleration time: changes with normal pregnancy and intrauterine growth retardation (Reed et al). 1989;161:1532-5
Mixed Müllerian tumors; *see* **Uterine neoplasms**
Monoclonal antibodies; *see* **Antibodies, monoclonal**
Monosaccharides
Significance of D-mannose as a sperm receptor site on the zona pellucida in human fertilization (Mori et al). 1989;161:207-11
Morbidity
Cocaine abuse during pregnancy: peripartum prevalence and perinatal outcome (Neerhof et al). 1989;161:633-8
Mortality, maternal; *see* **Maternal mortality**
MSH
Fetal intermediate lobe is stimulated by parturition (Facchinetti et al). 1989;161:1267-70
Müllerian tumors, mixed; *see* **Uterine neoplasms**

Muscle, smooth, vascular, animal
Effect of pregnancy on uterine and carotid artery response to norepinephrine, epinephrine, and phenylephrine in vessels with documented functional endothelium (Weiner et al). 1989;161:1605-10
***myc* genes**; *see* **Oncogenes**
Myometrium
Phosphorus 31 nuclear magnetic resonance examination of female reproductive tissues (Noyszewski et al). 1989;161:282-8
Vasopressin receptors in human pregnant myometrium and decidua: interactions with oxytocin and vasopressin agonists and antagonists (Ivanisevic et al). 1989;161:1637-43
Myometrium, animal
The antagonistic effect of oxytocin and relaxin on rat uterine segment contractility (Goldsmith et al). 1989;161:1644-9
Effect of a 48-hour Δ^4-androstenedione infusion on the pregnant rhesus monkey in the last third of gestation: changes in maternal plasma estradiol concentrations and myometrial contractility (Figueroa et al). 1989;161:481-6
Increased myometrial responsiveness to oxytocin during term and preterm labor (Garfield and Beier). 1989;161:454-61
Power spectrum analysis of myometrial electromyogram and intrauterine pressure changes in the pregnant rhesus monkey in late gestation (Hsu et al). 1989;161:467-73
Pregnancy-induced changes in the interaction of guinea pig myometrial β-adrenergic receptors with *l*-isoproterenol (Hatjis and Grogan). 1989;161:1633-6
Treatment of oophorectomized guinea pigs with intrauterine 17β-estradiol pellets may modulate myometrial β-adrenergic receptor binding properties (Hatjis et al). 1989;161:1628-32
Up-regulation of guinea pig myometrial adenylate cyclase activity by intrauterine estradiol and progesterone pellets (Hatjis and Koritnik). 1989;161:1073-8
Myometrium, microbiology
Short course of antibiotic therapy in treatment of postpartum endomyometritis (Morales et al). 1989;161:568-72

N

Narcotics
Fentanyl citrate analgesia during labor (Rayburn et al). 1989;161:202-6
Natriuretic peptides, atrial
Atrial natriuretic factor: the effects of pregnancy and a high-salt diet on atrial levels (Castro et al). 1989;161:1620-3
Atrial natriuretic factor maternal and fetal concentrations in severe preeclampsia (Hatjis et al). 1989;161:1015-9
Atrial natriuretic peptide during the menstrual cycle (Jensen et al). 1989;161:951-2
Atrial natriuretic peptide receptors in guinea pig placentas (Hatjis and Grogan). 1989;161:493-6
Fetal blood volume, urine flow, swallowing, and amniotic fluid volume responses to long-term intravascular infusions of saline (Brace). 1989;161:1049-54
Ovine fetal lung fluid response to atrial natriuretic factor (Castro et al). 1989;161:1337-43
Perinatal factors influencing atrial natriuretic peptide levels in umbilical arterial plasma at the time of delivery (Castro et al). 1989;161:623-7
Perinatal factors influencing atrial natriuretic peptide levels in umbilical arterial plasma at the time of delivery (Castro et al). (1989;161:623-7). 1989;161:1238 (Correction)
Plasma atrial natriuretic peptide in human fetus: response to intravascular blood transfusion (Panos et al). 1989;161:357-61
Neisseria gonorrhoeae
Randomized treatment of mucopurulent cervicitis with doxycycline or amoxicillin (Paavonen et al). 1989;161:128-35
Neonate; *see* **Infant, newborn**
Neoplasm antibodies; *see* **Antibodies, neoplasm**
Neoplasm metastasis
Prognostic significance of steroid receptors measured in primary metastatic and recurrent endometrial carcinoma (Borazjani et al). 1989;161:1253-7
Neoplasms; *see also specific neoplasm*
A clinical-pathologic study of mixed müllerian tumors of the uterus over a 16-year period The Medical College of Georgia experience (Gallup et al). 1989;161:533-9
Decreased β-carotene tissue levels in uterine leiomyomas and cancers of reproductive and nonreproductive organs (Palan et al). 1989;161:1649-52
Neoplasms, epidemiology
The cancer question: an overview of recent epidemiologic and retrospective data (Henderson). 1989;161:1859-64 (Symposium)
Neoplasms, placenta; *see* **Pregnancy complications, neoplastic**
Nerve compression syndromes
Nerve entrapment after Pfannenstiel incision (Piura) (Letter); (Sippo) (Reply). 1989;161:499-500
Neural tube defects
Amniotic fluid acetylcholinesterase ratios in prenatal diagnosis of fetal abnormalities (Kelly et al). 1989;161:703-5
Predictive values, relative risks, and overall benefits of high and low maternal serum α-fetoprotein screening in singleton pregnancies: new epidemiologic data (Milunsky et al). 1989;161:291-7
The role of ultrasonography and amniocentesis in the evaluation of pregnancies at risk for neural tube defects (Hogge et al). 1989;161:520-4
Neurofibromatosis
Neurofibromatosis and pregnancy (Mitterschiffthaler and Fuith) (Letter); (Blickstein) (Reply). 1989;161:501
Newborn; *see* **Infant, newborn**
Nicardipine
Fetal vascular responses to maternal nicardipine administration in the hypertensive ewe (Parisi et al). 1989;161:1035-9
Ovine fetal cardiorespiratory response to nicardipine (Holbrook et al). 1989;161:718-21
Placental vascular responses to nicardipine in the hypertensive ewe (Parisi et al). 1989;161:1039-43
Nicotinamide
Isolation and sequencing of a complementary deoxyribonucleic acid clone encoding human placental 17β-estradiol dehydrogenase: identification of the putative cofactor binding site (Gast et al). 1989;161:1726-31
Nifedipine
Cardiovascular and metabolic effects associated with nifedipine and ritodrine tocolysis (Ferguson et al). 1989;161:788-95
Doppler assessment of the fetal and uteroplacental circulation during nifedipine therapy for preterm labor (Mari et al). 1989;161:1514-8

Nifedipine—cont'd
Neuromuscular blockade with magnesium sulfate and nifedipine (Snyder and Cardwell). 1989;161:35-6
Nifedipine pharmacokinetics during preterm labor tocolysis (Ferguson et al). 1989;161:1485-90
Nomenclature; *see also* **Semantics**
Defining "primiparas" (Gooden) (Letter); (Thomson) (Reply). 1989;161:1417
Missed abortion: Still appropriate terminology? (Pridjian and Moawad). 1989;161:261-2 (Clin. opinion)
Nonstress test
The effect of vibroacoustic stimulation on the nonstress test at gestational ages of thirty-two weeks or less (Druzin et al). 1989;161:1476-8
Norepinephrine
Effect of pregnancy on uterine and carotid artery response to norepinephrine, epinephrine, and phenylephrine in vessels with documented functional endothelium (Weiner et al). 1989;161:1605-10
Nuclear magnetic resonance
Phosphorus 31 nuclear magnetic resonance examination of female reproductive tissues (Noyszewski et al). 1989;161:282-8
Nutrition
Effect of nutrient intake on premenstrual depression (Wurtman et al). 1989;161:1228-34
Nutritional status
Which is better, being small or thin? (Nikliński) (Letter); (Patterson) (Reply). 1989;161:1089-90

O

Obesity
The central role of obesity (hyperinsulinemia) in the pathogenesis of the polycystic ovary syndrome (Nestler et al). 1989;161:1095-7 (Clin. opinion)
Obstetrical forceps
Effect of physician characteristics on the cesarean birth rate (Berkowitz et al). 1989;161:146-9
Occipital bone, growth
In utero diagnosis of benign fetal macrocephaly (DeRosa et al). 1989;161:690-2
Oligomenorrhea
The patient's reaction to side effects of oral contraceptives (Hillard). 1989;161:1412-5 (Symposium)
Oncogenes
Immunocytochemical study of *ras* and *myc* proto-oncogene polypeptide expression in the human menstrual cycle (Odom et al). 1989;161:1663-8
Oncotic pressure; *see* **Cell membrane permeability**
Oocytes
Effects of platelet activating factor on mouse oocyte fertilization in vitro (Minhas et al). 1989;161:1714-7
In vivo administration of allopurinol affects ovulation and early embryonic development in rabbits (Miyazaki et al). 1989;161:1709-14
Semen predictors of in vitro fertilization and embryo cleavage (Daya et al). 1989;161:1284-9
Oophorectomy; *see* **Ovariectomy**
Oral contraceptives; *see* **Contraceptives, oral**
Osteoblasts
Human uterus-derived growth substances for rat bone cells and fibroblasts (Koutsilieris). 1989;161:1313-7
Osteoporosis
Estrogens in the prevention of osteoporosis in postmenopausal women (Genant et al). 1989;161:1842-6 (Symposium)
Outpatients
Outpatient triplet management: a contemporary review (Newman et al). 1989;161:547-5
Ovarian cancer; *see* **Ovarian diseases**
Ovarian cysts
Recurrence of functional ovarian cysts after laparoscopic fenestration (De Wilde). 1989;161:839 (Letter)
Ovarian diseases
Twin pregnancy in premature ovarian failure after estrogen treatment: a case report (Tang and Sawers). 1989;161:172-3
Ovarian diseases, animal
Compensatory ovarian hypertrophy occurs by a mechanism distinct from compensatory growth in the regenerating liver (Alvarez et al). 1989;161:1653-7
Ovarian neoplasms
CA 125 in the epithelium closely related to the embryonic ectoderm: the periderm and the amnion (Nanbu et al). 1989;161:462-7
CA 125 as an independent prognostic factor for survival in patients with epithelial ovarian cancer (Sevelda et al). 1989;161:1213-6
A case-control study of epithelial ovarian cancer (Hartge et al). 1989;161:10-6 (Clin. opinion)
Determination of cellular oncogene rearrangement or amplification in ovarian adenocarcinomas (Smith et al). 1989;161:911-5
The influence of human antimurine antibody on CA 125 levels in patients with ovarian cancer undergoing radioimmunotherapy or immunoscintigraphy with murine monoclonal antibody OC 125 (Muto et al). 1989;161:1206-12
Leiomyoma of the ovary with ascites and hydrothorax (Nicoll and Cox). 1989;161:177-8
Localization of gonadotropin binding sites in human ovarian neoplasms (Nakano et al). 1989;161:905-10
Pelvic and paraaortic lymphocysts after radical surgery because of cervical and ovarian cancer (Petru et al). 1989;161:937-41
Treatment of advanced refractory ovarian carcinoma with a gonadotropin-releasing hormone analogue (Bruckner and Motwani). 1989;161:1216-8
Ovariectomy
Compensatory ovarian hypertrophy occurs by a mechanism distinct from compensatory growth in the regenerating liver (Alvarez et al). 1989;161:1653-7
Treatment of oophorectomized guinea pigs with intrauterine 17β-estradiol pellets may modulate myometrial β-adrenergic receptor binding properties (Hatjis et al). 1989;161:1628-32
Ovary
Ovarian hyperstimulation presenting as acute hydrothorax after in vitro fertilization (Kingsland et al). 1989;161:381-2
Uterine development and endocrine relationships after menarche (Porcu et al). 1989;161:174-7
Vitamin D (soltriol), light, and reproduction (Stumpf and Denny). 1989;161:1375-84 (Curr. dev.)
Ovary, animal
Compensatory ovarian hypertrophy occurs by a mechanism distinct from compensatory growth in the regenerating liver (Alvarez et al). 1989;161:1653-7

Oviducts
Vitamin D (soltriol), light, and reproduction (Stumpf and Denny). 1989;161:1375-84 (Curr. dev.)
Ovulation
Effects of systemic administration of indomethacin on ovulation, luteinization, and steroidogenesis in the rabbit ovary (Katz et al). 1989;161:1361-6
In vivo administration of allopurinol affects ovulation and early embryonic development in rabbits (Miyazaki et al). 1989;161:1709-14
Ovulation induction
Peri-implantation phase endometrial estrogen and progesterone receptors: effect of ovulation induction with clomiphene citrate (Hecht et al). 1989;161:1688-93
Twin pregnancy in premature ovarian failure after estrogen treatment: a case report (Tang and Sawers). 1989;161:172-3
Oximetry
Continuous fetal monitoring with a pulse oximeter: a case of cord compression (Johnson and Johnson). 1989;161:1295-6
Oxygen consumption
Oxygen consumption during treadmill exercise before, during, and after pregnancy (Clapp). 1989;161:1458-64
Predicting maximal oxygen uptake from treadmill testing in trained and untrained women (Martin et al). 1989;161:1127-32
Oxytocin
The antagonistic effect of oxytocin and relaxin on rat uterine segment contractility (Goldsmith et al). 1989;161:1644-9
Increased myometrial responsiveness to oxytocin during term and preterm labor (Garfield and Beier). 1989;161:454-61
Oxytocin may explain neonatal seizures (Goodlin). 1989;161:259 (Letter)
Removing a retained placenta by oxytocin a controlled study (Wilken-Jensen et al). 1989;161:155-6
Vasopressin receptors in human pregnant myometrium and decidua: interactions with oxytocin and vasopressin agonists and antagonists (Ivanisevic et al). 1989;161:1637-43
Oxytocin, antagonists
In vitro uterine response to tetramethylpyrazine, the active constituent of *Chung Chong* (a traditional Chinese medicine) (Tuttle et al). 1989;161:1319-23

P

Papers
Papers of the Society for Gynecologic Investigation. 1989;161:1439-743
Papillomaviruses
Comparison of Cytobrush and cervicovaginal lavage sampling methods for the detection of genital human papillomavirus (Goldberg et al). 1989;161:1669-72
Increased frequency of detection of human papillomavirus deoxyribonucleic acid in exfoliated cervical cells during pregnancy (Rando et al). 1989;161:50-5
Mechanism for human papillomavirus transmission at birth (Sedlacek et al). 1989;161:55-9
Presence of human papillomavirus deoxyribonucleic acid (Beckmann et al) (Letter); (Kaufman et al) (Reply). 1989;161:1419-20
Parathyroid hormones
Erythrocyte cation metabolism in preeclampsia (Sowers et al). 1989;161:441-5
Partial thromboplastin time
The prevalence and biologic significance of lupus anticoagulant and anticardiolipin antibodies in a general obstetric population (Lockwood et al). 1989;161:369-73
Particle size
Absorption of oral progesterone is influenced by vehicle and particle size (Hargrove et al). 1989;161:948-51
Parturition; *see* **Labor**
Paternity
"Possibly" de novo translocations: prenatal risk counseling (Wassman et al). 1989;161:698-702
Pedophilia
Anal and perianal abnormalities in prepubertal victims of sexual abuse (Muram). 1989;161:278-81
Pelvic examination; *see* **Physical examination**
Pelvic neoplasms
Aggressive angiomyxoma first diagnosed as levator hernia (Sutton et al). 1989;161:73-5
Pemphigus
Pemphigus in pregnancy (Kanwar et al). 1989;161:995-6
Peptides
Human α- and β-calcitonin gene-related peptides are vasodilators in human chorionic plate vasculature (Firth and Pipkin). 1989;161:1318-9
Perfusion
Does insulin affect placental glucose metabolism and transfer? (Urbach et al). 1989;161:953-9
Peritoneal cavity
Peritoneal blood painting: an aid in the diagnosis of endometriosis (Redwine). 1989;161:865-6
Peritoneal cavity, cytology
Lymphocyte activity in the presence of peritoneal fluid from fertile women and infertile women with and without endometriosis (Hill and Anderson). 1989;161:861-4
Peritoneal lavage
Release of tumor necrosis factor-α by human peritoneal macrophages in vivo and in vitro (Halme). 1989;161:1718-25
Peritoneoscopy
Recurrence of functional ovarian cysts after laparoscopic fenestration (De Wilde). 1989;161:839 (Letter)
Pessaries
Transfer of prostaglandins to the fetus after prostaglandin E_2 vaginal pessary administration (MacKenzie et al). 1989;161:920-3
Pfannenstiel incision
Nerve entrapment after Pfannenstiel incision (Piura) (Letter); (Sippo) (Reply). 1989;161:499-500
pH; *see* **Hydrogen-ion concentration**
Phenylalanine
Maternal phenylketonuria and hyperphenylalaninemia: implications for medical practice in the United States (Luder and Greene). 1989;161:1102-5 (Clin. opinion)
Phenylephrine
Effect of pregnancy on uterine and carotid artery response to norepinephrine, epinephrine, and phenylephrine in vessels with documented functional endothelium (Weiner et al). 1989;161:1605-10
Phenylketonuria
Maternal phenylketonuria and hyperphenylalaninemia: implications for medical practice in the United States (Luder and Greene). 1989;161:1102-5 (Clin. opinion)

Phenytoin
Clinical experience with phenytoin prophylaxis in severe preeclampsia (Ryan et al). 1989;161:1297-304 (Curr. invest.)
Philosophy, medical
The impact of the acquired immunodeficiency syndrome epidemic on the philosophy of childbirth (Rotmensch et al). 1989;161:855-6 (Clin. opinion)
Phosphatidylglycerols
Uselessness of the phosphatidylglycerol assay for prediction of lung maturity (Egberts and Wijnands) (Letter); (Fadel) (Reply). 1989;161:1417-8
Phospholipid antibodies; *see* **Antibodies**
Phospholipids
Successful treatment of two women with antiphospholipid antibodies and refractory pregnancy losses with intravenous immunoglobulin infusions (Wapner et al). 1989;161:1271-2
Surfactant proteins in the diagnosis of fetal lung maturity. II. The 35 kd protein and phospholipids in complicated pregnancy (Hallman et al). 1989;161:965-9
Physical examination
Pelvic examinations by medical students (Cohen et al). 1989;161:1013-4
Physician's practice patterns
Effect of physician characteristics on the cesarean birth rate (Berkowitz et al). 1989;161:146-9
Pituitary gland
Fetal intermediate lobe is stimulated by parturition (Facchinetti et al). 1989;161:1267-70
Pituitary hormone releasing hormone, analogs
Treatment of advanced refractory ovarian carcinoma with a gonadotropin-releasing hormone analogue (Bruckner and Motwani). 1989;161:1216-8
Placenta
Abscess of allantoic duct remnant (Baill et al). 1989;161:334-6
Aspirin differentially affects thromboxane and prostacyclin production by trophoblast and villous core compartments of human placental villi (Nelson and Walsh). 1989;161:1593-8
Does insulin affect placental glucose metabolism and transfer? (Urbach et al). 1989;161:953-9
Effect of diagnostic and therapeutic cordocentesis on maternal serum α-fetoprotein concentration (Weiner et al). 1989;161:706-8
Effect of placental laterality on uterine artery resistance and development of preeclampsia and intrauterine growth retardation (Kofinas et al). 1989;161:1536-9
High glucose level decreases proliferation of cultured human fetal cells from placenta (Nelson and Curran). 1989;161:1553-8
Human α- and β-calcitonin gene-related peptides are vasodilators in human chorionic plate vasculature (Firth and Pipkin). 1989;161:1318-9
Increased placental progesterone may cause decreased placental prostacyclin production in preeclampsia (Walsh and Coulter). 1989;161:1586-92
A longitudinal study of the relationship between placental and fetal growth as measured by ultrasonography (Wolf et al). 1989;161:1140-5
Phosphorus 31 nuclear magnetic resonance examination of female reproductive tissues (Noyszewski et al). 1989;161:282-8
Removing a retained placenta by oxytocin a controlled study (Wilken-Jensen et al). 1989;161:155-6
Ultrasonographic criteria for the prenatal diagnosis of placental chorionicity in twin gestations (Winn et al). 1989;161:1540-2
Placenta, animal
Atrial natriuretic peptide receptors in guinea pig placentas (Hatjis and Grogan). 1989;161:493-6
Pharmacokinetics of azidothymidine during late pregnancy in Long-Evans rats (Little et al). 1989;161:732-4
Placental vascular responses to nicardipine in the hypertensive ewe (Parisi et al). 1989;161:1039-43
Placenta, ultrastructure
Ultrastructural aspects of preeclampsia. I. Placental bed and uterine boundary vessels (Shanklin and Sibai). 1989;161:735-41
Placenta accreta
Placenta percreta induced uterine rupture and resulted in intraabdominal abortion (Nagy). 1989;161:1185-6
Placenta diseases
Asymptomatic thrombocytopenia associated with chorioangioma of placenta (Limaye and Tchabo). 1989;161:76-7
Doppler velocimetry and placental disease (Bracero et al). 1989;161:388-93
Isolation of human immunodeficiency virus from the placenta or from maternal blood contaminating the placenta? (Greenspoon and Settlage) (Letter); (Hill et al) (Reply). 1989;161:501-2
Twin-to-twin transfusion syndrome: What are appropriate diagnostic criteria? (Danskin and Neilson). 1989;161:365-9
Placenta diseases, animal
Effect of placental embolization on the umbilical arterial velocity waveform in fetal sheep (Morrow et al). 1989;161:1055-60
Placenta neoplasms; *see* **Pregnancy complications, neoplastic**
Placental function tests
Doppler assessment of the fetal and uteroplacental circulation during nifedipine therapy for preterm labor (Mari et al). 1989;161:1514-8
Placental hormones
Aromatase in human fetal tissues (Doody and Carr). 1989;161:1694-7
Isolation and sequencing of a complementary deoxyribonucleic acid clone encoding human placental 17β-estradiol dehydrogenase; identification of the putative cofactor binding site (Gast et al). 1989;161:1726-31
Placental insufficiency
Cordocentesis in the diagnosis of intrauterine starvation (Economides et al). 1989;161:1004-8
Placental proteins; *see* **Pregnancy proteins**
Placental villi; *see* **Chorionic villi**
Plasma
Comparison of in vivo bioavailability of progestational agents into the rat uterus and liver and the effect of plasma protein binding (Van Voorhis et al). 1989;161:1698-703
Platelet activating factor
Effects of platelet activating factor on mouse oocyte fertilization in vitro (Minhas et al). 1989;161:1714-7
Platelet count
Can platelet volume predict progressive hypertensive disease in pregnancy? (Walker et al). 1989;161:676-9
Platelets; *see* **Blood platelets**

Pleural effusion
Noninvasive management of isolated bilateral fetal hydrothorax (Pijpers et al). 1989;161:330-2
Pneumonia
Pneumonia during pregnancy: Has modern technology improved maternal and fetal outcome? (Madinger et al). 1989;161:657-62
Polychondritis, relapsing
Relapsing polychondritis in pregnancy: a case report and review (Gimovsky and Nishiyama). 1989;161:332-4
Polycystic ovary syndrome
Androgen sulfate and glucuronide conjugates in nonhirsute and hirsute women with polycystic ovarian syndrome (Matteri et al). 1989;161:1704-9
The central role of obesity (hyperinsulinemia) in the pathogenesis of the polycystic ovary syndrome (Nestler et al). 1989;161:1095-7 (Clin. opinion)
Polycystic ovary syndrome, animal
Pattern of human chorionic gonadotropin binding in the polycystic ovary (Brawer et al). 1989;161:474-80
Postmature infant; *see* **Infant, postmature**
Postmenopausal bone loss; *see* **Osteoporosis**
Postoperative complications
Nerve entrapment after Pfannenstiel incision (Piura) (Letter); (Sippo) (Reply). 1989;161:499-500
Postpartum period, infection in; *see* **Puerperal infection**
PP14 secretory protein; *see* **Pregnancy proteins**
Predictive value of tests
Flow cytometry of normal, hyperplastic, and malignant human endometrium (Thornton et al). 1989;161:487-92
The predictive value of fetal breathing movement and Bishop score in the diagnosis of "true" preterm labor (Schreyer et al). 1989;161:886-9
Predictive value of increased plasma levels of fibronectin in gestational hypertension (Ballegeer et al). 1989;161:432-6
Predictive values, relative risks, and overall benefits of high and low maternal serum α-fetoprotein screening in singleton pregnancies: new epidemiologic data (Milunsky et al). 1989;161:291-7
Prednisone
Dosage and duration differences lead to diverse conclusions (Shulman) (Letter); (Hammond) (Reply). 1989;161:1744-6
Pre-eclampsia
Atrial natriuretic factor maternal and fetal concentrations in severe preeclampsia (Hatjis et al). 1989;161:1015-9
The central hemodynamics of severe preeclampsia (Mabie et al). 1989;161:1443-8
Clinical experience with phenytoin prophylaxis in severe preeclampsia (Ryan et al). 1989;161:1297-304 (Curr. invest.)
Effect of magnesium and preeclampsia on plasma cholinesterase activity (Marx) (Letter); (Kambam et al) (Reply). 1989;161:1754-5
Effect of placental laterality on uterine artery resistance and development of preeclampsia and intrauterine growth retardation (Kofinas et al). 1989;161:1536-9
Elevated liver enzymes and thrombocytopenia in the third trimester of pregnancy: an unusual case report and a review of the literature (Hannah et al). 1989;161:322-3
Erythrocyte cation metabolism in preeclampsia (Sowers et al). 1989;161:441-5
Increased placental progesterone may cause decreased placental prostacyclin production in preeclampsia (Walsh and Coulter). 1989;161:1586-92
Is central venous pressure monitoring "contraindicated" in patients with severe preeclampsia? (Woodward and Romanoff) (Letter); (Clark and Cotton) (Reply). 1989;161:837-9
Lipid peroxidation in pregnancy: new perspectives on preeclampsia (Hubel et al). 1989;161:1025-34 (Curr. dev.)
Magnesium supplementation during pregnancy: a double-blind randomized controlled clinical trial (Sibai et al). 1989;161:115-9
Predictive value of increased plasma levels of fibronectin in gestational hypertension (Ballegeer et al). 1989;161:432-6
Preeclampsia: an endothelial cell disorder (Roberts et al). 1989;161:1200-4
Prematurity among insulin-requiring diabetic gravid women (Greene et al). 1989;161:106-11
Ultrastructural aspects of preeclampsia. I. Placental bed and uterine boundary vessels (Shanklin and Sibai). 1989;161:735-41
Zinc, cadmium, and hypertension in parturient women (Lazebnik et al). 1989;161:437-40
Pregnancy
Central hemodynamic assessment of normal term pregnancy (Clark et al). 1989;161:1439-42
Exercise prescription in pregnancy: weight-bearing versus non-weight-bearing exercise (Artal et al). 1989;161:1464-9
Measurement of cardiac output in pregnancy by thoracic electrical bioimpedance and thermodilution (Masaki et al). 1989;161:630-4
The measuring of blood pressure during pregnancy (Villar et al). 1989;161:1019-24
Oxygen consumption during treadmill exercise before, during, and after pregnancy (Clapp). 1989;161:1458-64
Vasopressin receptors in human pregnant myometrium and decidua: interactions with oxytocin and vasopressin agonists and antagonists (Ivanisevic et al). 1989;161:1637-43
Pregnancy in adolescence
Maternity shelter care for adolescents: its effect on incidence of low birth weight (LaGuardia et al). 1989;161:303-6
Pregnancy, animal
Atrial natriuretic factor: the effects of pregnancy and a high-salt diet on atrial levels (Castro et al). 1989;161:1620-3
Effect of inhibiting prostaglandin synthesis in pregnant sheep with 4-aminoantipyrine under normothermic and hyperthermic conditions (Andrianakis et al). 1989;161:241-7
Effect of pregnancy on uterine and carotid artery response to norepinephrine, epinephrine, and phenylephrine in vessels with documented functional endothelium (Weiner et al). 1989;161:1605-10
Gestational diabetes in the BHE rat: influence of dietary fat (Bue et al). 1989;161:234-40
In vitro release of endothelium-derived relaxing factor by acetylcholine is increased during the guinea pig pregnancy (Weiner et al). 1989;161:1599-605
Lack of evidence of a vasodepressor role for relaxin in spontaneously hypertensive and normotensive pregnant rats (Ahokas et al). 1989;161:618-22
Lymph flow rate response to angiotensin II is decreased in pregnant sheep (Valenzuela and Longo). 1989;161:1615-9

Pregnancy, animal—cont'd
Pregnancy-induced changes in the interaction of guinea pig myometrial β-adrenergic receptors with *l*-isoproterenol (Hatjis and Grogan). 1989;161:1633-6
Progesterone antagonist lilopristone: a potent abortifacient in the common marmoset (Puri et al). 1989;161:248-53
Uncoupling of excitation from contraction in uterine smooth muscle in near-term ewes (Reid et al). 1989;161:229-33

Pregnancy in diabetes
Do the current standards for glucose tolerance testing in pregnancy represent a valid conversion of O'Sullivan's original criteria? (Sacks et al). 1989;161:638-41
Early pregnancy glycosylated hemoglobin, severity of diabetes, and fetal malformations (Lucas et al). 1989;161:426-31
Glycemic control in gestational diabetes mellitus How tight is tight enough: Small for gestational age versus large for gestational age? (Langer et al). 1989;161:646-53
How reliable is the fifty-gram, one-hour glucose screening test? (Sacks et al). 1989;161:642-5
Management of women with one abnormal oral glucose tolerance test value reduces adverse outcome in pregnancy (Langer et al). 1989;161:593-9
A population-based study of maternal and perinatal outcome in patients with gestational diabetes (Jacobson and Cousins). 1989;161:981-6
Pregnancy after aortofemoral bypass grafting in a diabetic patient (Bradley-Watson). 1989;161:200-1
Prematurity among insulin-requiring diabetic gravid women (Greene et al). 1989;161:106-11
Randomized trial of diet versus diet plus cardiovascular conditioning on glucose levels in gestational diabetes (Jovanovic-Peterson et al). 1989;161:415-9
Screening for gestational diabetes (Hunter) (Letter); (Weiner) (Reply). 1989;161:1423-4
Significant decrease in congenital malformations in newborn infants of an unselected population of diabetic women (Damm and Mølsted-Pedersen). 1989;161:1163-7

Pregnancy in diabetes, animal
Prolonged hyperinsulinemia reduces plasma fatty acid levels in the major lipid groups in fetal sheep (Ogburn et al). 1989;161:728-32

Pregnancy, ectopic
Cervical pregnancy after in vitro fertilization and embryo transfer (Weyerman et al). 1989;161:1145-6
Fertility after ectopic pregnancy (Mitchell et al). 1989;161:576-80
First successful intrauterine pregnancy after treatment of tubal pregnancy with prostaglandin $F_{2\alpha}$ (Egarter and Husslein). 1989;161:904
Local methotrexate injection: a nonsurgical treatment of ectopic pregnancy (Pansky et al). 1989;161:393-6
Low serum progesterone levels and tubal dysfunction a possible cause of ectopic pregnancy (Pulkkinen and Jaakkola). 1989;161:934-7
Maternal mortality in North Carolina: a forty-year experience (May and Greiss). 1989;161:555-61
Serial human chorionic gonadotropin determinations by fluoroimmunoassay for differentiation between intrauterine and ectopic gestation (Lindblom et al). 1989;161:397-400
Spontaneously resorbing ectopic pregnancy: preservation of human chorionic gonadotropin bioactivity despite declining steroid hormone levels (Sauer et al). 1989;161:1673-6
Successful treatment of a viable cervical pregnancy with methotrexate (Palti et al). 1989;161:1147-8
Transvaginal ultrasonography in patients at risk for ectopic pregnancy (Stiller et al). 1989;161:930-3
The use of transvaginal ultrasonography in the diagnosis of ectopic pregnancy (Timor-Tritsch et al). 1989;161:157-61
Vaginosonographic examination Routine procedure? (Furness) (Letter); (Bernaschek and Rudelstorfer) (Reply). 1989;161:499

Pregnancy, multiple
Multiple gestation with intrauterine insemination and menotropin therapy (Corsan et al) (Letter); (Dodson et al) (Reply). 1989;161:1751-2
Successful twin pregnancy after embryo donation to a patient with XY gonadal dysgenesis (Sauer et al). 1989;161:380-1
Twin pregnancy in premature ovarian failure after estrogen treatment: a case report (Tang and Sawers). 1989;161:172-3
Twin-to-twin transfusion syndrome: What are appropriate diagnostic criteria? (Danskin and Neilson). 1989;161:365-9

Pregnancy, prolonged
Macrosomia in the postdate pregnancy: Is routine ultrasonographic screening indicated? (Chervenak et al). 1989;161:753-6
Maternal-fetal outcomes in prolonged pregnancy (Cucco et al). 1989;161:916-20
Postdate fetal surveillance: Is 41 weeks too early? (Guidetti et al). 1989;161:91-3

Pregnancy, tubal; *see also* **Pregnancy, ectopic**
First successful intrauterine pregnancy after treatment of tubal pregnancy with prostaglandin $F_{2\alpha}$ (Egarter and Husslein). 1989;161:904
Local methotrexate injection: a nonsurgical treatment of ectopic pregnancy (Pansky et al). 1989;161:393-6

Pregnancy, unwanted
Attempted suicide and pregnancy (Czeizel and Lendvay). 1989;161:497 (Letter)

Pregnancy-associated alpha plasma protein
Immunoregulatory activity in supernatants from cultures of normal human trophoblast cells of the first trimester (Sanyal et al). 1989;161:446-53

Pregnancy complications
Abscess of allantoic duct remnant (Baill et al). 1989;161:334-6
Aromatase in human fetal tissues (Doody and Carr). 1989;161:1694-7
Candida warrants concern (Elliott) (Letter); (Smith) (Reply). 1989;161:503
The central hemodynamics of severe preeclampsia (Mabie et al). 1989;161:1443-8
Cocaine abuse during pregnancy: peripartum prevalence and perinatal outcome (Neerhof et al). 1989;161:633-8
Elevated liver enzymes and thrombocytopenia in the third trimester of pregnancy: an unusual case report and a review of the literature (Hannah et al). 1989;161:322-3
Erythrocyte cation metabolism in preeclampsia (Sowers et al). 1989;161:441-5
Is a decrease in plasma oncotic pressure enough to explain the edema of pregnancy? (Valenzuela). 1989;161:1624-7

Lipid peroxidation in pregnancy: new perspectives on preeclampsia (Hubel et al). 1989;161:1025-34 (Curr. dev.)
Mechanism for human papillomavirus transmission at birth (Sedlacek et al). 1989;161:55-9
Multidisciplinary team counseling for fetal anomalies (Lorenz and Kuhn). 1989;161:263-6 (Clin. opinion)
Neonatal mortality in normal birth weight babies: Does the level of hospital care make a difference? (Berg et al). 1989;161:86-91
Neurofibromatosis and pregnancy (Mitterschiffthaler and Fuith) (Letter); (Blickstein) (Reply). 1989;161:501
Pemphigus in pregnancy (Kanwar et al). 1989;161:995-6
Phosphorus 31 nuclear magnetic resonance examination of female reproductive tissues (Noyszewski et al). 1989;161:282-8
Pneumonia during pregnancy: Has modern technology improved maternal and fetal outcome? (Madinger et al). 1989;161:657-62
Predictive value of increased plasma levels of fibronectin in gestational hypertension (Ballegeer et al). 1989;161:432-6
Predictive values, relative risks, and overall benefits of high and low maternal serum α-fetoprotein screening in singleton pregnancies: new epidemiologic data (Milunsky et al). 1989;161:291-7
Prematurity among insulin-requiring diabetic gravid women (Greene et al). 1989;161:106-11
The prevalence and biologic significance of lupus anticoagulant and anticardiolipin antibodies in a general obstetric population (Lockwood et al). 1989;161:369-73
Prolactin levels in umbilical cord blood of human infants: relation to gestational age, maternal complications, and neonatal lung function (Parker et al). 1989;161:795-802
Prolongation of pregnancy and survival of twin B after loss of twin A at 21 weeks' gestation (Feichtinger et al). 1989;161:891-3
Relapsing polychondritis in pregnancy: a case report and review (Gimovsky and Nishiyama). 1989;161:332-4
Role of ferritin supported in diagnosis of anemias of pregnancy (Goodlin) (Letter); (Schifman) (Reply). 1989;161:258-9
The role of ultrasonography and amniocentesis in the evaluation of pregnancies at risk for neural tube defects (Hogge et al). 1989;161:520-4
Unexplained elevated maternal serum α-fetoprotein level associated with third-trimester problems (Stephens). 1989;161:500 (Letter)
Usefulness of continuous fetal heart rate monitoring during cesarean section (Petrikovsky et al). 1989;161:36-7
Zinc, cadmium, and hypertension in parturient women (Lazebnik et al). 1989;161:437-40

Pregnancy complications, animal

Effect of a 48-hour Δ^4-androstenedione infusion on the pregnant rhesus monkey in the last third of gestation: changes in maternal plasma estradiol concentrations and myometrial contractility (Figueroa et al). 1989;161:481-6
Gestational diabetes in the BHE rat: influence of dietary fat (Bue et al). 1989;161:234-40
Lack of evidence of a vasodepressor role for relaxin in spontaneously hypertensive and normotensive pregnant rats (Ahokas et al). 1989;161:618-22
Pharmacokinetics of azidothymidine during late pregnancy in Long-Evans rats (Little et al). 1989;161:732-4

Pregnancy complications, cardiovascular

Calcium intake and pregnancy-induced hypertension (Semchyshyn) (Letter); (Belizán and Villar) (Reply). 1989;161:834-5
Can platelet volume predict progressive hypertensive disease in pregnancy? (Walker et al). 1989;161:676-9
Ultrasonographic guidance for central venous access during pregnancy (Lee et al). 1989;161:1012-3

Pregnancy complications, hematologic

Maternal hemoglobin F levels may have an adverse effect on neonatal birth weight in pregnancies with sickle cell disease (Anyaegbunam et al). 1989;161:654-6
Thrombosis prophylaxis in pregnancy with use of subcutaneous heparin adjusted by monitoring heparin concentration in plasma (Dahlman et al). 1989;161:420-5

Pregnancy complications, infectious; *see also* **Amniotic fluid**

Fetal death from chlamydial infection across intact amniotic membranes (Thorp et al). 1989;161:1245-6
Immunosuppression in pregnant women infected with human immunodeficiency virus (Biggar et al). 1989;161:1239-44
Infection and labor. IV. Cachectin–tumor necrosis factor in the amniotic fluid of women with intraamniotic infection and preterm labor (Romero et al). 1989;161:336-41
Risk factors for intraamniotic infection: a prospective epidemiologic study (Soper et al). 1989;161:562-8

Pregnancy complications, neoplastic

Asymptomatic thrombocytopenia associated with chorioangioma of placenta (Limaye and Tchabo). 1989;161:76-7
Sarcoma associated wtih pregnancy (Kyodo et al). 1989;161:94-6

Pregnancy maintenance

Cardiac isoenzymes and electrocardiographic changes during ritodrine tocolysis (Hadi and Albazzaz). 1989;161:318-21
Prolongation of pregnancy and survival of twin B after loss of twin A at 21 weeks' gestation (Feichtinger et al). 1989;161:891-3

Pregnancy outcome

Acid-base status at birth and neurodevelopmental outcome at four and one-half years (Dennis et al). 1989;161:213-20
Antenatal ultrasonographic diagnosis of fetal seizure activity (Landy et al). 1989;161:308
Attempted suicide and pregnancy (Czeizel and Lendvay). 1989;161:497 (Letter)
Breech presentation after cesarean section: always a section (Ophir et al). 1989;161:25-8
Changing outcome of extremely premature infants (≤26 weeks' gestation and ≤750 gm): survival and follow-up at a tertiary center (Ferrara et al). 1989;161:1114-8
Cocaine abuse during pregnancy: peripartum prevalence and perinatal outcome (Neerhof et al). 1989;161:633-8
Data sought to link adverse pregnancy outcome with maternal serum α-fetoprotein levels in black gravid women (Lenke) (Letter); (Macri et al) (Reply). 1989;161:254-5
Doppler velocimetry and placental disease (Bracero et al). 1989;161:388-93
Early pregnancy glycosylated hemoglobin, severity of diabetes, and fetal malformations (Lucas et al). 1989;161:426-31
The effects of maternal exercise on early pregnancy outcome (Clapp). 1989;161:1453-7
Fetal and neonatal cardiovascular complications from β-sympathomimetic therapy for tocolysis (Katz and Seeds). 1989;161:1-9 (Clin. opinion)

Pregnancy outcome—cont'd
In utero cocaine exposure: observations of fetal behavioral state may predict neonatal outcome (Hume et al). 1989;161:685-90
The improving outcome of triplet pregnancies (Lipitz et al). 1989;161:1279-84
Magnesium supplementation during pregnancy: a double-blind randomized controlled clinical trial (Sibai et al). 1989;161:115-9
Management of the nonvertex second twin: primary cesarean section, external version, or primary breech extraction (Gocke et al). 1989;161:111-4
Management of women with one abnormal oral glucose tolerance test value reduces adverse outcome in pregnancy (Langer et al). 1989;161:593-9
Maternal and fetal blood flow velocity waveforms in patients with preterm labor: relationship to outcome (Brar et al). 1989;161:1519-22
Maternal-fetal outcomes in prolonged pregnancy (Cucco et al). 1989;161:916-20
Neonatal mortality in normal birth weight babies: Does the level of hospital care make a difference? (Berg et al). 1989;161:86-91
Noninvasive management of isolated bilateral fetal hydrothorax (Pijpers et al). 1989;161:330-2
Oxygen consumption during treadmill exercise before, during, and after pregnancy (Clapp). 1989;161:1458-64
Perinatal outcome in very preterm births with twin-twin transfusion syndrome (Shan and Chaffin). 1989;161:1111-3
A population-based study of maternal and perinatal outcome in patients with gestational diabetes (Jacobson and Cousins). 1989;161:981-6
Postdate fetal surveillance: Is 41 weeks too early? (Guidetti et al). 1989;161:91-3
Predictive values, relative risks, and overall benefits of high and low maternal serum α-fetoprotein screening in singleton pregnancies: new epidemiologic data (Milunsky et al). 1989;161:291-7
Pregnancy after aortofemoral bypass grafting in a diabetic patient (Bradley-Watson). 1989;161:200-1
Pregnancy in obstetrics residents (Milet). 1989;161:1422 (Letter)
Prematurity among insulin-requiring diabetic gravid women (Greene et al). 1989;161:106-11
The prevalence and biologic significance of lupus anticoagulant and anticardiolipin antibodies in a general obstetric population (Lockwood et al). 1989;161:369-73
Reproductive outcome after anesthesia and operation during pregnancy: registry study of 5405 cases (Mazze and Källén). 1989;161:1178-85
Successful pregnancy after a liver transplant (Sims et al). 1989;161:532-3
Vaginal birth after cesarean delivery in the twin gestation (Strong et al). 1989;161:29-32

Pregnancy outcome, animal
Gestational diabetes in the BHE rat: influence of dietary fat (Bue et al). 1989;161:234-40

Pregnancy proteins
Elevated serum levels of endometrial secretory protein PP14 in patients with advanced endometriosis: suppression by treatment with danazol and high-dose medroxyprogesterone acetate (Telimaa et al). 1989;161:866-71
Immunoregulatory activity in supernatants from cultures of normal human trophoblast cells of the first trimester (Sanyal et al). 1989;161:446-53

Pregnancy tests
Analytical and clinical sensitivity and specificity in pregnancy testing (Norman) (Letter); (Emancipator) (Reply). 1989;161:835-6
Vaginosonographic examination Routine procedure? (Furness) (Letter); (Bernaschek and Rudelstorfer) (Reply). 1989;161:499

Pregnancy trimester, animal, third
Power spectrum analysis of myometrial electromyogram and intrauterine pressure changes in the pregnant rhesus monkey in late gestation (Hsu et al). 1989;161:467-73

Pregnancy trimester, first
Cardiovascular changes in early pregnancy (Capeless and Clapp). 1989;161:1449-53
Dating the early pregnancy by sequential appearance of embryonic structures (Warren et al). 1989;161:747-53
First-trimester midgut herniation: a high-frequency transvaginal sonographic study (Timor-Tritsch et al). 1989;161:831-3
The frequency and management of uterine perforations during first-trimester abortions (Kaali et al). 1989;161:406-8
Immunoregulatory activity in supernatants from cultures of normal human trophoblast cells of the first trimester (Sanyal et al). 1989;161:446-53
Missed abortion: Still appropriate terminology? (Pridjian and Moawad). 1989;161:261-2 (Clin. opinion)

Pregnancy trimester, second
Does midtrimester ΔOD_{450} of amniotic fluid reflect severity of Rh disease? (Ananth and Queenan). 1989;161:47-9
The efficacy of fetal sonographic biometry in Down syndrome screening (Peters et al). 1989;161:297-300
Esterase activity in second- and third-trimester amniotic fluid: an indicator of chorioamnionitis (Hoskins et al). 1989;161:1543-5
Missed abortion: Still appropriate terminology? (Pridjian and Moawad). 1989;161:261-2 (Clin. opinion)

Pregnancy trimester, third
The effect of vibroacoustic stimulation on the nonstress test at gestational ages of thirty-two weeks or less (Druzin et al). 1989;161:1476-8
Effects of maternal hyperoxia on the biophysical assessment of fetuses with suspected intrauterine growth retardation (Ruedrich et al). 1989;161:188-92
Elevated liver enzymes and thrombocytopenia in the third trimester of pregnancy: an unusual case report and a review of the literature (Hannah et al). 1989;161:322-3
Esterase activity in second- and third-trimester amniotic fluid: an indicator of chorioamnionitis (Hoskins et al). 1989;161:1543-5
Individual growth curve standards in twins: prediction of third-trimester growth and birth characteristics (Stefos et al). 1989;161:179-83
Postdate fetal surveillance: Is 41 weeks too early? (Guidetti et al). 1989;161:91-3
Preterm and term fetal cardiac and movement responses to vibratory acoustic stimulation (Thomas et al). 1989;161:141-5
Unexplained elevated maternal serum α-fetoprotein level associated with third-trimester problems (Stephens). 1989;161:500 (Letter)

Pregnancy trimester, third, animal
Effect of a 48-hour Δ^4-androstenedione infusion on the

pregnant rhesus monkey in the last third of gestation: changes in maternal plasma estradiol concentrations and myometrial contractility (Figueroa et al). 1989;161: 481-6

Premature infant; *see* **Infant, premature**

Premature labor; *see* **Labor, premature**

Premature rupture of membranes; *see* **Fetal membranes, premature rupture**

Premenstrual syndrome

Depressive episodes in premenstrual syndrome (Mortola et al). 1989;161:1682-7

Effect of nutrient intake on premenstrual depression (Wurtman et al). 1989;161:1228-34

Prenatal care

Multidisciplinary team counseling for fetal anomalies (Lorenz and Kuhn). 1989;161:263-6 (Clin. opinion)

Prenatal diagnosis

Amniotic fluid acetylcholinesterase ratios in prenatal diagnosis of fetal abnormalities (Kelly et al). 1989;161:703-5

Analysis of fetal loss after transcervical chorionic villus sampling a review of 719 patients (Wade and Young). 1989;161:513-9

Enlarged cisterna magna in trisomy 18: prenatal ultrasonographic diagnosis (Thurmond et al). 1989;161:83-5

Fetal cardiac output in the isoimmunized pregnancy: a pulsed Doppler-echocardiographic study of patients undergoing intravascular intrauterine transfusion (Copel et al). 1989;161:361-5

First-trimester and early second-trimester diagnosis of nuchal cystic hygroma by transvaginal sonography: diverse prognosis of the septated from the nonseptated lesion (Bronshtein et al). 1989;161:78-82

In utero diagnosis of benign fetal macrocephaly (DeRosa et al). 1989;161:690-2

"Possibly" de novo translocations: prenatal risk counseling (Wassman et al). 1989;161:698-702

Pulsed Doppler flow-velocity waveforms in the prediction of fetal hematocrit of the severely isoimmunized pregnancy (Copel et al). 1989;161:341-4

Rapid chromosome analysis with spontaneously dividing cells derived from umbilical cord blood (fetal and neonatal) (Tipton et al). 1989;161:1546-8

Ultrasonographic criteria for the prenatal diagnosis of placental chorionicity in twin gestations (Winn et al). 1989;161:1540-2

Presentation, breech; *see* **Breech presentation**

Presidential address

The challenge of change revisited (Greiss). 1989;161:505-9 (Pres. address)

Preterm delivery; *see* **Infant, premature**

Preterm labor; *see* **Labor, premature**

Prevalence studies

Data sought to link adverse pregnancy outcome with maternal serum α-fetoprotein levels in black gravid women (Lenke) (Letter); (Macri et al) (Reply). 1989;161:254-5

Differences between white and Chinese populations in human leukocyte antigen sharing and gestational trophoblastic tumors (Ho et al). 1989;161:942-8

Prevous cesarean section; *see* **Cesarean section**

Professional practice

The challenge of change revisited (Greiss). 1989;161:505-9 (Pres. address)

Progestational hormones

Comparison of in vivo bioavailability of progestational agents into the rat uterus and liver and the effect of plasma protein binding (Van Voorhis et al). 1989;161:1698-703

Progesterone

Absorption of oral progesterone is influenced by vehicle and particle size (Hargrove et al). 1989;161:948-51

Effects of fetal sex and dexamethasone on preterm maternal serum concentrations of human chorionic gonadotropin, progesterone, estrone, estradiol, and estriol (Haning et al). 1989;161:1549-53

Increased placental progesterone may cause decreased placental prostacyclin production in preeclampsia (Walsh and Coulter). 1939;161:1586-92

Low serum progesterone levels and tubal dysfunction a possible cause of ectopic pregnancy (Pulkkinen and Jaakkola). 1989;161:934-7

Optimal time in the menstrual cycle for serum progesterone measurement to diagnose luteal phase defects (Daya). 1989;161:1009-11

Progesterone antagonist lilopristone: a potent abortifacient in the common marmoset (Puri et al). 1989;161:248-53

Spontaneously resorbing ectopic pregnancy: preservation of human chorionic gonadotropin bioactivity despite declining steroid hormone levels (Sauer et al). 1989;161:1673-6

Up-regulation of guinea pig myometrial adenylate cyclase activity by intrauterine estradiol and progesterone pellets (Hatjis and Koritnik). 1989;161:1073-8

Prognosis

CA 125 as an independent prognostic factor for survival in patients with epithelial ovarian cancer (Sevelda et al). 1989;161:1213-6

Prognostic significance of steroid receptors measured in primary metastatic and recurrent endometrial carcinoma (Borazjani et al). 1989;161:1253-7

Prolactin

Mechanisms that subserve estradiol's induction of increased prolactin concentrations: evidence of amplitude modulation of spontaneous prolactin secretory bursts (Veldhuis et al). 1989;161:1149-58

Prolactin levels in umbilical cord blood of human infants: relation to gestational age, maternal complications, and neonatal lung function (Parker et al). 1989;161:795-802

Proprioception

Effects of low-frequency vibration on human term fetuses (Gagnon et al). 1989;161:1479-85

Prospective studies

Discordant twins—a prospective study of the diagnostic value of real-time ultrasonography combined with umbilical artery velocimetry (Divon et al). 1989;161: 757-60

Primary stress urinary incontinence and pelvic relaxation: prospective randomized comparison of three different operations (Bergman et al). 1989;161:97-101

Prostacyclin; *see* **Prostaglandins**

Prostaglandins

Aspirin differentially affects thromboxane and prostacyclin production by trophoblast and villous core compartments of human placental villi (Nelson and Walsh). 1989;161:1593-8

Decreased in vitro production of 6-keto-prostaglandin $F_{1\alpha}$ by uterine arteries from postmenopausal women (Steinleitner et al). 1989;161:1677-81

Effect of acute intravascular volume expansion on human fetal prostaglandin concentrations (Weiner and Robillard). 1989;161:1494-7

Prostaglandins—cont'd
Effect of inhibiting prostaglandin synthesis in pregnant sheep with 4-aminoantipyrine under normothermic and hyperthermic conditions (Andrianakis et al). 1989;161:241-7
Effects of chronic fetal hyperinsulinemia on plasma arachidonic acid and prostaglandin concentrations (Stonestreet et al). 1989;161:894-9
Increased placental progesterone may cause decreased placental prostacyclin production in preeclampsia (Walsh and Coulter). 1989;161:1586-92
Transfer of prostaglandins to the fetus after prostaglandin E_2 vaginal pessary administration (MacKenzie et al). 1989;161:920-3
Prostaglandins E
Infection and labor. IV. Cachectin–tumor necrosis factor in the amniotic fluid of women with intraamniotic infection and preterm labor (Romero et al). 1989;161:336-41
Prostaglandin E_2 metabolism in the human fetal membranes (Cheung and Challis). 1989;161:1580-5
Transfer of prostaglandins to the fetus after prostaglandin E_2 vaginal pessary administration (MacKenzie et al). 1989;161:920-3
Prostaglandins F
Decreased in vitro production of 6-keto-prostaglandin $F_{1\alpha}$ by uterine arteries from postmenopausal women (Steinleitner et al). 1989;161:1677-81
5-Hydroxyeicosatetraenoic acid, leukotriene C_4, and prostaglandin $F_{2\alpha}$ in amniotic fluid before and during term and preterm labor (Walsh). 1989;161:1352-60
Prostaglandins F, synthetic
First successful intrauterine pregnancy after treatment of tubal pregnancy with prostaglandin $F_{2\alpha}$ (Egarter and Husslein). 1989;161:904
Protein binding
Comparison of in vivo bioavailability of progestational agents into the rat uterus and liver and the effect of plasma protein binding (Van Voorhis et al). 1989;161:1698-703
Proto-oncogenes
Immunocytochemical study of *ras* and *myc* proto-oncogene polypeptide expression in the human menstrual cycle (Odom et al). 1989;161:1663-8
Publications
Criticism of publication of pharmaceutical-supported research results draws response (Ledger) (Letter); (Brewer et al) (Reply). 1989;161:839-40
Puerperal disorders
Thrombosis prophylaxis in pregnancy with use of subcutaneous heparin adjusted by monitoring heparin concentration in plasma (Dahlman et al). 1989;161:420-5
Puerperal infection
Antepartum infection as a result of *Streptococcus pneumoniae* and sepsis in neonate (Andreu et al). 1989;161:1424-5 (Letter)
Methicillin-resistant staphylococcal mastitis (Kalstone). 1989;161:120
Short course of antibiotic therapy in treatment of postpartum endomyometritis (Morales et al). 1989;161:568-72
Pulmonary artery
Central hemodynamic assessment of normal term pregnancy (Clark et al). 1989;161:1439-42
The central hemodynamics of severe preeclampsia (Mabie et al). 1989;161:1443-8
Pulmonary artery catheterization in severe eclampsia (Gibbs). 1989;161:1089 (Letter)
Ultrasonographic guidance for central venous access during pregnancy (Lee et al). 1989;161:1012-3
Pulmonary artery, abnormalities
Pulmonary artery agenesis (Verp). 1989;161:1746-7 (Letter)
Pulmonary hypoplasia; *see* **Lung, abnormalities**
Pulmonary surfactants
Impact of antenatal dexamethasone administration on respiratory distress syndrome in surfactant-treated infants (Farrell et al). 1989;161:628-33
Surfactant proteins in the diagnosis of fetal lung maturity. II. The 35 kd protein and phospholipids in complicated pregnancy (Hallman et al). 1989;161:965-9
Pulsatile flow
Doppler assessment of the pulsatility index of the middle cerebral artery during constriction of the fetal ductus arteriosus after indomethacin therapy (Mari et al). 1989;161:1528-31
Umbilical artery flow velocity waveforms during acute hypoxemia and the relationship with hemodynamic changes in the fetal lamb (van Huisseling et al). 1989;161:1061-4

Q

Quality control
Understanding and eliminating errors in perinatal research (Block). 1989;161:5-9 (Clin. opinion)

R

Radioimmunoassay
The influence of human antimurine antibody on CA 125 levels in patients with ovarian cancer undergoing radioimmunotherapy or immunoscintigraphy with murine monoclonal antibody OC 125 (Muto et al). 1989;161:1206-12
Radiology department, hospital
Breast disease programs in obstetrics and gynecology: a plea for training in mammography (Gleicher). 1989;161:267-70 (Clin. opinion)
Random allocation
Delivery of fetuses with gastroschisis (Weiner). 1989;161:1089 (Letter)
Evaluating triphasic oral contraceptives: the rationale for a randomized trial (Grimes). 1989;161:1390-2 (Symposium)
Study design for the Triphasic Randomized Comparative Trial (Dickerson). 1989;161:1392-6 (Symposium)
Triphasic Randomized Clinical Trial: comparative frequency of intermenstrual bleeding (Droegemueller et al). 1989;161:1407-11 (Symposium)
Triphasic Randomized Clinical Trial: comparison of effects on carbohydrate metabolism (Bowes et al). 1989;161:1402-7 (Symposium)
***ras* genes**
Immunocytochemical study of *ras* and *myc* proto-oncogene polypeptide expression in the human menstrual cycle (Odom et al). 1989;161:1663-8
Receptors, adrenergic, beta, animal
Pregnancy-induced changes in the interaction of guinea pig myometrial β-adrenergic receptors with *l*-isoproterenol (Hatjis and Grogan). 1989;161:1633-6
Pulmonary β-adrenergic receptors and response do not mature precociously in growth-retarded rabbit fetuses (Lee et al). 1989;161:1044-9
Treatment of oophorectomized guinea pigs with intrauter-

ine 17β-estradiol pellets may modulate myometrial β-adrenergic receptor binding properties (Hatjis et al). 1989;161:1628-32

Receptors, androgen, deficiency
Seminoma in pubertal patient with androgen insensitivity syndrome (Hurt et al). 1989;161:530-1

Receptors, epidermal growth factor-urogastrone
Epidermal growth factor receptor expression in normal and malignant endometrium (Berchuck et al). 1989;161:1247-52

Receptors, estrogen
Immunohistochemical expression of TAG-72 in normal and malignant endometrium: correlation of antigen expression with estrogen receptor and progesterone receptor levels (Soisson et al). 1989;161:1258-63
Peri-implantation phase endometrial estrogen and progesterone receptors: effect of ovulation induction with clomiphene citrate (Hecht et al). 1989;161:1688-93

Receptors, insulin
Steroid biosynthesis in the Sertoli-Leydig cell tumor: effects of insulin and luteinizing hormone (Nagamani et al). 1989;161:1738-43

Receptors, pituitary hormone
Vasopressin receptors in human pregnant myometrium and decidua: interactions with oxytocin and vasopressin agonists and antagonists (Ivanisevic et al). 1989;161:1637-43

Receptors, progesterone
Immunohistochemical expression of TAG-72 in normal and malignant endometrium: correlation of antigen expression with estrogen receptor and progesterone receptor levels (Soisson et al). 1989;161:1258-63
Peri-implantation phase endometrial estrogen and progesterone receptors: effect of ovulation induction with clomiphene citrate (Hecht et al). 1989;161:1688-93

Receptors, sensory
Effects of low-frequency vibration on human term fetuses (Gagnon et al). 1989;161:1479-85

Receptors, steroid
Prognostic significance of steroid receptors measured in primary metastatic and recurrent endometrial carcinoma (Borazjani et al). 1989;161:1253-7

Regional medical programs
Neonatal resuscitation in community hospitals: a regional-based, team-oriented training program coordinated by the tertiary center (Moore et al). 1989;161:849-55 (Clin. opinion)

Registries
Reproductive outcome after anesthesia and operation during pregnancy: registry study of 5405 cases (Mazze and Källén). 1989;161:1178-85

Relapsing polychondritis; *see* **Polychondritis, relapsing**

Relaxin
The antagonistic effect of oxytocin and relaxin on rat uterine segment contractility (Goldsmith et al). 1989;161:1644-9
Lack of evidence of a vasodepressor role for relaxin in spontaneously hypertensive and normotensive pregnant rats (Ahokas et al). 1989;161:618-22
Relaxin in paired samples of serum and milk from women after term and preterm delivery (Eddie et al). 1989;161:970-3

Renal artery
Duplex Doppler ultrasonographic evaluation of the fetal renal artery in normal and abnormal fetuses (Veille and Kanaan). 1989;161:1502-7
Renal artery flow-velocity waveforms in normal and hypoxemic fetuses (Vyas et al). 1989;161:168-72

Renin-angiotensin system
The renin-angiotensin system during pregnancy in chronically instrumented, conscious rats (Conrad et al). 1989;161:1065-72

Repeat cesarean section; *see* **Cesarean section**

Reproduction
Gestational trophoblastic disease: a case-control study from the People's Republic of China (Brinton et al). 1989;161:121-7
Vitamin D (soltriol), light, and reproduction (Stumpf and Denny). 1989;161:1375-84 (Curr. dev.)

Research design
Delivery of fetuses with gastroschisis (Weiner). 1989;161:1089 (Letter)
Estrogen replacement therapy: what the future holds (Hammond). 1989;161:1864-8 (Symposium)
Evaluating triphasic oral contraceptives: the rationale for a randomized trial (Grimes). 1989;161:1390-2 (Symposium)
Intrauterine growth retardation: standards for diagnosis (Goldenberg et al). 1989;161:271-7 (Clin. opinion)
Study design for the Triphasic Randomized Comparative Trial (Dickerson). 1989;161:1392-6 (Symposium)
Triphasic Randomized Clinical Trial: comparative frequency of intermenstrual bleeding (Droegemueller et al). 1989;161:1407-11 (Symposium)
Triphasic Randomized Clinical Trial: comparison of effects on carbohydrate metabolism (Bowes et al). 1989;161:1402-7 (Symposium)
Understanding and eliminating errors in perinatal research (Block). 1989;161:5-9 (Clin. opinion)

Research support
Criticism of publication of pharmaceutical-supported research results draws response (Ledger) (Letter); (Brewer et al) (Reply). 1989;161:839-40

Respiratory acidosis
Continuous tissue pH monitoring in the term fetus (Small et al). 1989;161:323-9

Respiratory distress syndrome
Impact of antenatal dexamethasone administration on respiratory distress syndrome in surfactant-treated infants (Farrell et al). 1989;161:628-33
Prolactin levels in umbilical cord blood of human infants: relation to gestational age, maternal complications, and neonatal lung function (Parker et al). 1989;161:795-802
Surfactant proteins in the diagnosis of fetal lung maturity. II. The 35 kd protein and phospholipids in complicated pregnancy (Hallman et al). 1989;161:965-9
Uselessness of the phosphatidylglycerol assay for prediction of lung maturity (Egberts and Wijnands) (Letter); (Fadel) (Reply). 1989;161:1417-8

Respiratory insufficiency
Relapsing polychondritis in pregnancy: a case report and review (Gimovsky and Nishiyama). 1989;161:332-4

Resuscitation
Does terbutaline cause uterine atony and increase intraoperative blood loss? (Brown) (Letter); (Patriarco) (Reply). 1989;161:259
Neonatal resuscitation in community hospitals: a regional-based, team-oriented training program coordinated by

Resuscitation—cont'd
the tertiary center (Moore et al). 1989;161:849-55 (Clin. opinion)
Retrospective studies
The cancer question: an overview of recent epidemiologic and retrospective data (Henderson). 1989;161:1859-64 (Symposium)
Rh isoimmunization
Does midtrimester ΔOD_{450} of amniotic fluid reflect severity of Rh disease? (Ananth and Queenan). 1989;161:47-9
The effect of intravascular transfusion on umbilical venous pressure in anemic fetuses with and without hydrops (Weiner et al). 1989;161:1498-501
Fetal cardiac output in the isoimmunized pregnancy: a pulsed Doppler-echocardiographic study of patients undergoing intravascular intrauterine transfusion (Copel et al). 1989;161:361-5
Fetal heart rate patterns in red blood cell isoimmunized pregnancies (Nicolaides et al). 1989;161:351-6
Fetal liver length in normal and isoimmunized pregnancies (Roberts et al). 1989;161:42-6
Frequency and timing of intravascular intrauterine transfusions reconsidered (Voto and Margulies) (Letter); (Socol et al) (Reply). 1989;161:255-6
Isoimmunization to Cromer antigen in pregnancy (Sacks and Garratty). 1989;161:928-9
Maternal-fetal glucose gradient in normal pregnancies and in pregnancies complicated by alloimmunization and fetal growth retardation (Nicolini et al). 1989;161:924-7
Prediction of hematocrit decline after intravascular fetal transfusion (MacGregor et al). 1989;161:1491-3
Pulsed Doppler flow-velocity waveforms in the prediction of fetal hematocrit of the severely isoimmunized pregnancy (Copel et al). 1989;161:341-4
Two hundred intrauterine exchange transfusions in severe blood incompatibilities (Poissonnier et al). 1989;161:709-13
Risk factors
A case-control study of epithelial ovarian cancer (Hartge et al). 1989;161:10-6 (Clin. opinion)
Maternal mortality in North Carolina: a forty-year experience (May and Greiss). 1989;161:555-61
Neonatal mortality in normal birth weight babies: Does the level of hospital care make a difference? (Berg et al). 1989;161:86-91
"Possibly" de novo translocations: prenatal risk counseling (Wassman et al). 1989;161:698-702
Risk factors for intraamniotic infection: a prospective epidemiologic study (Soper et al). 1989;161:562-8
Risk factors for vulvar lichen sclerosus (Sideri et al). 1989;161:38-42
Vaginal birth after cesarean section: a reappraisal of risk (Yetman and Nolan). 1989;161:1119-23
Risk taking
Basic reference gambles recommended for utility assessment (Thornton and Lilford) (Letter); (Silver and Minogue) (Reply). 1989;161:256-7
Ritodrine
Cardiac isoenzymes and electrocardiographic changes during ritodrine tocolysis (Hadi and Albazzaz). 1989;161:318-21
Cardiovascular and metabolic effects associated with nifedipine and ritodrine tocolysis (Ferguson et al). 1989;161:788-95
Fetal and neonatal cardiovascular complications from β-sympathomimetic therapy for tocolysis (Katz and Seeds). 1989;161:1-9 (Clin. opinion)
Number clarification requested (Hatjis) (Letter); (Wilkins and Lynch) (Reply). 1989;161:1746
Pharmacokinetics of orally administered ritodrine (Caritis et al). 1989;161:32-5
Ruptured membranes; *see* **Fetal membranes, premature rupture**

S

Saline solution, hypertonic
Saline solution amnioinfusion for oligohydramnios after premature rupture of the membranes (Imanaka et al). 1989;161:102-6
Salpingitis
High hepatitis B carrier rate among non-Oriental patients with acute salpingitis (Smith et al). 1989;161:879-80
Sarcoma
Sarcoma associated wtih pregnancy (Kyodo et al). 1989;161:94-6
Scalp
Continuous tissue pH monitoring in the term fetus (Small et al). 1989;161:323-9
Secretary protein PP14; *see* **Pregnancy proteins**
Seizures
Antenatal ultrasonographic diagnosis of fetal seizure activity (Landy et al). 1989;161:308
Neonatal seizures and cesarean section (Boylan) (Letter); (Spellacy) (Reply). 1989;161:836-7
Oxytocin may explain neonatal seizures (Goodlin). 1989;161:259 (Letter)
Semantics; *see also* **Nomenclature**
Semantic changes suggested in hypertensive disorders (Reamy) (Letter); (Davey and MacGillivray) (Reply). 1989;161:1422-3
Semen, analysis
Semen predictors of in vitro fertilization and embryo cleavage (Daya et al). 1989;161:1284-9
Seminoma; *see* **Dysgerminoma**
Sensitivity and specificity (epidemiology)
Specifics of specificity and sensitivity (Kadar) (Letter); (Kolins) (Reply). 1989;161:1416-7
Sensory receptors; *see* **Receptors, sensory**
Serotonin
Effect of nutrient intake on premenstrual depression (Wurtman et al). 1989;161:1228-34
Sertoli cell tumor
Steroid biosynthesis in the Sertoli-Leydig cell tumor: effects of insulin and luteinizing hormone (Nagamani et al). 1989;161:1738-43
Sertoli cells
Molecular scanning of Yq11 (interval 6) in men with Sertoli-cell-only syndrome (Johnson et al). 1989;161:1732-7
Sex determination
Rapid determination of fetal sex by deoxyribonucleic acid amplification of Y chromosome–specific sequences (Pinckert et al). 1989;161:693-8
Sex hormones
Spontaneously resorbing ectopic pregnancy: preservation of human chorionic gonadotropin bioactivity despite declining steroid hormone levels (Sauer et al). 1989;161:1673-6
Treatment of oophorectomized guinea pigs with intrauterine 17β-estradiol pellets may modulate myometrial β-

adrenergic receptor binding properties (Hatjis et al). 1989;161:1628-32
Up-regulation of guinea pig myometrial adenylate cyclase activity by intrauterine estradiol and progesterone pellets (Hatjis and Koritnik). 1989;161:1073-8
Sex steroids, biosynthesis
Steroid biosynthesis in the Sertoli-Leydig cell tumor: effects of insulin and luteinizing hormone (Nagamani et al). 1989;161:1738-43
Sexual abuse, child; *see* **Child abuse, sexual**
Sexually transmitted diseases
High hepatitis B carrier rate among non-Oriental patients with acute salpingitis (Smith et al). 1989;161:879-80
Sickle cell anemia; *see* **Anemia, sickle cell**
Skeleton
Monitoring skeletal response to estrogen (Mazess et al). 1989;161:843-8 (Clin opinion)
Skull, growth
In utero diagnosis of benign fetal macrocephaly (DeRosa et al). 1989;161:690-2
Small for gestational age; *see* **Infant, small for gestational age**
Smoking
Effects of smoking and oral contraception on plasma β-carotene levels in healthy women (Palan et al). 1989;161:881-5
Social change
The challenge of change revisited (Greiss). 1989;161:505-9 (Pres. address)
Social conditions
Perinatal death as a result of social factors (Fribourg) (Letter); (Delke and Minkoff) (Reply). 1989;161:1748
Society for Gynecologic Investigation
Papers of the Society for Gynecologic Investigation. 1989;161:1439-743
Society of Perinatal Obstetricians
Transactions of the ninth annual meeting of the Society of Perinatal Obstetricians. 1989;161:593-833
Sodium, dietary
Atrial natriuretic factor: the effects of pregnancy and a high-salt diet on atrial levels (Castro et al). 1989;161:1620-3
South Atlantic Association of Obstetricians and Gynecologists
Transactions of the fifty-first annual meeting of the South Atlantic Association of Obstetricians and Gynecologists. 1989;161:505-92
Spectroscopy, magnetic resonance; *see* **Nuclear magnetic resonance**
Spectrum analysis
Power spectrum analysis of myometrial electromyogram and intrauterine pressure changes in the pregnant rhesus monkey in late gestation (Hsu et al). 1989;161:467-73
Sperm agglutination
Dosage and duration differences lead to diverse conclusions (Shulman) (Letter); (Hammond) (Reply). 1989;161:1744-6
Sperm-ovum interactions
Significance of D-mannose as a sperm receptor site on the zona pellucida in human fertilization (Mori et al). 1989;161:207-11
Spermatogenesis
Molecular scanning of Yq11 (interval 6) in men with Sertoli-cell-only syndrome (Johnson et al). 1989;161:1732-7
Spermatozoa
Relationship between circulating antisperm antibodies in women and autoantibodies on the ejaculated sperm of their partners (Witkin and Chaudhry). 1989;161:900-3
Significance of D-mannose as a sperm receptor site on the zona pellucida in human fertilization (Mori et al). 1989;161:207-11
Sperm antibodies and infertility (Shulman) (Letter); (Witkin) (Reply). 1989;161:497-9
Stains and staining
Comparison of predelivery versus postdelivery Kleihauer–Betke stains in cases of fetal death (Owen et al). 1989;161:663-6
Staphylococcus aureus
Methicillin-resistant staphylococcal mastitis (Kalstone). 1989;161:120
Starvation
Cordocentesis in the diagnosis of intrauterine starvation (Economides et al). 1989;161:1004-8
Statistics
Understanding and eliminating errors in perinatal research (Block). 1989;161:5-9 (Clin. opinion)
Steroids, biosynthesis
Effects of systemic administration of indomethacin on ovulation, luteinization, and steroidogenesis in the rabbit ovary (Katz et al). 1989;161:1361-6
Stillbirth; *see* **Fetal death**
Streptococcus pneumoniae
Antepartum infection as a result of *Streptococcus pneumoniae* and sepsis in neonate (Andreu et al). 1989;161:1424-5 (Letter)
Stress urinary incontinence; *see* **Urinary incontinence, stress**
Sudden infant death
Perinatal death as a result of social factors (Fribourg) (Letter); (Delke and Minkoff) (Reply). 1989;161:1748
Suicide, attempted
Attempted suicide and pregnancy (Czeizel and Lendvay). 1989;161:497 (Letter)
Suppressor cells; *see also* **Immunosuppression**
Immunoregulatory activity in supernatants from cultures of normal human trophoblast cells of the first trimester (Sanyal et al). 1989;161:446-53
Surfactants; *see* **Pulmonary surfactants**
Surgery, operative
Primary stress urinary incontinence and pelvic relaxation: prospective, randomized comparison of three different operations (Bergman et al). 1989;161:97-101
Surgical flaps
A new surgical technique to treat refractory labial fusion in the elderly (Johnson et al). 1989;161:289-90
Surgical staplers
Evaluation of surgical staples in cesarean section (Burkett et al). 1989;161:540-7
Swallowing; *see* **Deglutition**
Swan-Ganz catheter; *see* **Catheterization, Swan-Ganz**
Sympathomimetics
Effects of terbutaline sulfate on fetal cardiac function (Petersen et al). 1989;161:509-12
Fetal and neonatal cardiovascular complications from β-sympathomimetic therapy for tocolysis (Katz and Seeds). 1989;161:1-9 (Clin. opinion)

T

Tachycardia
Preterm and term fetal cardiac and movement responses to vibratory acoustic stimulation (Thomas et al). 1989;161:141-5

TAG-72; *see* **Antigens, neoplasm**
Terbutaline
Does terbutaline cause uterine atony and increase intraoperative blood loss? (Brown) (Letter); (Patriarco) (Reply). 1989;161:259
Effects of terbutaline sulfate on fetal cardiac function (Petersen et al). 1989;161:509-12
Fetal and neonatal cardiovascular complications from β-sympathomimetic therapy for tocolysis (Katz and Seeds). 1989;161:1-9 (Clin. opinion)
Testicular feminization
Seminoma in pubertal patient with androgen insensitivity syndrome (Hurt et al). 1989;161:530-1
Tetramethylpyrazine
In vitro uterine response to tetramethylpyrazine, the active constituent of *Chung Chong* (a traditional Chinese medicine) (Tuttle et al). 1989;161:1319-23
Thalassemia
Detection of fetal blood (Leiberman et al) (Letter); (Cardwell) (Reply). 1989;161:257-8
Theca cells
Pattern of human chorionic gonadotropin binding in the polycystic ovary (Brawer et al). 1989;161:474-80
Thermodilation
Measurement of cardiac output in pregnancy by thoracic electrical bioimpedance and thermodilution (Masaki et al). 1989;161:680-4
Third trimester, pregnancy; *see* **Pregnancy trimester, third**
Thoracic duct, animal
Effect of whole-body pH changes on thoracic duct lymph flow in anesthetized sheep (Valenzuela et al). 1989;161:1566-70
Thoracic electrical bioimpedance; *see* **Cardiography, impedance**
Thrombocytopenia
Elevated liver enzymes and thrombocytopenia in the third trimester of pregnancy: an unusual case report and a review of the literature (Hannah et al). 1989;161:322-3
Thrombocytopenia and cordocentesis clarifications requested (Weiner). 1989;161:1091-2 (Letter)
Thromboembolism
Thrombosis prophylaxis in pregnancy with use of subcutaneous heparin adjusted by monitoring heparin concentration in plasma (Dahlman et al). 1989;161:420-5
Thromboxane synthetase, antagonists
Effects of thromboxane synthetase inhibition on maternal-fetal homeostasis in gravid ewes with ovine pregnancy-induced hypertension (Keith et al). 1989;161:1305-13
Thromboxanes
Aspirin differentially affects thromboxane and prostacyclin production by trophoblast and villous core compartments of human placental villi (Nelson and Walsh). 1989;161:1593-8
Increased placental progesterone may cause decreased placental prostacyclin production in preeclampsia (Walsh and Coulter). 1989;161:1586-92
Tissue culture
Human uterus-derived growth substances for rat bone cells and fibroblasts (Koutsilieris). 1989;161:1313-7
Tissue pH; *see* **Hydrogen-ion concentration**
Tobramycin
Short course of antibiotic therapy in treatment of postpartum endomyometritis (Morales et al). 1989;161:568-72
Tocolysis
Cardiac isoenzymes and electrocardiographic changes during ritodrine tocolysis (Hadi and Albazzaz). 1989;161:318-21
Cardiovascular and metabolic effects associated with nifedipine and ritodrine tocolysis (Ferguson et al). 1989;161:788-95
Controlled trial of hydration and bed rest versus bed rest alone in the evaluation of preterm uterine contractions (Pircon et al). 1989;161:775-9
The effect of magnesium sulfate tocolysis on the fetal biophysical profile (Peaceman et al). 1989;161:771-4
Fetal and neonatal cardiovascular complications from β-sympathomimetic therapy for tocolysis (Katz and Seeds). 1989;161:1-9 (Clin. opinion)
Impact of residual amniotic fluid volume in patients receiving parenteral tocolysis after premature rupture of the membranes (Silver et al). 1989;161:784-7
Nifedipine pharmacokinetics during preterm labor tocolysis (Ferguson et al). 1989;161:1485-90
Pharmacokinetics of orally administered ritodrine (Caritis et al). 1989;161:32-5
Uncoupling of excitation from contraction in uterine smooth muscle in near-term ewes (Reid et al). 1989;161:229-33
Tocolytic agents
Fetal and neonatal cardiovascular complications from β-sympathomimetic therapy for tocolysis (Katz and Seeds). 1989;161:1-9 (Clin. opinion)
Neuromuscular blockade with magnesium sulfate and nifedipine (Snyder and Cardwell). 1989;161:35-6
Number clarification requested (Hatjis) (Letter); (Wilkins and Lynch) (Reply). 1989;161:1746
Pharmacokinetics of orally administered ritodrine (Caritis et al). 1989;161:32-5
Transactions
Transactions of the fifty-first annual meeting of the South Atlantic Association of Obstetricians and Gynecologists. 1989;161:505-92
Transactions of the ninth annual meeting of the Society of Perinatal Obstetricians. 1989;161:593-833
Translocation
"Possibly" de novo translocations: prenatal risk counseling (Wassman et al). 1989;161:698-702
Transposition of great vessels
Anesthetic management of labor in a patient with dextrocardia, congenitally corrected transposition, Wolff-Parkinson-White syndrome, and congestive heart failure (Sellers et al). 1989;161:1001-3
Treadmill test; *see* **Exercise test**
Trial of labor
Basic reference gambles recommended for utility assessment (Thornton and Lilford) (Letter); (Silver and Minogue) (Reply). 1989;161:256-7
Breech presentation after cesarean section: always a section (Ophir et al). 1989;161:25-8
Vaginal birth after cesarean delivery in the twin gestation (Strong et al). 1989;161:29-32
Tricuspid valve
Human fetal tricuspid and mitral deceleration time: changes with normal pregnancy and intrauterine growth retardation (Reed et al). 1989;161:1532-5
Triplets
The improving outcome of triplet pregnancies (Lipitz et al). 1989;161:1279-84
Outpatient triplet management: a contemporary review (Newman et al). 1989;161:547-5

Trisomy
Enlarged cisterna magna in trisomy 18: prenatal ultrasonographic diagnosis (Thurmond et al). 1989;161:83-5
Trisomy 21; *see* **Down's syndrome**
Trophoblast
Aspirin differentially affects thromboxane and prostacyclin production by trophoblast and villous core compartments of human placental villi (Nelson and Walsh). 1989;161:1593-8
Immunoregulatory activity in supernatants from cultures of normal human trophoblast cells of the first trimester (Sanyal et al). 1989;161:446-53
Trophoblastic tumor
Differences between white and Chinese populations in human leukocyte antigen sharing and gestational trophoblastic tumors (Ho et al). 1989;161:942-8
Gestational trophoblastic disease: a case-control study from the People's Republic of China (Brinton et al). 1989;161:121-7
Gestational trophoblastic disease and use of oral contraceptives (Rosenberg et al). 1989;161:1087-8 (Letter)
Tubal pregnancy; *see* **Pregnancy, tubal**
Tumor antigens; *see* **Antigens, neoplasm**
Tumor cells, cultured
A monoclonal antibody (MSN-1) against a newly established uterine endometrial cancer cell line (SNG-II) and its application to immunohistochemistry and flow cytometry (Nozawa et al). 1989;161:1079-86
Tumor necrosis factor
Infection and labor. IV. Cachectin–tumor necrosis factor in the amniotic fluid of women with intraamniotic infection and preterm labor (Romero et al). 1989;161:336-41
Release of tumor necrosis factor-α by human peritoneal macrophages in vivo and in vitro (Halme). 1989;161:1718-25
Tumors; *see* **Neoplasms**
Twins
Discordant twins—a prospective study of the diagnostic value of real-time ultrasonography combined with umbilical artery velocimetry (Divon et al). 1989;161:757-60
Hemodynamic changes during twin pregnancy: a Doppler and M-mode echocardiographic study (Robson et al). 1989;161:1273-8
Individual growth curve standards in twins: prediction of third-trimester growth and birth characteristics (Stefos et al). 1989;161:179-83
Management of the nonvertex second twin: primary cesarean section, external version, or primary breech extraction (Gocke et al). 1989;161:111-4
Perinatal outcome in very preterm births with twin-twin transfusion syndrome (Shan and Chaffin). 1989;161:1111-3
Prolongation of pregnancy and survival of twin B after loss of twin A at 21 weeks' gestation (Feichtinger et al). 1989;161:891-3
Successful twin pregnancy after embryo donation to a patient with XY gonadal dysgenesis (Sauer et al). 1989;161:380-1
Twin-to-twin transfusion syndrome: What are appropriate diagnostic criteria? (Danskin and Neilson). 1989;161:365-9
Ultrasonographic criteria for the prenatal diagnosis of placental chorionicity in twin gestations (Winn et al). 1989;161:1540-2
Twins, dizygotic
Twin pregnancy in premature ovarian failure after estrogen treatment: a case report (Tang and Sawers). 1989;161:172-3

U

Ultrasonic diagnosis
Antenatal ultrasonographic diagnosis of fetal seizure activity (Landy et al). 1989;161:308
Birth weight prediction from remote ultrasonographic examination (Spinnato et al). 1989;161:742-7
Clinical management of the fetus with markedly diminished umbilical artery end-diastolic flow (Divon et al). 1989;161:1523-7
Comparison of six different ultrasonographic methods for predicting lethal fetal pulmonary hypoplasia (Vintzileos et al). 1989;161:606-12
Concurrence of mouthing movement and rapid eye movement/non–rapid eye movement phases with advance in gestation of the human fetus (Horimoto et al). 1989;161:344-51
Dandy-Walker syndrome: a review of fifteen cases evaluated by prenatal sonography (Russ et al). 1989;161:401-6
Dating the early pregnancy by sequential appearance of embryonic structures (Warren et al). 1989;161:747-53
Discordant twins—a prospective study of the diagnostic value of real-time ultrasonography combined with umbilical artery velocimetry (Divon et al). 1989;161:757-60
Doppler assessment of the fetal and uteroplacental circulation during nifedipine therapy for preterm labor (Mari et al). 1989;161:1514-8
Doppler assessment of the pulsatility index of the middle cerebral artery during constriction of the fetal ductus arteriosus after indomethacin therapy (Mari et al). 1989;161:1528-31
Duplex Doppler ultrasonographic evaluation of the fetal renal artery in normal and abnormal fetuses (Veille and Kanaan). 1989;161:1502-7
Effect of placental embolization on the umbilical arterial velocity waveform in fetal sheep (Morrow et al). 1989;161:1055-60
The efficacy of fetal sonographic biometry in Down syndrome screening (Peters et al). 1989;161:297-300
Empty bladder recommended in initial ultrasonographic examinations (Stephens). 1989;161:1088-9 (Letter)
Enlarged cisterna magna in trisomy 18: prenatal ultrasonographic diagnosis (Thurmond et al). 1989;161:83-5
Estimating gestational age in the term pregnancy with a model based on multiple indices of fetal maturity (Goldstein et al). 1989;161:1235-8
Evaluation of pulsed Doppler echocardiography for measurement of aortic blood flow in the fetal lamb (Veille et al). 1989;161:1610-4
Fetal cardiac output in the isoimmunized pregnancy: a pulsed Doppler-echocardiographic study of patients undergoing intravascular intrauterine transfusion (Copel et al). 1989;161:361-5
Fetal liver length in normal and isoimmunized pregnancies (Roberts et al). 1989;161:42-6
Fetal radius length: a critical evaluation of race as a factor in gestational age assessment (Hill et al). 1989;161:193-9
First-trimester and early second-trimester diagnosis of nuchal cystic hygroma by transvaginal sonography: diverse

Ultrasonic diagnosis—cont'd
prognosis of the septated from the nonseptated lesion (Bronshtein et al). 1989;161:78-82
First-trimester midgut herniation: a high-frequency transvaginal sonographic study (Timor-Tritsch et al). 1989;161:831-3
Hemodynamic changes during twin pregnancy: a Doppler and M-mode echocardiographic study (Robson et al). 1989;161:1273-8
Human fetal tricuspid and mitral deceleration time: changes with normal pregnancy and intrauterine growth retardation (Reed et al). 1989;161:1532-5
The importance of ultrasonography in infertile women with "forgotten" intrauterine contraceptive devices (Ron-El et al). 1989;161:211-2
Intrapartum Doppler velocimetry, amniotic fluid volume, and fetal heart rate as predictors of subsequent fetal distress. I. An initial report (Sarno et al). 1989;161:1508-14
A longitudinal study of the relationship between placental and fetal growth as measured by ultrasonography (Wolf et al). 1989;161:1140-5
Longitudinal ultrasonographic study of the ovarian suppressive activity of a low-dose triphasic oral contraceptive during correct and incorrect pill intake (Hamilton and Hoogland). 1989;161:1159-62
Macrosomia in the postdate pregnancy: Is routine ultrasonographic screening indicated? (Chervenak et al). 1989;161:753-6
Maternal and fetal blood flow velocity waveforms in patients with preterm labor: relationship to outcome (Brar et al). 1989;161:1519-22
Measurement of fetal urine production in normal pregnancy by real-time ultrasonography (Rabinowitz et al). 1989;161:1264-6
Missed abortion: Still appropriate terminology? (Pridjian and Moawad). 1989;161:261-2 (Clin. opinion)
Prenatal informed consent for sonogram: an indication for obstetric ultrasonography (Chervenak et al). 1989;161:857-60 (Clin. opinion)
Pulsed Doppler flow-velocity waveforms in the prediction of fetal hematocrit of the severely isoimmunized pregnancy (Copel et al). 1989;161:341-4
Race and gender factors omitted from results (Ansbacher) (Letter); (Goldstein) (Reply). 1989;161:502-3
The role of ultrasonography and amniocentesis in the evaluation of pregnancies at risk for neural tube defects (Hogge et al). 1989;161:520-4
Screening with Doppler velocimetry in labor (Feinkind et al). 1989;161:765-70
Systolic/diastolic ratios and waveform shapes (Bewley) (Letter); (Schulman) (Reply). 1989;161:1420-1
Techniques differ in use of Doppler ultrasonography (Easterling and Benedetti) (Letter); (Lee and Rokey) (Reply). 1989;161:1748-50
Transvaginal ultrasonography in patients at risk for ectopic pregnancy (Stiller et al). 1989;161:930-3
Twin-to-twin transfusion syndrome: What are appropriate diagnostic criteria? (Danskin and Neilson). 1989;161:365-9
Ultrasonographic criteria for the prenatal diagnosis of placental chorionicity in twin gestations (Winn et al). 1989;161:1540-2
Ultrasonographic guidance for central venous access during pregnancy (Lee et al). 1989;161:1012-3
Ultrasonographic measurement of fetal femur length in growth disturbances (Abramowicz et al). 1989;161:1137-40
Umbilical artery flow velocity waveforms during acute hypoxemia and the relationship with hemodynamic changes in the fetal lamb (van Huisseling et al). 1989;161:1061-4
The use of color Doppler imaging for prenatal diagnosis of umbilical cord anomalies: report of three cases (Jauniaux et al). 1989;161:1195-7
The use of an indwelling Doppler probe to study acute changes in umbilical artery waveforms in the fetal sheep (Abitbol et al). 1989;161:1324-31
The use of transvaginal ultrasonography in the diagnosis of ectopic pregnancy (Timor-Tritsch et al). 1989;161:157-61
Vaginosonographic examination Routine procedure? (Furness) (Letter); (Bernaschek and Rudelstorfer) (Reply). 1989;161:499

Umbilical arteries
Clinical management of the fetus with markedly diminished umbilical artery end-diastolic flow (Divon et al). 1989;161:1523-7
Discordant twins a prospective study of the diagnostic value of real-time ultrasonography combined with umbilical artery velocimetry (Divon et al). 1989;161:757-60
Doppler umbilical artery waveform indices normal values from fourteen to forty-two weeks (Hendricks et al). 1989;161:761-5
Doppler velocimetry and placental disease (Bracero et al). 1989;161:388-93
Perinatal factors influencing atrial natriuretic peptide levels in umbilical arterial plasma at the time of delivery (Castro et al). 1989;161:623-7
Perinatal factors influencing atrial natriuretic peptide levels in umbilical arterial plasma at the time of delivery (Castro et al). (1989;161:623-7). 1989;161:1238 (Correction)

Umbilical arteries, animal
Effect of placental embolization on the umbilical arterial velocity waveform in fetal sheep (Morrow et al). 1989;161:1055-60
Umbilical artery flow velocity waveforms during acute hypoxemia and the relationship with hemodynamic changes in the fetal lamb (van Huisseling et al). 1989;161:1061-4
The use of an indwelling Doppler probe to study acute changes in umbilical artery waveforms in the fetal sheep (Abitbol et al). 1989;161:1324-31

Umbilical cord
Abscess of allantoic duct remnant (Baill et al). 1989;161:334-6
Continuous fetal monitoring with a pulse oximeter: a case of cord compression (Johnson and Johnson). 1989;161:1295-6

Umbilical cord, abnormalities
The use of color Doppler imaging for prenatal diagnosis of umbilical cord anomalies: report of three cases (Jauniaux et al). 1989;161:1195-7

Umbilical cord blood; *see* **Fetal blood**

Umbilical veins
The effect of intravascular transfusion on umbilical venous pressure in anemic fetuses with and without hydrops (Weiner et al). 1989;161:1498-501
Removing a retained placenta by oxytocin a controlled study (Wilken-Jensen et al). 1989;161:155-6

Uncoupling agents
Uncoupling of excitation from contraction in uterine

smooth muscle in near-term ewes (Reid et al). 1989;161:229-33

Urinary incontinence, stress

Primary stress urinary incontinence and pelvic relaxation: prospective randomized comparison of three different operations (Bergman et al). 1989;161:97-101

Urine, animal

Fetal blood volume, urine flow, swallowing, and amniotic fluid volume responses to long-term intravascular infusions of saline (Brace). 1989;161:1049-54

Urodynamics

Primary stress urinary incontinence and pelvic relaxation: prospective randomized comparison of three different operations (Bergman et al). 1989;161:97-101

Uterine contraction

The antagonistic effect of oxytocin and relaxin on rat uterine segment contractility (Goldsmith et al). 1989;161:1644-9

Controlled trial of hydration and bed rest versus bed rest alone in the evaluation of preterm uterine contractions (Pircon et al). 1989;161:775-9

Maternal hemodynamic effects of uterine contractions by M-mode and pulsed-Doppler echocardiography (Lee et al). 1989;161:974-7

Results of uterine activity studies in agreement, but methods differ (Török and Gáti) (Letter); (Nageotte) (Reply). 1989;161:1753-4

Uncoupling of excitation from contraction in uterine smooth muscle in near-term ewes (Reid et al). 1989;161:229-33

Uterine neoplasms

Anal submucosal injection: a new route for drug administration in pelvic malignancies. IV. Submucosal anal injection in the treatment of cancer of uterine cervix—preliminary study (Shafik). 1989;161:69-72

A clinical-pathologic study of mixed müllerian tumors of the uterus over a 16-year period The Medical College of Georgia experience (Gallup et al). 1989;161:533-9

Decreased β-carotene tissue levels in uterine leiomyomas and cancers of reproductive and nonreproductive organs (Palan et al). 1989;161:1649-52

Epidermal growth factor receptor expression in normal and malignant endometrium (Berchuck et al). 1989;161:1247-52

Flow cytometry of normal, hyperplastic, and malignant human endometrium (Thornton et al). 1989;161:487-92

Immunohistochemical expression of TAG-72 in normal and malignant endometrium: correlation of antigen expression with estrogen receptor and progesterone receptor levels (Soisson et al). 1989;161:1258-63

A monoclonal antibody (MSN-1) against a newly established uterine endometrial cancer cell line (SNG-II) and its application to immunohistochemistry and flow cytometry (Nozawa et al). 1989;161:1079-86

Phase II trial of ifosfamide and mesna in mixed mesodermal tumors of the uterus (A Gynecologic Oncology Group Study) (Sutton et al). 1989;161:309-12

Prognostic significance of steroid receptors measured in primary metastatic and recurrent endometrial carcinoma (Borazjani et al). 1989;161:1253-7

Uterine perforation

The frequency and management of uterine perforations during first-trimester abortions (Kaali et al). 1989;161:406-8

Uterine rupture

Placenta percreta induced uterine rupture and resulted in intraabdominal abortion (Nagy). 1989;161:1185-6

Uterine rupture: Are intrauterine pressure catheters useful in the diagnosis? (Rodriguez et al). 1989;161:666-9

Uterus

Uterine development and endocrine relationships after menarche (Porcu et al). 1989;161:174-7

Uterus, animal

Comparison of in vivo bioavailability of progestational agents into the rat uterus and liver and the effect of plasma protein binding (Van Voorhis et al). 1989;161:1698-703

Effect of pregnancy on uterine and carotid artery response to norepinephrine, epinephrine, and phenylephrine in vessels with documented functional endothelium (Weiner et al). 1989;161:1605-10

In vitro release of endothelium-derived relaxing factor by acetylcholine is increased during the guinea pig pregnancy (Weiner et al). 1989;161:1599-605

Power spectrum analysis of myometrial electromyogram and intrauterine pressure changes in the pregnant rhesus monkey in late gestation (Hsu et al). 1989;161:467-73

Uterus, blood supply

Decreased in vitro production of 6-keto-prostaglandin $F_{1\alpha}$ by uterine arteries from postmenopausal women (Steinleitner et al). 1989;161:1677-81

Effect of placental laterality on uterine artery resistance and development of preeclampsia and intrauterine growth retardation (Kofinas et al). 1989;161:1536-9

Uterus, drug effects

Does terbutaline cause uterine atony and increase intraoperative blood loss? (Brown) (Letter); (Patriarco) (Reply). 1989;161:259

In vitro uterine response to tetramethylpyrazine, the active constituent of *Chung Chong* (a traditional Chinese medicine) (Tuttle et al). 1989;161:1319-23

Uterus, histology

Histologic and immunologic study of uterine biopsy tissue of women with incipient abortion (Michel et al). 1989;161:409-14

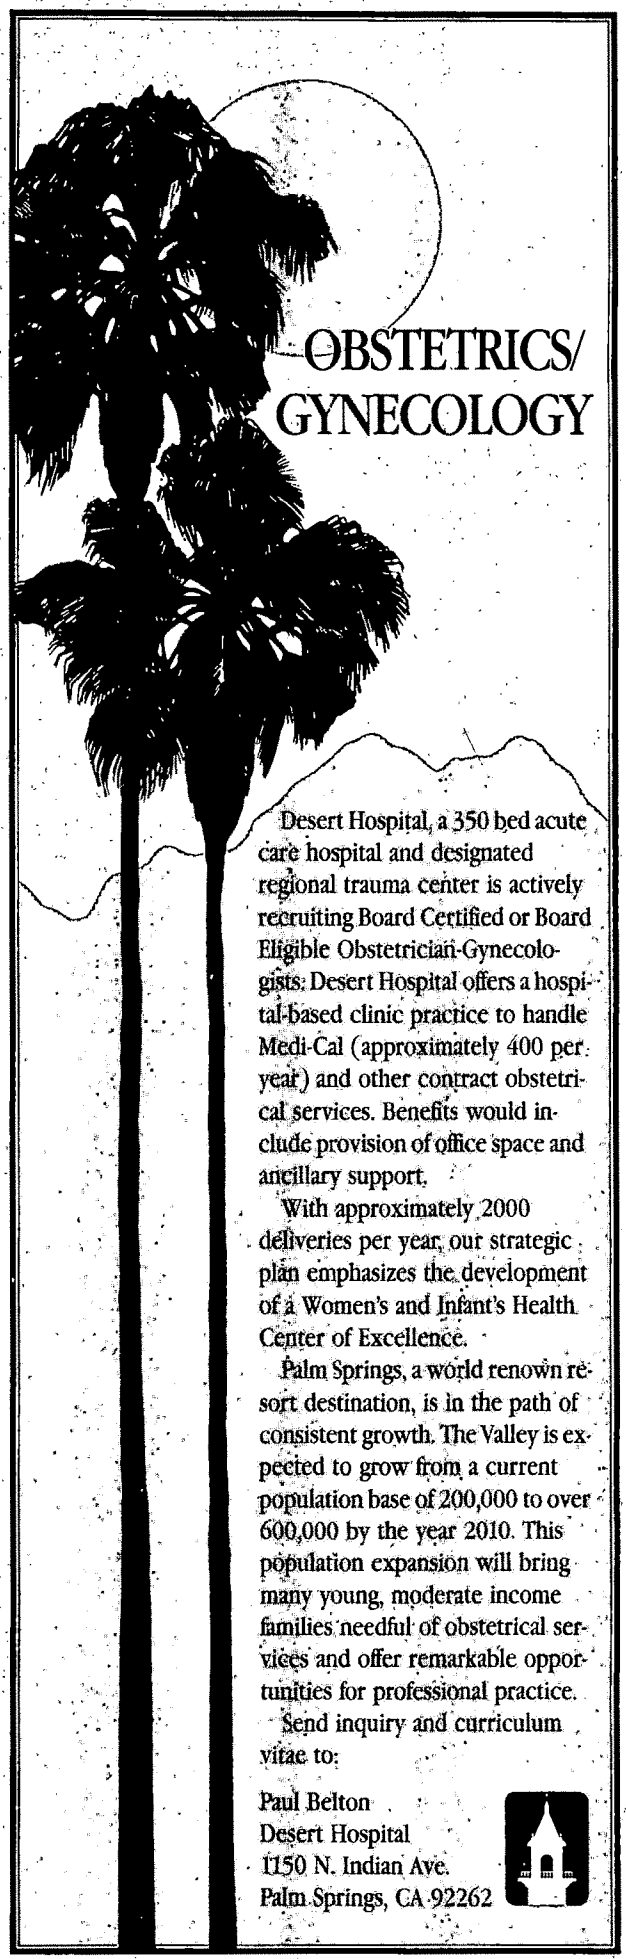
JOHNS HOPKINS HEALTH SYSTEM medical group needs additional physicians in OB/GYN for full-time and part-time positions at new and established offices throughout the greater Baltimore area. Physicians must be board certified or active candidates, and eligible for Maryland license and DEA certificate. Interviewing now for next summer; some positions available immediately. Equal Employment Opportunity Employer. Send current curriculum vitae to: Recruiting Coordinator; Office of Medical Affairs; Wyman Park Medical Associates; 3100 Wyman Park Drive; Baltimore, Maryland 21211.



SOUTHERN CALIFORNIA

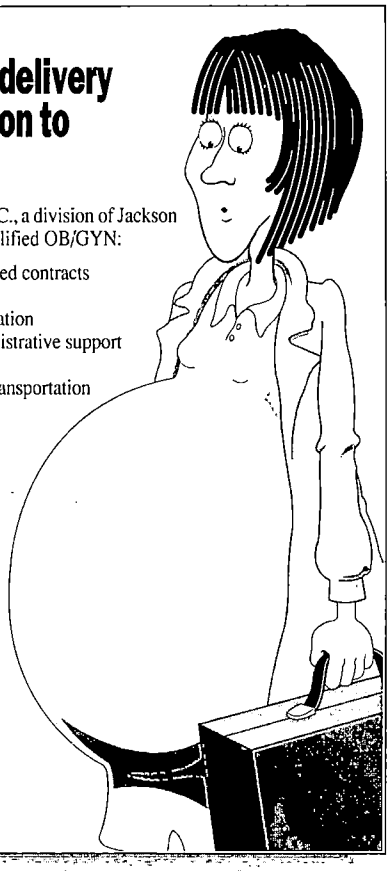
Los Angeles County

There is now an attractive opportunity to join two young and busy board-certified OB/GYN's practicing in a Los Angeles County community of 116,000. This is a rapidly expanding six-year-old practice and a third member is needed as soon as possible. They are offering generous financial arrangements leading to early partnership.

For more information send CV to: Manager, Professional Relations, Humana Inc., Dept. OB-12, 500 West Main Street, Louisville, KY 40201-1438. Or call TOLL-FREE 1-800-626-1590.

OBSTETRICS/ GYNECOLOGY

Desert Hospital, a 350 bed acute care hospital and designated regional trauma center is actively recruiting Board Certified or Board Eligible Obstetrician-Gynecologists. Desert Hospital offers a hospital-based clinic practice to handle Medi-Cal (approximately 400 per year) and other contract obstetrical services. Benefits would include provision of office space and ancillary support.



With approximately 2000 deliveries per year, our strategic plan emphasizes the development of a Women's and Infant's Health Center of Excellence.

Palm Springs, a world renown resort destination, is in the path of consistent growth. The Valley is expected to grow from a current population base of 200,000 to over 600,000 by the year 2010. This population expansion will bring many young, moderate income families needful of obstetrical services and offer remarkable opportunities for professional practice.

Send inquiry and curriculum vitae to:

Paul Belton
Desert Hospital
1150 N. Indian Ave.
Palm Springs, CA 92262

Be in on the delivery of the solution to OB staffing.

LOCUM TENENS, INC., a division of Jackson & Coker, offers the qualified OB/GYN:

- 3 to 9 month guaranteed contracts
- competitive daily rate
- licensing and coordination
- knowledgeable administrative support
- round trip airfare
- on-site housing and transportation
- permanent practice opportunities

OB/GYN

WANTED: Obstetrician/Gynecologist, Board Certified or eligible physician to join existing 3 member OB/GYN Department in 22 member multi-specialty group practice in the Lakes Region of central N.H. Position offers an outstanding professional, financial, and life-style opportunity. Respond with C.V. to Alan Awrich,M.D.,Laconia Clinic, 724 Main Street, Laconia, NH 03246.

SPECIAL DELIVERIES. SPECIAL CHALLENGES.

The Southern California Permanente Medical Group invites you to join a unique prepaid health care program. Our multispecialty group practice is a partnership composed of and managed by SCPMG physicians.

Board eligible/certified **PERINATOLOGISTS** are needed for our high-volume obstetric services which handles 3,000-6,000 deliveries per year. Opportunities exist both to join and create high risk services.

There are positions available to practice Perinatology exclusively. Perinatologists who are interested in performing other aspects of obstetrics and gynecology may do so. We also have positions available for Endocrinologists and General Obstetrician-Gynecologists. University affiliation and clinical research are encouraged.

Our compensation is competitive and benefits are outstanding. They include: professional liability, medical and dental coverage, vacation and sick leave, continuing education, life insurance and retirement plans. **After two years full-time employment, physicians are eligible to be considered for partnership.**

For a physician application, please call or write to: William G. McCormick, M.D., Physician Recruitment, Dept. 006, Walnut Center, Pasadena, CA 91188-8013. (714) 829-5365.

PRIDE & POTENTIAL

PERINATOLOGIST

Illinois, Chicago—Lutheran General Hospital is seeking a fourth Perinatologist for an excellent opportunity in direct patient care, teaching and clinical research. Lutheran General is a 713-bed teaching hospital affiliated with the University of Illinois College of Medicine in Chicago. It is a designated tertiary care center with 4500 deliveries annually and has an active maternal transport service of over 200 a year. The Obstetrics and Gynecology Department has a residency program, subspecialists in Gynecology/Endocrinology and Gynecology/Oncology. There is a 36-bed neonatal NICU with five neonatologists and a fellowship program. There is also a large referral service for genetic counseling and prenatal diagnoses, and more than 750 genetic amniocentesis are performed annually. We have recently opened a large Perinatal Center office.

The hospital is located in an attractive northwest suburb of Chicago. We offer a competitive salary with a generous incentive plan and an excellent benefit package.

Please send your curriculum vitae to Dr. Haim Elrad, Chief of Obstetrics and Director of Maternal-Fetal Medicine, Department of Obstetrics and Gynecology, or call 708/606-6998. Equal Opportunity Employer.

The Medical Center of Delaware, an 1100 bed, tertiary care major teaching affiliate of Thomas Jefferson University, seeks a full-time chairman of the Department of Obstetrics-Gynecology. The Medical Center is the major trauma referral center for the State of Delaware. There are approved programs in Ob-Gyn, surgery, internal medicine, emergency medicine, pediatrics, radiology, and family practice, plus a transitional program and a medicine/pediatric program. Over 6,500 deliveries with a 25% cesarean section rate are done annually and 4,300 gynecologic operations are performed annually with approximately 3,500 of these being major procedures and 800 of these minor. Two thirds of the procedures performed are on an outpatient basis. Approximately 32,078 surgical operations are performed annually with 12,282 inpatient procedures and 19,796 outpatient procedures. Candidates should have proven administrative ability, experience in managing an ob-gyn service; experience in developing, enhancing and/or upgrading clinical services, education programs and research; and the ability to maintain and guide the ob-gyn residency program. The successful candidate will have a senior academic appointment at Jefferson Medical College of the Thomas Jefferson University in Philadelphia, Pennsylvania. Please send curriculum vitae and three references independently to: George Hilty, M.D., Chairman, Search Committee, Medical Center of Delaware, c/o of Patti Falkowski, CMSC, P.O. Box 1668, Wilmington, DE 19899. The Medical Center of Delaware is an affirmative action/equal opportunity employer.

HARTFORD HOSPITAL
DIRECTOR OF AMBULATORY OB/GYN

The Department of Obstetrics and Gynecology at Hartford Hospital is seeking a fulltime salaried board certified/board eligible Director of Ambulatory OB/GYN. We are looking for an individual with innovative ideas in resident and medical student education coupled with an ability to make the Outpatient Department function most efficiently. The OPD presently has approximately 21,000 patient visits annually.

The OB/GYN Department has divisions of Maternal-Fetal Medicine, Gyn-Oncology, and Reproductive Endocrinology. It also includes 49 BC/BE attendings, 16 residents and 6 medical students on two month clinical rotations from the University of Connecticut and Dartmouth.

Located in the capital city of 'Classic Connecticut,' Hartford Hospital is a tertiary care 885 bed institution with approximately 225 house officers. Dr. Stephen L. Curry will become the permanent fulltime Director of the Department on January 1, 1990.

Academic appointment at the University of Connecticut will be commensurate with training and experience.

Please send your curriculum vitae to:

Miami, Florida 33101

AN EQUAL OPPORTUNITY/AFFIRMATIVE ACTION EMPLOYER

SUBURBAN PITTSBURGH

A 12-year-old, 18-physician multi-specialty group seeks to expand its services by adding two OB/GYNs to its medical staff. They are affiliated with a 350-bed community hospital and currently have four office locations. The four pediatrician group members will offer a built-in referral base for the OB/GYNs.

Facilities at the offices include a state-licensed lab, mammography, sonography, diagnostic radiology, and much more. Centralized billing is provided for all physicians along with the assistance of a full component of staff which includes clerical support, medical assistants, nurses, and laboratory and radiology technicians.

This opportunity offers a competitive income guarantee, malpractice insurance, pension/profit sharing program, and a highly attractive partnership option. Due to the specialty structure of the group, the partnership buy-in will be minimal for the initial OB/GYNs joining the group. Additional corporate ventures will also be open to new members.

Academic Position
In Reproductive Endocrinology and Infertility

The University of Calgary Faculty of Medicine invites applications for an academic position in the Department of Obstetrics and Gynaecology. The successful applicant will also receive an appointment at the Foothills Hospital, southern Alberta's major referral and teaching hospital.

Interested applicants should be qualified in obstetrics and gynaecology and hold the Fellowship of the Royal College of Physicians and Surgeons of Canada, or an equivalent recognized certification, and possess proven ability and experience in the area of Reproductive Endocrinology and Infertility.

Responsibilities will include teaching and patient care of the undergraduate and postgraduate level, in addition to directing research within the area and collaborating with an established Reproductive Medicine Research Group. In addition to basic and clinical research, the successful applicant will be involved in an active in-vitro fertilization program. Rank and salary will be commensurate with experience and qualifications.

In accordance with Canadian immigration requirements, priority will be given to Canadian citizens and permanent residents of Canada. The University of Calgary has an Employment Equity Program and encourages applications from all qualified candidates, including women, aboriginal people, visible minorities, and people with disabilities.

Please submit a curriculum vitae and the names and addresses of three referees in confidence by December 31, 1989 to:

Control Medical Problems More Effectively *And Decrease Risks!*

NEW!

PERIOPERATIVE MANAGEMENT OF THE SURGICAL PATIENT

By Michael J. Breslow, M.D.; Clair F. Miller, M.D.; and Mark C. Rogers, M.D.

Controlling medical problems in surgical patients may well be one of your biggest challenges. Practical and succinct, this new book presents a rational approach to monitoring and managing surgical patients.

- *examines the effects of anesthesia and surgical stress on the patient to keep you informed of potential problems*
- *reviews specific medical problems associated with increased perioperative morbidity and mortality*
- *identifies controversial areas and reviews the appropriate literature to help you know how to best handle the problem*
- *addresses ambulatory care including specific considerations, increased risk factors associated with patient evaluation and medical protocols*

OBSTETRICS/GYNECOLOGY REPORT

The depth of texts, the timeliness of journals . . .

OBSTETRICS/GYNECOLOGY REPORT is designed with the **busy practitioner** in mind. It identifies the most important clinical advances and issues in your field and synthesizes **for you** the current, relevant information on these topics.

- Four issues every 12 months.
- Each issue focuses on two topics of current clinical interest.
- Subspecialty areas covered by the REPORT include: infectious disease, reproductive endo-fertility, maternal-fetal medicine, oncology, gynecologic urology, and general obstetrics and gynecology.
- Comprehensive coverage of the selected topics, from new developments to cases of interest.
- Articles written by leaders in the field.
- 450 pages per year; no advertisements.

Our editorial board of prominent physicians is committed to offering you an insightful, reliable, and practical resource that is truly beneficial to clinical practice.

OBSTETRICS/GYNECOLOGY REPORT offers you:

- coverage of clinical advances in the specialty
- opinions and consultations from experts in the specialty
- discussions of controversial issues
- case studies
- information on new techniques, products, and equipment
- reviews of current literature

Risk-free guarantee for all subscribers: Give your first issue of the REPORT a thorough review. If you are not completely satisfied, you may cancel your subscription within 30 days and receive a full refund!

PARTNERSHIP FOR A DRUG-FREE AMERICA

Your comprehensive reference guide to a decade of valuable clinical information . . .

Ten-Year Cumulative Index (1978-1987) to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY

Now you have easy access to 10 years of clinical information, indexed in one convenient source — the Ten-Year Cumulative Index to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY.

This hard-cover index is a comprehensive guide to more than 30,000 pages of original articles, case reports, letters, and editorials published in the Journal from 1978 through 1987 (volumes 130 to 157). These influential, peer-reviewed papers are indexed both by subject and by author in this 800-page volume.

The Cumulative Index features:

- 4,331 subject headings, containing 24,126 references. Each subject entry lists the complete article title, author(s), volume, page, and year of publication.
- 22,456 author entries, listing contributor, respective article title, author-to-author referral, volume, page, and publication date.

The Cumulative Index is a great time-saver for locating information on clinical topics of immediate or historical significance in obstetrics and gynecology. There's no need to search for index issues from each year.

Order this important reference guide for your personal library!

21- and 28-day regimens

ORTHO-NOVUM® 777 Tablets Spectacular!

norethindrone/ethinyl estradiol

Each white tablet contains 0.5 mg norethindrone and 0.035 mg ethinyl estradiol. Each light peach tablet contains 0.75 mg norethindrone and 0.035 mg ethinyl estradiol. Each peach tablet contains 1 mg norethindrone and 0.035 mg ethinyl estradiol. Each green tablet in 28 day regimen contains inert ingredients.

IMPORTANT NOTE—This information is a BRIEF SUMMARY of the complete prescribing information provided with the product and therefore should not be used as the basis for prescribing the product. This summary was prepared by deleting from the complete prescribing information certain text, tables and references. The physician should be thoroughly familiar with the complete prescribing information before prescribing the product.

INDICATIONS AND USAGE: PREVENTION OF PREGNANCY.

CONTRAINDICATIONS: Oral contraceptives should not be used in women who currently have the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep vein thrombophlebitis or thromboembolic disorders. 3. Cerebral vascular or coronary artery disease. 4. Known or suspected carcinoma of the breast. 5. Carcinoma of the endometrium or other known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Cholestatic jaundice of pregnancy or jaundice with prior pill use. 8. Hepatic adenomas or carcinomas. 9. Known or suspected pregnancy.

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risks of several serious conditions including myocardial infarction, thromboembolism, stroke, hepatic neoplasia, and gallbladder disease, although the risk of serious morbidity or mortality is very small in healthy women without underlying risk factors. The risk of morbidity and mortality increases significantly in the presence of other underlying risk factors such as hypertension, hyperlipidemias, obesity and diabetes. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks. The information contained in this brief summary is principally based on studies carried out in patients who used oral contraceptives with higher formulations of estrogens and progestogens than those in common use today. The effect of long term use of the oral contraceptives with lower formulations of both estrogens and progestogens remains to be determined. Throughout this brief summary epidemiological studies reported are of two types: retrospective or case control studies and prospective or cohort studies. Case control studies provide a measure of the relative risk of a disease, namely a *ratio* of the incidence of a disease among oral contraceptive users to that among nonusers. The relative risk does not provide information on the actual clinical occurrence of a disease. Cohort studies provide a measure of attributable risk, which is the *difference* in the incidence of disease between oral contraceptive users and nonusers. The attributable risk does provide information about the actual occurrence of a disease in the population. For further information, the reader is referred to a text on epidemiological methods. 1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS. a. Myocardial Infarction. An increased risk of myocardial infarction has been associated with oral contraceptive use. This risk is primarily in smokers or women with other underlying risk factors for coronary artery disease such as hypertension, hypercholesterolemia, morbid obesity, and diabetes. The relative risk of heart attack for current oral contraceptive users has been estimated to be two to six. The risk is very low under the age of 30. Smoking in combination with oral contraceptive use has been shown to contribute substantially to the incidence of myocardial infarctions in women in their mid-thirties or older with smoking accounting for the majority of excess cases. Mortality rates associated with circulatory disease have been shown to increase substantially in smokers, especially in those 35 years of age and older among women who use oral contraceptives. Oral contraceptives may compound the effects of well-known risk factors, such as hypertension, diabetes, hyperlipidemias, age and obesity. In particular, some progestogens are known to decrease HDL cholesterol and cause glucose intolerance, while estrogens may create a state of hyperinsulinism. Oral contraceptives have been shown to increase blood pressure among users (see section 9 in WARNINGS). Similar effects on risk factors have been associated with an increased risk of heart disease. Oral contraceptives must be used with caution in women with cardiovascular disease risk factors. b. Thromboembolism. An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Case control studies have found the relative risk of users compared to non-users to be 3 for the first episode of superficial venous thrombosis, 4 to 11 for deep vein thrombosis or pulmonary embolism, and 1.5 to 6 for women with predisposing conditions for venous thromboembolic disease. Cohort studies have shown the relative risk to be somewhat lower, about 3 for new cases and about 4.5 for new cases requiring hospitalization. The risk of thromboembolic disease associated with oral contraceptives is not related to length of use and disappears after pill use is stopped. A two- to four-fold increase in relative risk of post-operative thromboembolic complications has been reported with the use of oral contraceptives. The relative risk of venous thrombosis in women who have predisposing conditions is twice that of women without such medical conditions. If feasible, oral contraceptives should be discontinued at least four weeks prior to and for two weeks after elective surgery of a type associated with an increase in risk of thromboembolism and during and following prolonged immobilization. Since the immediate postpartum period is also associated with an increased risk of thromboembolism, oral contraceptives should be started no earlier than four weeks after delivery in women who elect not to breast feed. c. Cerebrovascular diseases. Oral contraceptives have been shown to increase both the relative and attributable risks of cerebrovascular events (thrombotic and hemorrhagic strokes), although, in general, the risk is greatest among older (>35 years), hypertensive women who also smoke. Hypertension was found to be a risk factor for both users and non-users, for both types of strokes, and smoking interacted to increase the risk of stroke. In a large study, the relative risk of thrombotic strokes has been shown to range from 3 for normotensive users to 14 for users with severe hypertension. The relative risk of hemorrhagic stroke is reported to be 1.2 for non-smokers who used oral contraceptives, 2.6 for smokers who did not use oral contraceptives, 7.6 for smokers who used oral contraceptives, 1.8 for normotensive users and 25.7 for users with severe hypertension. The attributable risk is also greater in older women. d. Dose-related risk of vascular disease from oral contraceptives. A positive association has been observed between the amount of estrogen and progestogen in oral contraceptives and the risk of vascular disease. A decline in serum high density lipoproteins (HDL) has been reported with many progestational agents. A decline in serum high density lipoproteins has been associated with an increased incidence of ischemic heart disease. Because estrogens increase HDL cholesterol, the net effect of an oral contraceptive depends on a balance achieved between doses of estrogen and progestogen and the activity of the progestogen used in the contraceptive. The activity and amount of both hormones should be considered in the choice of an oral contraceptive. Minimizing exposure to estrogen and progestogen is in keeping with good principles of therapeutics. For any particular estrogen/progestogen combination, the dosage regimen prescribed should be one which contains the least amount of estrogen and progestogen that is compatible with a low failure rate and the needs of the individual patient. New acceptors of oral contraceptive agents should be started on preparations containing 0.035 mg or less of estrogen. e. Persistence of risk of vascular disease. There are two studies which have shown persistence of risk of vascular disease for ever-users of oral contraceptives. In a study in the United States, the risk of developing myocardial infarction after discontinuing oral contraceptives persists for at least 9 years for women 40-49 years who had used oral contraceptives for five or more years, but this increased risk was not demonstrated in other age groups. In another study in Great Britain, the risk of developing cerebrovascular disease persisted for at least 6 years after discontinuation of oral contraceptives, although excess risk was very small. However, both studies were performed with oral contraceptive formulations containing 50 micrograms or higher of estrogens. 2. ESTIMATES OF MORTALITY FROM CONTRACEPTIVE USE. One study gathered data from a variety of sources which have estimated the mortality rate associated with different methods of contraception at different ages. These estimates include the combined risk of death associated with contraceptive methods plus the risk attributable to pregnancy in the event of method failure. Each method of contraception has its specific benefits and risks. The study concluded that with the exception of oral contraceptive users 35 and older who smoke and 40 and older who do not smoke, mortality associated with all methods of birth control is low and below that associated with childbirth. However, smokers 35 and older and non-smokers 40 and older who use oral contraceptives have a significant increase in mortality higher than those using other methods of birth control. These facts must be weighed in conjunction with failure rates for other methods and the risk associated with subsequent pregnancy. 3. CARCINOMA OF THE REPRODUCTIVE ORGANS. Numerous epidemiological studies have been performed on the incidence of breast, endometrial, ovarian and cervical cancer in women using oral contraceptives. While there are conflicting reports most studies suggest that use of oral contraceptives is not associated with an overall increase in the risk of developing breast cancer. Some studies have reported an increased relative risk of developing breast cancer, particularly at a younger age. This increased relative risk appears to be related to duration of use. Some studies suggest that oral contraceptive use has been associated with an increase in the risk of cervical intraepithelial neoplasia in some populations of women. However, there continues to be controversy about the extent to which such findings may be due to differences in sexual behavior and other factors. 4. HEPATIC NEOPLASIA. Benign hepatic adenomas are associated with oral contraceptive use, although the incidence of benign tumors is rare in the United States. Indirect calculations have estimated the attributable risk to be in the range of 3.3 cases/100,000 for users, a risk that increases after four or more years of use especially with oral contraceptives of higher dose. Rupture of benign, hepatic adenomas may cause death through intra-abdominal hemorrhage. Studies from Britain have shown an increased risk of developing hepatocellular carcinoma in long-term (>8 years) oral contraceptive users. However, these cancers are rare in the U.S. and the attributable risk (the excess incidence) of liver cancers in oral contraceptive users approaches less than one per million users. 5. OCULAR LESIONS. There have been clinical case reports of retinal thrombosis associated with the use of oral contraceptives. Oral contraceptives should be discontinued if there is unexplained partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions. Appropriate diagnostic and therapeutic measures should be undertaken immediately. 6. ORAL CONTRACEPTIVE USE BEFORE OR DURING EARLY PREGNANCY. Extensive epidemiological studies have revealed no increased risk of birth defects in women who have used oral contraceptives prior to pregnancy. The majority of recent studies also do not indicate a teratogenic effect, particularly in so far as cardiac anomalies and limb reduction defects are concerned, when taken inadvertently during early pregnancy. The administration of oral contraceptives to induce withdrawal bleeding should not be used as a test for pregnancy. Oral contraceptives should not be used during pregnancy to treat threatened or habitual abortion. It is recommended that for any patient who has missed two consecutive periods pregnancy should be ruled out before continuing oral contraceptive use. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period. Oral contraceptive use should be discontinued until pregnancy is ruled out. 7. GALLBLADDER DISEASE. Earlier studies have reported an increased lifetime relative risk of gallbladder surgery in users of oral contraceptives and estrogens. More recent studies, however, have shown that the relative risk of developing gallbladder disease among oral contraceptive users may be minimal. The recent findings of minimal risk may be related to the use of oral contraceptive formulations containing lower hormonal doses of estrogens and progestogens. 8. CARBOHYDRATE AND LIPID METABOLIC EFFECTS. Oral contraceptives have been shown to cause a decrease in glucose tolerance in a significant percentage of users. This effect has been shown to be directly related to estrogen dose. Progestogens increase insulin secretion and create insulin resistance, this effect varying with different progestational agents. However, in the non-diabetic woman, oral contraceptives appear to have no effect on fasting blood glucose. Because of these demonstrated effects prediabetic and diabetic women in particular should be carefully monitored while taking oral contraceptives. A small proportion of women will have persistent hypertriglyceridemia while on the pill. As discussed earlier (see WARNINGS 1a and 1d), changes in serum triglycerides and lipoprotein levels have been reported in oral contraceptive users. 9. ELEVATED BLOOD PRESSURE. An increase in blood pressure has been reported in women taking oral contraceptives, and this increase is more likely in older oral contraceptive users and with extended duration of use. Data from the Royal College of General Practitioners and subsequent randomized trials have shown that the incidence of hypertension increases with increasing progestational activity. Women with a history of hypertension or hypertension-related diseases, or renal disease, should be encouraged to use another method of contraception. If women elect to use oral contraceptives, they should be monitored closely and if significant elevation of blood pressure occurs, oral contraceptives should be discontinued. For most women, elevated blood pressure will return to normal after stopping oral contraceptives, and there is no difference in the occurrence of hypertension between former and never users. 10. HEADACHE. The onset or exacerbation of migraine or development of headache with a new pattern which is recurrent, persistent or severe requires discontinuation of oral contraceptives and evaluation of the cause. 11. BLEEDING IRREGULARITIES. Breakthrough bleeding and spotting are sometimes encountered in patients on oral contraceptives, especially during the first three months of use. Non-hormonal causes should be considered and adequate diagnostic measures taken to rule out malignancy or pregnancy in the event of breakthrough bleeding as in the case of any abnormal vaginal bleeding. If pathology has been excluded, time or a change to another formulation may solve the problem. In the event of amenorrhea, pregnancy should be ruled out. Some women may encounter post-pill amenorrhea or oligomenorrhea, especially when such a condition was preexistent. 12. ECTOPIC PREGNANCY. Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. **PRECAUTIONS:** 1. PHYSICAL EXAMINATION AND FOLLOW UP. A complete medical history and physical examination should be taken prior to the initiation or reinstitution of oral contraceptives and at least annually during use of oral contraceptives. These physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including cervical cytology, and relevant laboratory tests. In case of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be conducted to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules should be monitored with particular care. 2. LIPID DISORDERS. Women who are being treated for hyperlipidemias should be followed closely if they elect to use oral contraceptives. Some progestogens may elevate LDL levels and may render the control of hyperlipidemias more difficult. 3. LIVER FUNCTION. If jaundice develops in any woman receiving such drugs, the medication should be discontinued. Steroid hormones may be poorly metabolized in patients with impaired liver function. 4. FLUID RETENTION. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention. 5. EMOTIONAL DISORDERS. Women with a history of depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. 6. CONTACT LENSES. Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist. 7. DRUG INTERACTIONS. Reduced efficacy and increased incidence of breakthrough bleeding and menstrual irregularities have been associated with concomitant use of rifampin. A similar association, though less marked, has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and possibly with griseofulvin, ampicillin and tetracyclines. 8. INTERACTIONS WITH LABORATORY TESTS. Certain endocrine and liver function tests and blood components may be affected by oral contraceptives: a. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. b. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or by radio-immunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. c. Other binding proteins may be elevated in serum. d. Sex-binding globulins are increased and result in elevated levels of total circulating sex steroids and corticoids; however, free or biologically active levels remain unchanged. e. Triglycerides may be increased. f. Glucose tolerance may be decreased. g. Serum folate levels may be depressed by oral contraceptive therapy. This may be of clinical significance if a woman becomes pregnant shortly after discontinuing oral contraceptives. 9. CARCINOGENESIS. See WARNINGS section 10. PREGNANCY. Pregnancy Category X. See CONTRAINDICATIONS and WARNINGS sections. 11. NURSING MOTHERS. Small amounts of oral contraceptive steroids have been identified in the milk of nursing mothers and a few adverse effects on the child have been reported, including jaundice and breast enlargement. In addition, oral contraceptives given in the postpartum period may interfere with lactation by decreasing the quantity and quality of breast milk. If possible, the nursing mother should be advised not to use oral contraceptives but to use other forms of contraception until she has completely weaned her child. **INFORMATION FOR THE PATIENT: See Patient Package Insert. ADVERSE REACTIONS:** An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see WARNINGS section). Thrombophlebitis and venous thrombosis with or without embolism. Arterial thromboembolism. Pulmonary embolism. Myocardial infarction. Cerebral hemorrhage. Cerebral thrombosis. Hypertension. Gallbladder disease. Hepatic adenomas or benign liver tumors. The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea. Vomiting. Gastrointestinal symptoms (such as abdominal cramps and bloating). Breakthrough bleeding. Spotting. Change in menstrual flow. Amenorrhea. Temporary infertility after discontinuation of treatment. Edema. Melasma which may persist. Breast changes: tenderness, enlargement, secretion. Change in weight (increase or decrease). Change in cervical erosion and secretion. Diminution in lactation when given immediately postpartum. Cholestatic jaundice. Migraine. Rash (allergic). Mental depression. Reduced tolerance to carbohydrates. Vaginal candidiasis. Change in corneal curvature (steepening). Intolerance to contact lenses. The following adverse reactions have been reported in users of oral contraceptives and the association has been neither confirmed nor refuted: Pre-menstrual syndrome. Cataracts. Changes in appetite. Cystitis-like syndrome. Headache. Nervousness. Dizziness. Hirsutism. Loss of scalp hair. Erythema multiforme. Erythema nodosum. Hemorrhagic eruption. Vaginitis. Porphyria. Impaired renal function. Hemolytic uremic syndrome. Acne. Changes in libido. Colitis. **OVERDOSAGE:** Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea and withdrawal bleeding may occur in females.

Estrogen replacement therapy: An overview 1825
Daniel R. Mishell, Jr., MD
Los Angeles, California

Because supplementation with exogenous estrogen mitigates or prevents the undesirable and often life-limiting sequelae of estrogen deficiency, nearly all postmenopausal women should receive estrogen replacement therapy.

Biosynthesis and physiologic effects of estrogen and pathophysiologic effects of estrogen deficiency: A review 1828
Wulf H. Utian, MD, PhD
Cleveland, Ohio

Postmenopausal women experience various health problems, such as cardiovascular disease, osteoporosis, neuroendocrine changes, and urogenital atrophy because of lack of estrogen production.

Estrogen replacement therapy: Indications, contraindications, and agent selection 1832
Morris Notelovitz, MD
Gainesville, Florida

Estrogens relieve deficiency-related symptoms, decrease the rate of fractures, and confer cardioprotection for postmenopausal women and have therefore proved beneficial to selected postmenopausal women.

Estrogens in the prevention of osteoporosis in postmenopausal women 1842
Harry K. Genant, MD, David J. Baylink, MD, and J. C. Gallagher, MD
San Francisco and Loma Linda, California, and Omaha, Nebraska

Estrogen replacement therapy started at menopause prevents bone loss and reduces the risk of fractures associated with menopause.

Estrogen replacement therapy: An overview

Daniel R. Mishell, Jr., MD

Los Angeles, California

Levels of circulating estrogen fall during the perimenopausal period, resulting in changes in the postmenopausal woman's genitourinary tract, central nervous and cardiovascular systems, skin, and bone. Exogenous estrogen minimizes the benign symptoms and prevents the increased incidence of osteoporosis and atherosclerotic heart disease that accompany estrogen deficiency. Thus to avoid the recognized problems of estrogen deficiency, nearly all women should begin a lifelong course of estrogen replacement therapy during the perimenopausal period. (AM J OBSTET GYNECOL 1989;161:1825-7.)

Key words: Estrogen replacement therapy

During menopause the ovarian follicles stop secreting estradiol into the circulation. Except in obese women, sufficient amounts of estrone will not be converted from androstenedione in peripheral adipose tissue to maintain premenopausal, physiologic levels of circulating estrogen. Therefore, untreated women may experience the consequences of estrogen deficiency (as summarized below), including changes in their genitourinary tracts, central nervous and cardiovascular systems, skin, and bone, during approximately one third of their average life spans. Because supplementation with exogenous estrogen mitigates or prevents the undesirable and often life-limiting sequelae of estrogen deficiency,[1-5] nearly all postmenopausal women should receive estrogen replacement therapy. Given estrogen's high benefit-to-risk ratio in this setting, the real therapeutic challenge is to identify the few inappropriate candidates for estrogen replacement therapy who are at increased risk for unwanted, adverse effects. Once these women are identified, the remainder can use estrogen replacement therapy so that they can continue to enjoy the same quality of life they experienced before menopause.

End organ changes due to estrogen deficiency during menopause

Estrogen deficiency may manifest as changes in a woman's genital tract. The postmenopausal woman may complain of itching, bleeding, or dyspareunia, which are symptoms of atrophic vaginitis. She may also experience pruritus and pain from atrophic changes of her vulva (kraurosis vulvae). Loss of tone of supporting ligaments and elastic tissue can lead to uterine prolapse and hernias in the anterior (cystocele) and posterior (rectocele) vaginal wall. Estrogen replacement therapy can prevent the vaginal and vulvar atrophy associated with menopause and maintain the normal tone of supporting structures to the uterus and vagina.

The untreated postmenopausal woman may also experience dysuria and other symptoms associated with senile urethritis,[6] a syndrome caused by atrophy of the bladder and urethral mucosa. Subsequent alterations in urethral and bladder pressure can cause urgency and stress incontinence and urinary frequency.[7] Using exogenous estrogens either prevents or relieves the urinary tract symptoms of menopause.[8-10]

Hot flashes, the pathognomonic symptom of menopause and the one that most frequently prompts the postmenopausal woman to seek medical care, are usually acute, short-lived events that initially occur several times daily, often during sleep.[11,12] The rate of decrease in estrogen levels during the menopausal period is directly related to the severity of hot flashes, which are the body's homeostatic response to estrogen deficiency-

induced changes in central nervous system thermoregulatory centers (i.e., peripheral blood flow increases and perspiration occurs in an attempt to dissipate heat). Thus women commonly experience hot flashes during the first 2 years of menopause, after which symptoms gradually subside.

Women may experience symptoms of anxiety and depression more frequently during the menopausal period. In placebo-controlled trials, estrogen replacement therapy has proved effective in relieving hot flashes[1, 2] and symptoms of anxiety and depression.[3-5]

The absence of estrogen may cause the skin to become thinner and more wrinkled due to less collagen in the dermis. Estrogen stimulates the synthesis of collagen, a protein that makes up 90% of the dermis. In postmenopausal women receiving estrogen replacement therapy, the collagen in their dermis is maintained at premenopausal levels.[13]

Declining levels of estrogen during menopause lead to an increased rate of bone resorption and greater urinary excretion of calcium,[14] resulting in reduced bone density. Women may remain asymptomatic for about 10 years. By this time they have typically lost 15% of their bone mass,[15] setting the stage for fractures. Trabecular bone in the spine and distal radius are affected more rapidly than cortical bone in the axial skeleton. Therefore, osteoporotic hip fractures usually begin to occur around the seventh decade of life, increasing exponentially after the age of 80 years.

Postmenopausal osteoporosis affects approximately 25% (5 million) of white and Oriental women. It occurs less frequently in obese women and in blacks. Wasserman and Barzel[16] estimated that in 1987 about 300,000 hip fractures occurred in the American population, predominantly in women. The 6-month mortality rate associated with hip fractures approached 10%, and acute health care costs were estimated at $4 billion annually. One third of the patients with hip fractures required skilled nursing home care once discharged from the hospital, accounting for additional costs of $2 billion per year. Estrogen replacement therapy not only prevents loss of bone mass,[17, 18] it also reduces the risk of bone fractures[15, 19] to a rate comparable to that in men matched for age.

Oral estrogen has a cardioprotective effect, most likely because it increases high-density lipoprotein cholesterol and reduces low-density lipoprotein cholesterol levels.[20] Estrogen replacement therapy reduces the incidence of myocardial infarction in postmenopausal women and prolonges their life span.[21] In numerous case-control and cohort studies, estrogen users have a crude and adjusted relative risk of cardiovascular disease approximately half that of their untreated counterparts. These data have been further corroborated in a multicenter trial in which the use of estrogens significantly reduced the cardiovascular disease-associated death rate per 10,000 women for each decade between the ages of 50 and 80 years; the age-adjusted relative risk of death due to cardiovascular disease in estrogen users was 0.34.[22] The relative risk of death due to stroke was also reduced by about 50% in postmenopausal women using estrogen.[23]

Estrogen replacement therapy: Benefit versus risk

The benefits of estrogen replacement therapy are clear, improving both the quality and the quantity of the postmenopausal woman's life. Several studies have shown that estrogen users are less likely to die from all causes compared with nonusers.[24, 25] Although estrogen replacement therapy's benefit is greatest among women who have had oophorectomies, those who have intact uteri also benefit.

Before we could universally recommend using this therapy in postmenopausal women, we had to resolve the question of an association between estrogen replacement therapy and cancer. Most case-control studies show that exogenous postmenopausal estrogen replacement neither increases nor reduces the risk of breast cancer.[26] Furthermore, although unopposed estrogen may cause endometrial cancer, the concomitant, appropriate use of a progestational agent not only prevents this risk but may also lower it to below that of untreated women.[27]

Contraindications to estrogen replacement therapy include acute liver disease, previously diagnosed breast or endometrial cancer, and, probably, thromboembolic disorders. Chronic liver disease, obesity, and, possibly, a history of thromboembolism are relative contraindications.

We now generally consider that the benefits of estrogen replacement therapy far outweigh its risks. To avoid the problems associated with estrogen deficiency, women should begin a lifelong course of estrogen replacement therapy during the perimenopausal period.

Summary

Estrogen replacement therapy should be considered for all postmenopausal women. The goals of estrogen replacement therapy are to minimize the benign symptoms and to reverse the predictable osteoporosis and atherosclerotic heart disease that can accompany estrogen deficiency. In this way we hope to reduce the high morbidity, mortality, and health care costs associated with the sequelae of untreated menopause.

Biosynthesis and physiologic effects of estrogen and pathophysiologic effects of estrogen deficiency: A review

Wulf H. Utian, MD, PhD
Cleveland, Ohio

Women are increasingly spending more years of their lives beyond the menopause, which places them at risk for various health problems due to estrogen deficiency. Tissues and organs with estrogen receptors such as the ovaries, endometrium, vaginal epithelium, hypothalmus, urinary tract, and skin are directly affected by a lack of estrogen production. Other tissues in which estrogen receptors have not been consistently identified, such as bone, are also affected by waning levels of estrogen. The postmenopausal woman frequently experiences neuroendocrine changes (hot flashes) that often dissipate over time and a steady rise in her risk of cardiovascular disease, which approaches that in men of comparable age. (AM J OBSTET GYNECOL 1989;161:1828-31.)

Key words: Estrogen deficiency, menopause

In 1980, men and women aged 65 years or older represented 11.3% of the population, a percentage that is expected to increase.[1] As the average life span of the American population continues to increase, the number of women who live beyond the age of menopause is growing significantly. Currently there are about 230 million people in the United States, of whom 118 million (51%) are women. About one third of these (39 million) are 45 years old or older, and almost 13.5% (16 million) are 65 years old or older.

What do all these statistics mean? Simply stated, compared with their ancestors, more women will live a significantly increasing number of years beyond menopause, placing them at risk for various health problems that can be caused by ovarian failure and a lack of estrogen production.

The current median age of menopause is 50 years. However, approximately 8% of women undergo premature menopause before the age of 40 years.[2] During the time of the climacteric (the phase in the aging of women that marks the transition from the reproductive to the nonreproductive stage of life),[3] several months may pass between menstrual periods. This unpredictable perimenopausal menstrual pattern makes identifying the onset of menopause difficult. Therefore, the diagnosis of menopause is usually made retrospectively after a women experiences her last menstrual period.

Table I. World Health Organization definitions[4]

Menopause:	Permanent cessation of menstruation resulting from loss of ovarian function
Perimenopausal:	Climacteric; the period immediately before menopause and at least 5 years after menopause
Postmenopausal:	The period dating from the menopause, which can only be assessed in retrospect

Table I provides the World Health Organization standard definitions of the terms menopausal, perimenopausal, and postmenopausal.

Research has looked for factors that may influence the age at which menopause occurs. For instance, women who smoke may have lower serum estrogen levels than nonsmokers and, on average, may also experience menopause at an earlier age. For the most part, directly associating specific factors as a cause for early or late menopause is difficult because so many variables exist.

Physiology of menopause

As a woman ages, ovarian function begins to fail. The number of follicles in the ovaries decreases, and less estrogen is synthesized. A deficiency of follicular inhibin and estrogen leads to decreased negative feedback on the anterior pituitary gland, which results in an increase in levels of follicle-stimulating hormone and luteinizing hormone. In postmenopausal women, the amount of follicle-stimulating hormone present is greater than the amount of luteinizing hormone, which is the opposite of what is found in premenopausal women. Feedback sensitivity on the hypothala-

Table II. Potential problems of the untreated climacteric[5]

Target Organ	*Possible symptom or problem*
Vulva	Atrophy, dystrophy, pruritus vulvae
Vagina	Dyspareunia, blood-stained discharge, vaginitis
Bladder and urethra	Cystourethritis, ectropion, frequency and/or urgency, stress incontinence
Uterus and pelvic floor	Uterovaginal prolapse
Skin and mucous membranes	Atrophy, dryness, or pruritus; easily traumatized; loss of resilience and pliability; dry hair or loss of hair; minor hirsutism of face; dry mouth
Vocal cords	Voice changes (reduction in upper register)
Cardiovascular system	Atherosclerosis, angina, and coronary heart disease
Skeleton	Osteoporosis with related fractures, backache
Breasts	Reduced size, softer consistency, drooping
Neuroendocrine system	Hot flashes, psychologic disturbances

mus and anterior pituitary glands may also decrease (Fig. 1).

The predominant estrogen in premenopausal women is estradiol, which is produced primarily by the ovary. Estrone, a less active form of estrogen, is the predominant form in postmenopausal women. Most postmenopausal estrone is synthesized in the periphery, predominantly in adipose tissue, by the conversion of androstenedione to estrone (Fig. 2)[5].

As these hormonal changes occur, the amount of total circulating estrogen may be reduced, with a potential decline in menstruation usually around the age of 40 years. The decline manifests as irregular cycles with a lighter menstrual flow, less frequent menses, and finally a total absence of menstruation. If anovulatory cycles occur, the absence of progesterone can result in irregularly heavy menstrual periods.

The tissues or organs directly affected by this relative estrogen deficiency are those with specific estrogen receptors, such as the ovaries, endometrium, vaginal epithelium, hypothalamus, urinary tract, and skin. Other tissues in which estrogen receptors have not been inconsistently identified, such as bone,[6-7] are nevertheless affected by a lack of estrogen (Fig. 3). Table II[5] summarizes the resultant symptoms or problems that may occur when these various tissues and organs become estrogen deficient.

Urogenital atrophy manifests as a loss of soft tissue elasticity and a decrease in muscle tone and secretions. Usually the uterus shrinks and the vagina undergoes progressive thinning and shortening, with a loss of the rugal pattern. These vaginal changes are a common cause of pruritis in postmenopausal women and they may be responsible for complaints of dyspareunia. Vaginal atrophy also puts the woman at increased risk of vaginal trauma and infection. The increased risk of infection is probably due, in part, to the slight increase in vaginal pH associated with changes in the bacterial flora.

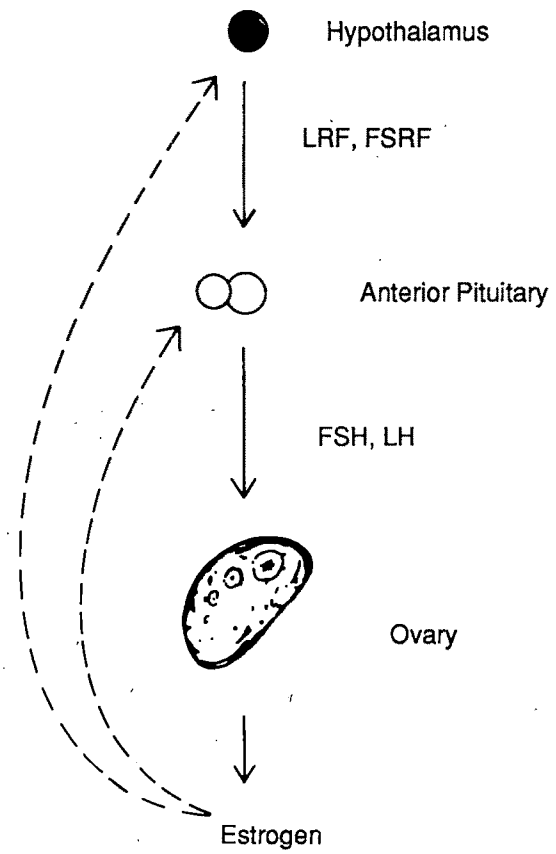

Fig. 1. Feedback control of the anterior pituitary and ovary by the hypothalmus. *LRF,* Luteotropin (or luteinizing hormone [LH]) releasing factor; *FSRF,* follicle stimulating releasing factor; *FSH,* follicle stimulating hormone.

Similar changes also occur in the urethra and the trigone area of the bladder. Urethral atrophy may lead to the "urethral syndrome," in which women have a recurrent abacterial urethritis characterized by symptoms of dysuria, frequency and urgency of urination, nocturia, and postvoid dribbling.

Other atrophic changes may also occur. The amount of collagen in the skin decreases, and the skin becomes thinner. The breasts also diminish in size, become softer, and may droop.

Systemic problems related to menopause

The risk of cardiovascular disease is higher in men compared with age-matched women before the age of

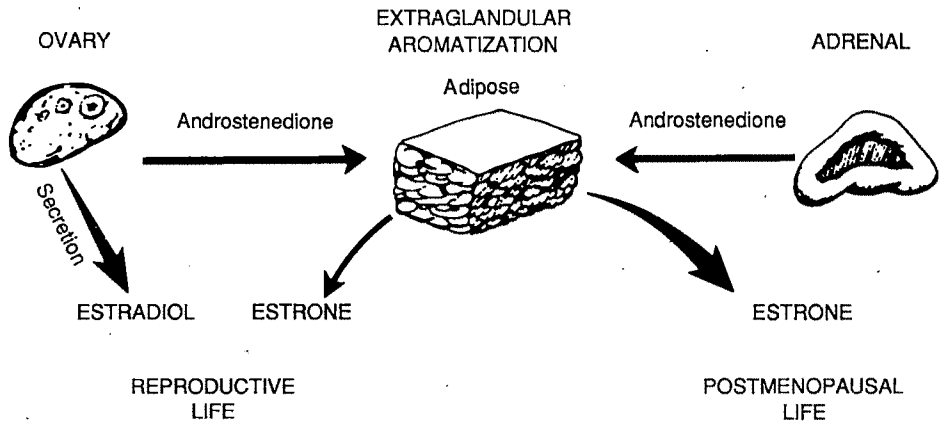

Fig. 2. Sources of estrogen during reproductive and postmenopausal life. (Reprinted with permission from Carr BR, MacDonald PC. In: Stollerman GH, Harrington WJ, Lamont JT, eds. Advances in internal medicine. Chicago: Year Book Medical Publishers, 1983.)

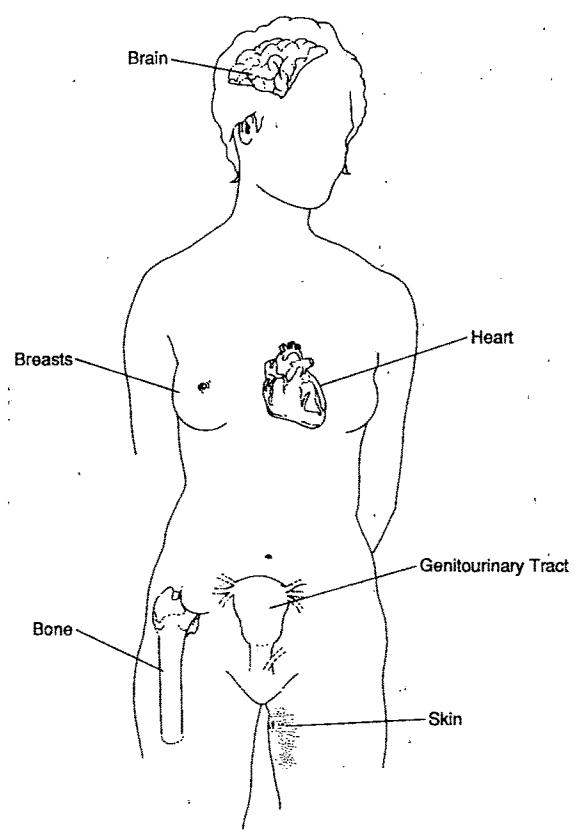

Fig. 3. Tissues and organs affected by estrogen deficiency.

40 to 45 years. During the perimenopausal period, the risk of cardiovascular disease in women begins to increase to a rate similar to that in men (Fig. 4).[8] The decrease in estrogen production is thought to be responsible for this acceleration of risk.

After cardiovascular disease, the most significant problem related to estrogen deficiency is osteoporosis. By the age of 80 years, about 25% of all women have sustained one or more fractures of the proximal femur, vertebrae, or distal radius. Hip fractures are associated with high morbidity and mortality rates. The management of hip fractures constitutes a large public health care expense and carries with it about a 20% mortality rate within the first year.

Table III. Psychologic complaints of perimenopausal and postmenopausal women

Decreased energy and drive	Mood fluctuations
Difficulty concentrating	Tension
Irritability	Depression
Aggressiveness	Introversion
Nervous exhaustion	Sense of internal frustration and inadequacy
Intolerance of loneliness	Anxiety
Marital troubles	Headache
Antisocial behavior patterns	Insomnia

Neuroendocrine problems are also relatively common in perimenopausal and postmenopausal women. Hot flashes, which can begin several years before the actual menopause, occur in 75% to 85% of climacteric women. One postulated mechanism is that the temperature-regulating set point of the hypothalamus may be reset downward. Most women describe a sudden onset of warmth and vasodilation, often visible as a red flush that is most apparent over the face and chest. The flush usually lasts from 30 seconds to 5 minutes and may occur every few minutes or only once or twice a week. Other vasomotor symptoms include nausea, dizziness, weakness, headaches, palpitations, diaphoresis, and night sweats. Women who experience hot flashes may also complain of sleep disturbances, characterized by an increased number of awakenings and increased fatigue.

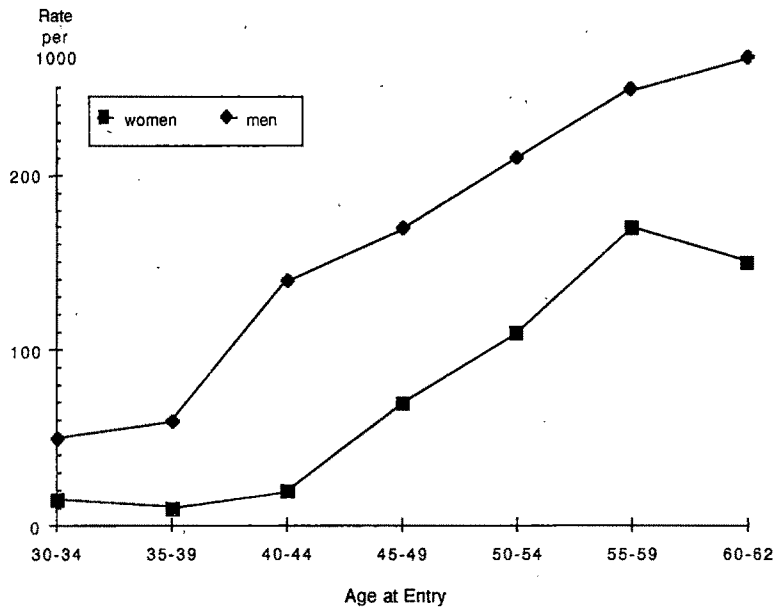

Fig. 4. Incidence of coronary heart disease based on age and sex. (Reprinted with permission from Castelli WP. Am J Med 1984;76(2A):4-12.)

Many other psychologic changes associated with menopause have been reported and studied. These changes are probably due to the interactive effects of endocrine changes, sociocultural effects, and psychologic factors in each individual. The complaints are usually multiple, vague, and nonspecific. They may be related to vasomotor symptoms and a lack of sleep. Table III lists a variety of complaints that perimenopausal and postmenopausal women report. The severity of psychologic complaints during the menopausal years are usually mild, not continuous, and tend to fluctuate.

Women may associate menopause with old age and feelings of asexuality. Hopefully, women's attitudes, as well as society's, are changing today to shatter the myth that women past the age of menopause lose their sexuality.

Summary

A woman who is 50 years old today can expect to live to 89 years of age. By the year 2000, more women will be spending a larger percentage of their life beyond the age of 40 years. The numbers alone dictate addressing the issues that surround menopause. There are still many myths to dispel and facts to discover that could promote a healthier, more productive life-style for women in this age group. Meanwhile, what we do know is that the benefits of estrogen replacement therapy can improve the quality of life for postmenopausal women.

Estrogen replacement therapy: Indications, contraindications, and agent selection

Morris Notelovitz, MD
Gainesville, Florida

Three groups of indications exist for postmenopausal estrogen use: relief of symptoms related to estrogen deficiency, osteoporosis prophylaxis and treatment, and cardioprotection. Estrogen replacement therapy enhances a woman's sense of well-being and reduces the morbidity, mortality, and health care costs associated with osteoporosis and atherosclerotic heart disease. There are a few absolute contraindications to estrogen replacement therapy. Many estrogen preparations are currently available in the United States. Establishing equivalencies among the different preparations is complicated by the many physiologic and pharmacologic effects of estrogens and the variety of treatment end points used. Most estrogens have the same biologic effect provided equivalent blood levels are achieved. Estrogen replacement therapy has proved beneficial to selected postmenopausal women. (Am J Obstet Gynecol 1989;161:1832-41.)

Key words: Estrogen, menopause, indications, contraindications

The average age at which menopause occurs is 50 years. More than 30 million women in the United States are more than 50 years old, with an average life expectancy of 81 years. Therefore, a women in the United States can expect to live more than one third of her life in the postmenopausal state.[1] Ovarian function diminishes gradually; the climacteric (reproductive senescence) begins at about the age of 35 years and ends some 15 years after menopause.[2] In this context, menopause per se is a relatively inconsequential event. It does, however, herald the onset of changes that can have far-reaching consequences on future health, primarily cardiovascular disease and osteoporosis. This review will summarize only a small fraction of the extensive research on the use of hormone-additive[2] or estrogen replacement therapy.

Indications

Three groups of indications exist for the use of postmenopausal estrogens: symptoms related to estrogen deficiency such as vasomotor symptoms, atrophic changes of the vagina and other genitourinary tissues, and certain psychologic/mood changes; osteoporosis prophylaxis and treatment; and prevention of cardiovascular morbidity and death.

The symptomatic menopause

Hot flashes. Vasomotor "hot flashes" occur in 85% of perimenopausal women, 25% of whom will experience symptoms sufficiently severe to prompt them to seek medical care.[3] In 82% of women the symptoms persist for more than 1 year.[2] Most women do not require exogenous estrogens to control vasomotor symptoms for more than 3 to 5 years, although in some women symptoms persist for many years.[2-4] Estrogen replacement therapy for control of vasomotor symptoms should use the lowest possible dose that controls symptoms; therapy can be tapered over a few years and then withdrawn.

Vaginal atrophy. Atrophic changes of the vagina, urethra, and bladder base occur in virtually all women 4 to 5 years after menopause. Symptoms include dyspareunia, repeated vaginal infections, and dysuria. Twenty-five percent of women will seek medical attention because of these symptoms.[3] Unfortunately, symptoms often recur when estrogen replacement therapy is discontinued, indicating that long-term or indefinite therapy may be needed.[3] Again, the lowest effective dose for control of symptoms should be used.

Psychologic changes. Mood changes such as irritability, depression, insomnia, impaired memory, and crying jags are common "hormone-related" symptoms that frequently precede and postdate menopause. In many instances these changes are estrogen dependent. Utian coined the phrase "mental tonic" effect to describe the sense of well-being that most women experience when taking exogenous estrogen. Depression may be due to numerous nonhormonal conditions; care must be taken to exclude those women with endogenous depression. A simple test is to give a trial dose of estrogen to patients who have no other stigmata of a central nervous system problem. If the patient improves, the therapy is continued; if not, an appropriate referral to a psychiatrist is warranted. Clinicians should remember that certain

progestins, especially medroxyprogesterone acetate, may "exacerbate" depression in susceptible women.

Osteoporosis. A great deal of attention has focused on using estrogen replacement therapy for prophylaxis and treatment of osteoporosis. This interest is appropriate given the significant impact this preventable disease has on the health of countless menopausal women.

Osteoporosis affects 15 to 20 million Americans and accounts for 1.3 million fractures per year in the United States.[5,6] The risk of vertebral fractures in white women is 25% by the age of 50 years; by the age of 75 years the risk increases to 50%.[7] Hip fractures represent the most serious complication of osteoporosis. Each year more than 120,000 elderly women sustain hip fractures; 15% to 17% die from associated complications.[8,9] Osteoporosis-associated health care costs are estimated to be $6 billion annually.[6]

Normal bone metabolism and risk factors for osteoporosis. Put simplistically, two cell types influence the skeletal bone mass volume, the primary determinant of osteoporotic fractures. Osteoclasts break down bone mineral and collagen, whereas osteoblasts lay down new bone tissue (osteoid). Both men and women reach maximal trabecular (vertebral) bone mass between the ages of 25 to 30 years and maximal cortical (compact) bone mass by the age of 35 years. Thereafter, cortical bone mass undergoes a net demineralization of 0.3% to 0.5% per year. After menopause, however, women lose 2% to 3% of their cortical bone mass and 5% to 8% of their trabecular bone mass annually.[10-13] An accelerated rate of bone loss (perimenopausal/climacteric) occurs 3 to 6 years after menopause; the rate of bone loss decreases after the age of 65 years.[14] A more detailed overview of osteogenesis is available elsewhere.[15]

After 15 to 20 years of bone loss, about 50% of trabecular and 30% of cortical bone mass will have eroded. As a result of this accelerated breakdown in bone mass, postmenopausal women are at high risk for the development of involutional osteoporosis. A number of traditional risk factors for the development of osteoporosis are listed in Table I.[14-19] We[14] and others have shown that these "risk factors" are rather insensitive, and that measuring bone mass is the only realistic way of identifying women at risk and quantifying their degree of bone mineral deficiency (osteopenia). This allows for appropriate and specific intervention, both hormonal and nonhormonal.

Efficacy of estrogen replacement therapy in postmenopausal osteoporosis prophylaxis. It is clear that estrogen deficiency contributes to bone loss,[20] and that estrogen replacement therapy reduces loss of bone mineral.[21-26] Most importantly, this therapy reduces the risk of bone fractures.[21,27-31]

Several reviews have recently addressed the value of estrogen replacement therapy in treating postmenopausal women.[5,6,13-15,32-35] For example, Weiss et al.[28] demonstrated a 50% to 60% reduction in the risk of fractures with the use of 0.625 to 1.25 mg of conjugated estrogens daily. Concomitant use of calcium may decrease the minimum effective dose of estrogen necessary to prevent bone loss (Table II).[13] In a study investigating the effects of several pharmacologic treatments, estrogen replacement therapy in combination with vitamin D and calcium and/or fluoride produced the greatest reduction in the rate of vertebral fractures compared with calcium and vitamin D alone or a calcium and fluoride combination (Table III).[31] A consensus panel has recommended that estrogen replacement therapy be used in postmenopausal women at risk for osteoporosis.[36]

If the impact of estrogen replacement therapy is clearly beneficial, why aren't all women receiving such therapy? There are two main reasons. First, 75% of all postmenopausal women will not develop osteoporosis, so the clinical indication is not present. Also significant are women's attitudes toward this therapy. In a recent survey, only 27% of postmenopausal women not receiving estrogen replacement therapy knew that estrogen deficiency was a risk factor for osteoporosis, compared with 89% of those taking estrogen replacement therapy, suggesting the need for further patient education. A physician's recommendation of estrogen replacement therapy was highly associated with its use, suggesting that prescribers have a powerful role in influencing decisions. Also, a woman's concern about estrogen's side effects, an issue with a high degree of visibility in the lay press, may lead her to decide not to

Table I. Risk factors for osteoporosis

Primary risk factors	*Secondary risk factors*
White or Oriental race	Chronic renal failure
Women of Northern Europe	Gastrectomy and intestinal bypass
Family history of osteoporosis	Malabsorption syndromes
Petite, small frame	Multiple myeloma
Poor nutrition	Hyperparathyroidism
Low calcium intake	Hyperthyroidism
Lack of physical activity	Adrenocortical overactivity
Decreased weight and muscle mass	Diabetes mellitus
Nulliparity	Anticonvulsants (phenytoin)
Premature or surgical menopause	Aluminum antacids
Cigarette smoking	Thyroid extracts (>180 mg/day)
Excessive alcohol intake	
High-fiber diets	
High-caffeine intake	
High-protein diet	
High-sodium diet	
High-phosphate diet	

Table II. Minimum effective estrogen dosages for preventing bone loss

	Estrogen (mg)	*Serum estradiol level (pg/ml)*	*Estrogen (mg) plus calcium**
17 β-Estradiol cream	1.5	50-60	—
Micronized estradiol	2.0	50-60	1.0
Conjugated estrogens	0.625	50-60	0.3
Estrone sulfate	0.625	50-60	—

use or to discontinue use of estrogen replacement therapy.[37] Simply put, the following clinical guidelines should be followed: All women at high risk (especially low bone mass) should be treated with estrogen replacement therapy; the remainder should be regularly monitored and treated if their rate or degree of "natural" bone loss is excessive.

Cardiovascular disease. Concern about estrogen use and an increased cardiovascular risk has been tainted by the association with oral contraceptives. The association is, at best, controversial; more likely estrogen replacement therapy has a beneficial effect on cardiovascular disease risk. The use of synthetic estrogens in men (e.g., in treating prostatic carcinoma[38]) and case-control trials of birth control pills in women[39-42] reveal a positive correlation between exogenous estrogens and risk of cardiovascular disease. A recent report from the Framingham study suggested a relationship between postmenopausal estrogen use and an increased cardiovascular risk.[43] In contrast, most studies examining postmenopausal estrogen use show a reduction in cardiovascular risk or no effect.[44-48] Indeed, animal data demonstrate that estrogen treatment may retard the development of atherosclerotic coronary lesions.[49]

Recent studies of estrogen replacement therapy have demonstrated the potential benefit of estrogens on the risk of cardiovascular disease. In three important trials, a risk reduction for stroke,[50] myocardial infarction,[51] and cardiovascular death[52] was associated with this therapy's use. Estrogen replacement therapy was associated with a relative risk for death from stroke of 0.53; recent users (those using estrogens at the time of the questionnaire) had a relative risk of 0.21.[50] In another analysis therapy was associated with a 41% reduction in deaths and a 29% reduction in morbidity due to acute myocardial infarctions.[51] Finally, in an 8.5-year mean follow-up period, estrogen replacement therapy was associated with a relative risk of cardiovascular death of 0.54.[52]

Several postulates have been advanced to explain this decrease in cardiovascular death. By far, the leading hypothesis is an estrogen replacement therapy–induced reduction in low-density lipoprotein (LDL) cholesterol and an increase in high-density lipoprotein (HDL) cholesterol.[53-55] Estrogens increase HDL_2 cholesterol and its associated apolipoproteins, A1 and A2.[56] This effect occurs with both oral and nonoral ethinyl estradiol,[57] but with only oral (not vaginal) conjugated estrogens.[58] Percutaneous estradiol cream reduced total and LDL cholesterol, but did not change HDL cholesterol.[59] To date, the transdermal patch has not produced as favorable an effect on lipids and lipoproteins.[56, 60, 61]

Synthetic progestins have an effect opposite to that of estrogens on lipoproteins: HDL cholesterol is decreased and LDL cholesterol is increased.[62] At conventional doses, progestins appear to ameliorate or abolish estrogen's beneficial effect on lipoproteins, a critical predictor of coronary heart disease risk.[63-65] In one study the addition of a "naturalized" oral micronized progesterone at a dose of 200 mg/day to percutaneous estradiol for 12 days per cycle resulted in no further change in total and LDL cholesterol and an increase in HDL cholesterol.[59] The same was noted in an 18-month study involving naturally menopausal women using cyclic conjugated equine estrogen (both 0.625 and 1.25 mg) and a 7-day course of 10 mg medroxyprogesterone acetate for week. A practical point: Patients with an intact uterus who are at risk for cardiovascular disease should be given relatively "high-dose" daily estrogen replacement therapy (e.g., 1.25 mg conjugated equine estrogen) and cyclic progestins (e.g., 5 mg medroxyprogesterone acetate for the first 2 weeks of each

Table IV. Cautions and contraindications to estrogen replacement therapy

month).[64] A recent study has shown that a regimen similar to this results in an overall increase in plasma HDL-cholesterol. Most hysterectomized menopausal women do not need added progestins.

We have generally believed that hypertension, by far the most significant risk factor for stroke, is a relative contraindication for estrogen replacement therapy.[66, 67] However, Paganini-Hill et al.[50] reported a reduction in the incidence of mortality from stroke in estrogen replacement therapy users with and without histories of hypertension. Indeed, although some women may experience an elevation in blood pressure when given estrogens, most studies report a reduction in blood pressure with this therapy.[68-70] Thus some experts do not feel that hypertension is a contraindication to therapy.[71] There may be a difference between the "natural estrogens" and their more potent synthetic counterparts, because ethinyl estradiol stimulates renin substrate and thus may pose a risk.[56] Progestins, on the other hand, can produce a dose-related elevation in blood pressure.[72]

Another possible mechanism for estrogens' beneficial effect on cardiovascular disease is enhanced prostacyclin production, resulting in vasodilatation. This effect is also opposed by progestins.[73]

Contraindications

There are few absolute contraindications to estrogen replacement therapy: recent myocardial infarction, cerebrovascular accident or transient ischemic attack, and recurrent, active, or spontaneous thromboembolic disease (Table IV). Acute liver disease, history of or active breast cancer, and poorly differentiated endometrial cancer are other, noncardiovascular-related contraindications.

Breast cancer. Disagreement exists regarding the possible association of estrogen replacement therapy and breast cancer. Some investigators have demonstrated a small but significant increase in risk of breast cancer,[74] whereas others have concluded that estrogen therapy does not increase the risk of breast cancer and may, in fact, improve the prognosis of those in whom breast cancer develops during therapy.[75, 76] Others feel that whereas high doses of estrogens may be associated with a slight increase in risk of breast cancer, low doses (<0.625 mg/day of conjugated estrogens) may not be associated with such a risk.[35, 74, 77] However, most believe that estrogen replacement therapy is absolutely contraindicated in patients with breast cancer.[35, 78] Although some feel that only women with surgically removed benign breast tumors are at increased risk,[71] all women taking this therapy should be encouraged to practice monthly breast self-examination, to be examined yearly by a physician, and to have regular mammograms. The potential protective role of added progestins is still not clear.

Endometrial cancer. In 1987 there were 35,000 new cases of endometrial cancer in the United States and 2900 deaths from endometrial cancer. The disease is usually diagnosed at an early stage; those with stage 1 disease have a 92% 5-year survival rate and those with stage 2 disease have an 84% 5-year survival rate.[33] The first reports of an association between endometrial cancer and estrogen use were published in 1975.[79, 80] This

‡Case-fatality rate for exogenous estrogen-induced endometrial cancer estimated at one eighth the normal rate.

risk has been well established: Estrogen users have a four- to eightfold increase (range two- to twenty-fold)[33, 35, 79-82] in risk of developing endometrial cancer compared with those not taking estrogens.

The risk is related to many factors, including duration of use, dosage (Table V)[83], method of administration, drug-free interval, and concomitant progestin use. In one evaluation, a dose of 0.625 mg/day of conjugated estrogens was associated with a 1.8-fold increased risk, whereas a dose of 1.25 mg/day was associated with a 12.7-fold increased risk.[84] These same investigators also determined that duration of therapy correlated with risk: Those using estrogens for less than 5 years had no increase in risk, those with a 5- to 9-year usage history had a 4.1-fold increase in risk, and those with more than 10 years of use had an 11.6-fold increased risk. A drug-free interval of 4 days per month was associated with a reduction in risk compared with continuous use,[81, 84] although other investigators have noted no difference in the rate of endometrial hyperplasia with cyclic (3 weeks on, 1 week off) estrogen therapy compared with continuous therapy.[85] An increased risk of endometrial cancer persists after discontinuation of therapy.[81]

Two studies published in 1979 determined that using a progestin with the estrogen was associated with a risk of endometrial cancer comparable to that of postmenopausal women not receiving hormonal therapy.[76, 86] In one study a high dose of estrogen was used (2.5 mg/day conjugated estrogen) with 10 mg/day medroxyprogesterone acetate for 7 days per cycle.[76] When unopposed by progestins, estrogen promoted endometrial hyperplasia. Because progestins confer protection, concurrent progestin therapy with estrogen replacement therapy, either for a few days per month or continuously, is generally recommended and prac-

Table VII. Estrogen preparations

Generic name	*Brand name*	*Components*	*Available doses*
Natural			
Micronized estradiol	Estrace	100% 17β-Estradiol*	1 mg, 2 mg

Equine estrogen			
Conjugated estrogens	Premarin	50%-60% Estrone sulfates; 22.5%-32.5% sodium equilin sulfate; 7.5%-20% unspecified conjugated estrogens	0.3 mg, 0.625 mg, 0.9 mg, 1.25 mg, 2.5 mg
Synthetic			
Ethinyl estradiol	Estinyl	100% Ethinyl estradiol	0.02 mg, 0.05 mg, 0.5 mg
Diethylstilbestrol	DES	100% Diethylstilbestrol	0.1 mg, 0.5 mg (higher doses used for other indications)

*Converted to estrone sulfate during absorption.

ticed.[35, 75, 76] Others oppose the addition of a progestin because endometrial cancer is relatively rare and is nonfatal in most cases and because progestins oppose the beneficial lipoprotein effects of estrogens. A nonclinical study comparing a low-dose estrogen regimen with a combination regimen showed a higher relative risk of endometrial cancer but a greater net reduction in deaths (based on cardioprotective effects) for the group taking estrogen alone (Table VI).[73] The question of progestin supplementation remains controversial,[33, 73] but most physicians prescribe a 10-day cyclic course of progestins with long-term estrogen replacement therapy in women with an intact uterus.

Coagulation and thrombosis. Estrogens produce several effects on coagulation, complicating determinations of their exact net effect. Estrogen tends to reduce endothelial prostacyclin production.[87] Synthetic estrogens may specifically or preferentially increase prostacyclin activity, but this area requires further investigation.[88] Progestins may increase[89] or reduce[90] prostacyclin activity. Because thromboxane has the opposite effect and in addition increases platelet adhesiveness, women taking estrogen replacement therapy (especially those with high-risk profiles) should take 60 to 80 mg of aspirin every other day. This low dose inhibits thromboxane synthesis more than that of prostaglandin, allowing the latter to exert its preventive effect on blood flow and platelet adhesion.

Platelet aggregation is generally unchanged by estrogens,[91] although one study demonstrated an increase.[92] Virtually all clotting factors have been shown to be elevated in women receiving synthetic estrogens (ethinyl estradiol, diethylstilbestrol), with factors II, VII, IX, X, XII, and fibrinogen being elevated most frequently. This phenomenon is primarily related to the potency of the estrogen used. The elevations are more marked with ethinyl estradiol and less marked with the estriol-containing agents.[91] Clotting factor elevations were not observed in women receiving estrogen via patches[60] or ointment.[61]

Table VIII. Serum estrogen levels 24 hours after 25 days of treatment with estrone sulfate, conjugated estrogens, or estradiol

	Total estradiol (pg/ml)	*Total estrone (pg/ml)*
Baseline	10	37
Estrone sulfate	34	125
Conjugated estrogens	40	153
Micronized estradiol	40	150

From Lobo RA. Obstet Gynecol Clin North Am 1987; 14:143-67.

No clinically significant increase in coagulation factors has been observed with the use of the natural estrogens.[56, 93, 94] For example, the alterations in clotting factors seen with 30 μg/day of ethinyl estradiol did not occur with 3 mg/day of estrone sulfate.[56, 94] Despite their effect on clotting factors, estrogens do not lead to a hypercoagulable state; the observed increase in clotting factors occurs because proenzymes remain inactive until exposed to injured endothelium. Antithrombin III is not reduced to clinically relevant levels by either oral estrogen replacement therapy or transdermal estrogens.[91] Clinical trials have not shown any increase in risk of thromboembolism in postmenopausal women receiving estrogen replacement therapy.[75]

Plasminogen, a major factor in the fibrinolytic pathway, and especially plasminogen activity are elevated by estrogen administration.[95] This effect, which is enhanced by combination estrogen/progestin therapy,[95] is seen even with low-dose oral contraceptives.[96] This, combined with the persistence of normal antithrombin III activity, ensures against inappropriate venous thrombosis.

Neurologic effects. Estrogens may potentiate headaches and migraines. In one trial of 87 women who experienced migraine headaches while receiving estrogens, 58% experienced a reduction in symptoms with a dose reduction. The mean latency period was ap-

proximately 4 weeks.[97] Thus reducing the dose may relieve migraine headaches, a relative contraindication to the use of estrogens. Parenteral testosterone administration often alleviates this infrequent, but troublesome, side effect (Gambrell RD, personal communication, 1989).

Agent selection: differences between preparations

Alternate routes of administration. Estrogens are well absorbed transdermally and from deposition in subcutaneous fat. These routes circumvent a first-pass hepatic effect. Intravaginal administration of conjugated estrogens, when corrected for dose, results in less stimulation of hepatic proteins;[56] with ethinyl estradiol, circumventing the portal pathway does not affect hepatic protein production.[57] Estrogens' stimulation of hepatic proteins, however, results in no apparent clinical disadvantage. The proved decrease in cardiovascular risk is in fact based on the use of oral estrogen, possibly (in part) by its pharmacologic effect on the liver and its ability to synthesize the cardioprotective lipoprotein HDL cholesterol.

Estradiol pellet implants may be useful for relatively noncompliant patients, as these deliver steady levels of estradiol for 4 to 6 months.[98] In one study, 25 mg of 17β-estradiol (delivering an estradiol level of 60 pg/ml) was as effective as a 50 mg dose (delivering estradiol levels of 80 to 100 pg/ml) in maintaining bone mass.[14]

Estrogen preparations. Three classes of estrogens are used for estrogen replacement therapy in the U.S. (Table VII). Natural estrogens include estradiol and estrone. 17β-Estradiol is not well absorbed except in a micronized form. Adequate estrogen levels may be attained when other forms of micronized estradiol (Estrace) are administered. However, because of the enterohepatic conversion of estradiol to estrone, the primary estrogen in the peripheral circulation is estrone. Estrone is administered as estrone sulfate (Ogen). Conjugated estrogens (Premarin) contain up to 33% equine estrogens, primarily equilin sulfate. The synthetic estrogens are ethinyl estradiol (Estinyl) and diethylstilbestrol. Because of a potent first-pass effect, a reduction in bioavailability of up to 30% occurs with any oral estrogen. Except for piperazine estrone sulfate (Ogen), all oral estrogens are converted primarily to estrone.[56] When Lobo[56] measured free and total serum estradiol levels and total estrone levels after 25 days of oral administration of 0.625 mg of conjugated estrogens or piperazine estrone sulfate or 1 mg of estradiol, values for the three products were similar (Table VIII).[56]

Establishing equivalencies among different estrogen preparations is complicated by the many physiologic and pharmacologic effects of estrogens and the various end points of treatment measured. Estrogen potency can be measured in terms of gonadotropin suppression (luteinizing hormone and follicle-stimulating hormone) and hepatic protein production (angiotensinogen, corticosteroid-binding globulin, and sex hormone–binding globulin).

Potency can also be measured in terms of a reduction of urinary calcium corrected for urinary creatinine, a measure of prevention of bone demineralization. Additionally, estrogenic potency can be assessed in terms of maturation of vaginal epithelial cells. Investigators have attempted to quantify estrogenic potency using one or more of these parameters and to compare different agents using these measures.[56, 99-102]

In a study involving 23 healthy postmenopausal women, Mashchak et al.[102] found that the potencies of five estrogen preparations differed depending on which parameter was used to measure potency (Table IX). At doses that produced comparable effects on serum follicle-stimulating hormone, piperazine estrone sulfate and micronized estradiol had less of an effect on hepatic protein stimulation than the other preparations. For example, conjugated estrogens had a 2.5- to 3.5-fold greater stimulatory effect on serum corticosteroid-binding globulin, sex hormone–binding globulin, and angiotensinogen compared with estrone sulfate and micronized estradiol.[102] No dose-response relationship was found for leutenizing hormone suppression in this study; this effect may likely have been obscured by interpatient variation.

Most estrogens have the same biologic effect, irrespective of the type or route of administration, provided equivalent blood levels are reached. The route of administration may alter the patient's response.

Combination therapy. The scope of this article precludes appropriate discussion of combined therapy with estrogen; only two of the commonly prescribed preparations (calcium and progestins) will be discussed.

Combination of estrogens with calcium and bone loss. The coadministration of 1500 mg/day of elemental calcium with 0.3 mg of conjugated equine estrogen was as effective as 0.625 mg of estrogen without calcium in maintaining bone mass.[9, 103, 104] Thus when calcium is added to the regimen, lower doses of estrogens may be effective. Given the decreased likelihood of low-dose estrogens to stimulate the endometrium, this approach may be more acceptable to elderly women who are averse to menstruation (induced by the need for progestins when higher doses of estrogen are used).

Combination of estrogens with progestins. Progestins may exert antiresorptive effects on bone[25] and may act synergistically with estrogens to increase bone mass.[105] Megestrol acetate, 80 to 160 mg/day, slows the rate of bone loss and may be useful when estrogens are contraindicated.[14]

Cyclic therapy with estrogen and progestin can result in resumption of menses, a "side effect" few women relish. Making menses regular and predictable or achieving amenorrhea improves acceptance. To regulate menses, one can administer estrogen on a daily basis with progestin added for the first 2 weeks of each month[14] or give medroxyprogesterone acetate, 10 mg/day, for the last 10 days of each cycle.[106] Alternatively, estrogen and progestin can be given continuously (e.g., estrone sulfate or conjugated estrogen, 0.625 mg/day, plus medroxyprogesterone acetate, 2.5 mg/day).[14] This regimen will cause some withdrawal bleeding over the first 6 months, usually followed by amenorrhea.[107] Restricting the number of endometrial biopsies also helps. Provided the patient bleeds at appropriate times (e.g., from day 12 or after when taking cyclic progestins), some experts advise against biopsy. However, taking two biopsies may be prudent, with one 3 months after starting estrogen replacement therapy and the other 1 year later.[14] Women taking estrogen replacement therapy alone require yearly biopsies. All patients with "abnormal" bleeding need further testing through curettage with or without hysteroscopy.

Conclusion

Estrogen replacement therapy enhances a woman's feeling of well-being and reduces the morbidity, mortality, and health care costs associated with osteoporosis and atherosclerotic heart disease. Menopause is often referred to as an endocrinopathy, thus justifying the "routine" use of estrogen. Postmenopausal women do not, however, have a "disease." Many nonhormonal interventions—primarily nutrition and exercise—impact positively and equally well on well-being, bone metabolism, and cardiovascular fitness and can (and should) be used as substitutes for or additions to medical treatment.

It is only appropriate and fair that both the patient and the physician be more fully aware of this fact, and that hormonal therapy (estrogen alone or in combination with a progestin) be used on an individual and selective basis in postmenopausal women.

Estrogens in the prevention of osteoporosis in postmenopausal women

Harry K. Genant, MD,[a] David J. Baylink, MD,[b] and J. C. Gallagher, MD[c]
San Francisco and Loma Linda, California, and Omaha, Nebraska

Menopause-related bone loss leaves a woman at high risk for fractures. Estrogen use by postmenopausal women, especially when started within 3 years of the last menstrual period, prevents bone loss and reduces the risk of osteoporotic fractures. Estrogens do not restore lost bone. Withdrawal of estrogen therapy is followed by significant bone loss, thus suggesting that long-term therapy is needed. Concomitant progesterone therapy does not impair estrogen's bone-preserving activity. (AM J OBSTET GYNECOL 1989;161:1842-6.)

Key words: Estrogen, menopause, osteoporosis

Osteoporosis currently affects between 15 to 20 million individuals in the United States. About 1.2 million fractures occur annually as a result of osteoporosis, disabling many elderly adults.[1] Vertebral crush fractures are the most frequent fractures, accounting for 50% of all fractures. The risk of sustaining a crush fracture is high, with 25% of individuals over 70 years old showing radiographic evidence of these fractures. About 5% to 10% of these patients remain asymptomatic.[2] Osteoporosis may also account for 150,000 to 200,000 hip fractures annually in the United States, with about 80% resulting from minor trauma. Approximately 10% of patients with hip fracture die within 6 months of the fracture due to surgical complications; another 100,000 to 150,000 patients require institutionalization for rehabilitation after the hip fracture.[2] The total health care costs for fractures in the United States are estimated to be about $6 billion annually.

Bone turnover and postmenopausal loss

The skeleton consists of two bone types: cortical bone, which is responsible for 80% of the total bone mass, and trabecular bone, whose honeycomb structure provides greater surface area per unit volume than does cortical bone. Because the kinetic process of bone resorption and formation (i.e., turnover) occurs on bone surfaces, trabecular bone turns over more rapidly, perhaps four to eight times as fast as cortical bone.[1]

Table I. Minimum dosages of estrogen to prevent postmenopausal bone loss

Estrogen preparation	*Effective dose (mg)*
Conjugated equine estrogens	0.625
Ethinyl estradiol	0.02
Estrone sulfate	0.625

During the years the skeleton is maturing, and before the perimenopausal period, the amounts of bone resorbed and formed remain approximately equal. Once a woman reaches about 40 years of age, resorption begins to exceed formation by about 0.5% per year. When menopause begins, the amount of bone being resorbed increases sharply, while the amount being formed increases only moderately.[3] Consequently, each year losses of 1% to 3% of cortical bone and up to 5% of trabecular bone occur. The accelerated erosion of bone lasts about 10 to 15 years, after which bone loss is considerably diminished. Bone loss may actually stop after the eighth decade.[3]

Menopause-related bone loss results in a 15% to 30% decrease in trabecular bone and a 10% to 15% reduction in cortical bone.[4] Therefore, estrogen deficiency is responsible for one third to one half the bone lost during a woman's lifetime. Over 20 years, 50% of trabecular and 30% of cortical bone mass will be lost. This kind of reduction in total bone mass leaves a woman at high risk for fracture. By the age of 70 years, 15% of women will experience a wrist fracture, 25% a vertebral fracture, and 15% a hip fracture.

Mechanism of estrogen's actions

The precise mechanism by which estrogen prevents bone loss is not known. Exogenous estrogen administration reverses the biochemical changes associated with estrogen withdrawal, including decreases in serum cal-

Table II. Studies demonstrating beneficial effect of estrogens in oophorectomized women

Study	*Patients*	*Daily estrogen dose*	*Study design*	*Study duration (yr)*	*Bone measurement*	*Comments*
Aitken et al.[10] (1973)	50 Control 53 Treated	Mestranol average dose: 23 μg	Prospective, randomized, double-blind, controlled	1	Radiographic morphometry of hand; photon absorptiometry of third metacarpal	Sixteen patients in treated group and 15 in control group completed <1 year of the study
Meema et al.[11] (1975)	29 Control 53 Treated	0.625 or 1.25 mg CEE	Prospective, nonrandomized, uncontrolled	4+	Radiographic densitometry of third metacarpal	No breakdown of patients receiving 0.625 mg vs. 1.25 mg
Lindsay et al.[6] (1976)	57 Control 63 Treated	Mestranol mean daily dose: 24.8 μg	Prospective, double-blind	5	Photon absorptiometry: midpoint of third metacarpal, right hand	Midradius photon absorptiometry was performed in 46 of 63 treated patients 3 years after entering the study
Lindsay et al.[12] (1978)	14 Control 27 Treated	Mestranol mean daily dose: 27.6 μg	Prospective, double-blind, controlled	8	Same as above	Patients studied were part of original sample described in reference 6
Lindsay et al.[13] (1980)	42 Control 58 Treated	Mestranol mean daily dose: 23.3 μg; range 1 to 30 μg	Prospective, double-blind, controlled	9	Same as above; also photon absorptiometry of the midradius	Same as above
Genant et al.[14] (1982)	9 Control 27 Treated	CEE, 0.15 to 0.6 mg	Prospective, double-blind, controlled	2	Radiogrammetry of second metacarpal midshaft; photon absorptiometry of distal radius; CT of spine	Several CEE doses were used: 0.15 mg (n = 8), 0.3 mg (n = 6), 0.45 mg (n = 8), 0.6 mg (n = 6); determined a dose-response curve: doses <0.6 mg were adequate to prevent vertebral bone loss

CEE, Conjugated equine estrogen; *CT*, computed tomography.

cium, phosphorus, alkaline phosphatase, and osteocalcin levels and urinary output of calcium and hydroxyproline.[2] Conflicting changes are seen in the regulatory hormones that control calcium homeostasis. Levels of parathyroid hormone have been shown to fall, although data on this issue are conflicting.

All estrogens are probably not equally effective against postmenopausal bone loss (Table I) because they have different potencies depending on the end organ being studied.[5] Lindsay et al.[6] found that 25 μg of mestranol was needed to prevent bone loss; 0.625 mg is the accepted dose of conjugated estrogens.

As previously mentioned, estrogen deficiency increases the rate of bone resorption, resulting in more remodeling sites. Estrogen use by a postmenopausal woman stabilizes bone density by preventing further loss.[7,8] This phenomenon can best be explained by considering what occurs during the remodeling cycle: Estrogen reduces the rate of bone resorption, allowing the normal mineralization of the remodeling unit. Once resorption and formation return to equilibrium, usually in 6 to 24 months, bone mass stabilizes due to a slower turnover rate and an improvement in the coupling of bone formation to resorption. However, despite their preventative effects, estrogens do not restore lost bone; thus a woman with poor skeletal density at menopause may still be at risk for fractures even with estrogen replacement.

Prevention of bone loss after oophorectomy

Some 50 years have passed since Albright et al.[9] first described osteoporosis as a consequence of ovarian failure or removal. Estrogen deficiency's major role in the pathogenesis of postmenopausal osteoporosis is now well appreciated. Oral estrogen replacement therapy is the only consistently effective modality currently available to prevent bone loss after either oophorectomy or menopause.

Table III. Studies showing positive effects of estrogens on bone loss in postmenopausal women

Study	*Patients*	*Daily estrogen dose*	*Study design*	*Study duration (yr)*	*Bone measurement*	*Comments*
Recker et al.[15] (1977)	18 Treated 20 Control	0.625 mg CEE + 5 mg methyltestosterone	Randomized, uncontrolled	2	Radiogrammetry; photon absorptiometry of distal radius	
Horsman et al.[16] (1977)	19 Treated 18 Control	Ethinyl estradiol 25 or 50 μg		2	Photon absorptiometry of midpoint of third metacarpal	
Nachtigall et al.[17] (1979)	67 Treated 62 Control	CEE 2.5 mg + medroxyprogesterone	Prospective, randomized, double-blind	10	Photon absorptiometry of midpoint of third metacarpal	
Christiansen et al.[18] (1981)	Part I: 43 Treated 51 Control Part II: 35 Treated 42 Control	Trisequens forte	Prospective, randomized, double-blind	2	Photon absorptiometry	All patients also received 500 mg elemental calcium
Lindsay et al.[19] (1984)	120 Treated 30 Control	CEE	Prospective, single-blind, controlled	2	Photon absorptiometry and radiogrammetry of third right metacarpal	30 patients each received CEE 0.15 mg, 0.3 mg, 0.625 mg, 1.25 mg
Ettinger et al.[20] (1987)	15 Treated 25 Control	CEE 0.3 mg	Nonblinded, uncontrolled	2	Photon absorptiometry of distal radius; dual photon absorptiometry of L2-L4	All treated patients also received 1500 mg elemental calcium
Riis et al.[21] (1987)	11 Treated 11 Control	3 mg 17-β-estradiol percutaneously	Randomized, double-blind, controlled	2	Same as above	
Genant et al.[22] (1989)	94 Treated 28 Control	Estrone sulfate 0.3125 mg, 0.625 mg, 1.25 mg	Double-blind, randomized, controlled	1	CT of spine	All patients also received 1000 mg of elemental calcium

CEE, Conjugated equine estrogen; *CT*, computed tomography.

In several studies estrogens have been shown to reduce cortical and vertebral bone loss significantly in oophorectomized women (Table II).[6, 10-14] Of particular significance was the finding of a relationship between estrogen dose and vertebral response.[14] Specifically, doses of conjugated equine estrogens less than 0.6 mg/day were inadequate to prevent vertebral bone loss consistently.

Various forms of estrogen are also effective in preventing bone loss in postmenopausal women. Table III[15-22] lists several studies that reported consistent benefit from the use of estrogens. Nachtigall et al.[17] were the first to show long-term benefits with estrogens in a prospective, double-blind study. They found that conjugated equine estrogens with progesterone protected against postmenopausal bone mass loss for at least 10 years. Furthermore, estrogen prevented bone loss most effectively when begun within 3 years of the last menstrual period, during which interval the rate of bone loss is greatest. Lindsay et al.[19] and Christiansen et al.[18] independently demonstrated that estrogens were effective in preventing bone loss and that withdrawal of therapy was followed by significant bone loss, suggesting that long-term therapy is needed. Ettinger et al.[20] showed that a reduced dose of conjugated estrogen (0.3 mg) combined with 1500 mg of total calcium offered the same level of protection against bone loss as the 0.625 mg estrogen dose alone. More recently, another form of estrogen, estrone sulfate, protected against vertebral bone loss after a 1-year trial at doses of 0.625 and 1.25 mg ($p < 0.05$ versus placebo).[22]

Effect of estrogens on fracture incidence

Although data establishing estrogens' effectiveness against bone loss after oophorectomy and menopause are convincing, the real measure of estrogen therapy's efficacy is its effect on the risk of fracture. Numerous studies (Table IV)[23-29] support the efficacy of estrogen therapy in reducing fractures. Although estrogen therapy does not completely eliminate osteoporotic fractures, it does significantly reduce their occurrence.

Studies have consistently demonstrated that estrogens reduce the incidence of wrist fractures and, most importantly, hip fractures. Collectively, these data show an inverse relationship between the risk of hip fracture and estrogen use and predict a 50% reduction in the rate of fractures with long-term estrogen use. In a prospective, randomized trial, Lindsay et al.[26] found that

Table IV. Effect of estrogens on rates of fracture

Study	*Patients*	*Study design*	*Length of study (yr)*	*Fracture site studied*	*Comments*
Gordan et al.[23] (1973)	120 Postmenopausal women	Prospective, uncontrolled, nonrandomized	25	Unspecified	Total of 1664 patient-years studied; all patients received estrogens within 2 years of entering study
Hammond et al.[24] (1979)	301 Cases 309 Control	Retrospective	5+	Unspecified	Thirty percent of treated used 0.625 mg, 33.4% used 1.25 mg of CEE; 15% of controls fractured, 8.6% of treated patients fractured
Hutchinson et al.[25] (1979)	80 Cases 30 Control	Retrospective, case-control	3	Hip and distal radius	Odds ratio 3.0; increases to 3.8 if estrogens begun within 5 years of menopause
Lindsay et al.[26] (1980)	58 Treated 42 Control	Prospective, nonrandomized	Mean of 9	Spine and radius	Significant reduction in wedge deformities of T9 and L2
Weiss et al.[27] (1980)	327 Cases 576 Control	Retrospective, case-control	1	Hip and distal radius	Relative risk 1.0 for no estrogen use, 0.43 for current estrogen use
Paganini-Hill et al.[28] (1981)	91 Cases 166 Control	Retrospective, case-control	5	Hip	Risk ratio for estrogen used >60 months was 0.42
Kreiger et al.[29] (1982)	98 Cases 884 Control	Retrospective, case-control	2	HIp	Odds ratio for fracture was 0.5 for estrogen use >6 months

CEE, Conjugated equine estrogen.

estrogens reduced vertebral deformities in oophorectomized women.

Effect of estrogens with progesterone in preventing bone loss

Progestational agents are often added to an estrogen regimen to prevent the complications of unopposed estrogen on the endometrium. Initial studies using either C-21 progestins (medroxyprogesterone) or 19-norprogestogens (norgestrel and norethindrone) combined with estrogens have shown that progesterone does not impair estrogen's bone-preserving function.[20, 21, 30] Used alone, 19-nor-17β-hydroxyprogesterone protects against bone loss.[31] In studying the use of norgestrel and norethindrone (also 19-norprogestins) alone, Hart et al.[32] determined that only norethindrone was effective over a 2-year period. Additional study is needed to confirm the osteotrophic role of progestogens when used as single-agent therapy.

Prevention versus treatment of osteoporosis with estrogens

Data support the practice of starting hormonal replacement therapy as soon after menopause begins as possible to achieve maximum beneficial effects. Because menopause-induced bone loss is greatest in the 5 to 10 years immediately after menopause and because estrogen will only prevent loss of bone mass, it is uncertain whether a woman should begin estrogen replacement therapy 10 to 15 years after menopause if osteoporosis is the only indication for its use.

The duration of therapy is less well defined. Existing data suggest that estrogen's protective effects persist only as long as it is being taken. Discontinuation of therapy causes rapid bone loss.[12] Epidemiologic data suggest that at least 6 years of therapy are need to reduce the risk of osteoporotic fractures significantly.[28] Postmenopausal women should receive estrogens for at least 15 years, and some investigators recommend longer term therapy. The risk of long-term estrogen use must be balanced against the long-term benefits.

Because the use of estrogen replacement therapy for preventing bone loss requires long-term dosing, patient education is essential. Only 30% of women comply with their prescribed estrogen regimen.[33] In one review, of those women receiving estrogens for the first time, 20% to 30% never had the prescription filled, 20% stopped therapy within the first 9 months, and another 10% used it on an intermittent basis (i.e., when they remembered to). Intermittent therapy may be sufficient to alleviate vasomotor symptoms, but is not adequate for preventing postmenopausal bone loss.

Conclusion

Estrogen replacement therapy that is begun at the time of menopause prevents bone loss and decreases fractures. The use of estrogen in established osteoporosis is less well accepted, because estrogens do not replace bone mass that has been lost. Postmenopausal women should take estrogens for at least 15 years, after which time continuing therapy may or may not be indicated.

Estrogen replacement and cardiovascular disease: Serum lipids and blood pressure effects

William R. Hazzard, MD
Winston-Salem, North Carolina

Coronary heart disease, a major cause of morbidity and death, is the leading cause of death in older women, with an incidence that approaches that in men of comparable age. Estrogen favorably alters lipid metabolism and should therefore diminish the risk for coronary heart disease in estrogen users. Epidemiologic data from case-control and prospective cohort studies have suggested that estrogen use may confer protection from cardiovascular disease and decrease all-cause mortality rates in postmenopausal women. Because the age-adjusted mortality rate due to heart disease among American women is approximately four times the combined mortality rate due to endometrial and breast cancers, even modest changes in the risk of fatal heart disease after estrogen use would dramatically impact the overall risk-benefit equation. (Am J Obstet Gynecol 1989;161:1847-53.)

Key words: Estrogen, cardiovascular disease, lipids, blood pressure

Cardiovascular disease is a major cause of morbidity and death in modern society. Risk factors for cardiovascular disease include elevated blood pressure, impaired glucose tolerance, abnormal blood lipid levels, cigarette smoking, male sex, and advanced age. Elevated blood pressure and alterations in lipoprotein metabolism are major contributors to cardiovascular disease in general and to coronary heart disease in particular.[1-3]

Lipids, lipoproteins, and coronary heart disease risk

Prospective epidemiologic studies over the past three decades have documented a linear relationship between dietary fat consumption, serum total cholesterol, and the incidence of coronary heart disease.[4-15] These population studies were stimulated by the observation that patients with clinical manifestations of coronary heart disease had higher cholesterol levels than did control subjects. Longitudinal epidemiologic studies have documented an association between coronary heart disease risk in the general population and lipoprotein values, which are proportional to the serum total cholesterol.[6] Coronary heart disease risk increases as cholesterol values increase. Lipid components can be evaluated in terms of serum total cholesterol, triglycerides, and high-density lipoprotein (HDL), low-density lipoprotein (LDL), and very low-density lipoprotein (VLDL) cholesterol fractions. The relationship between increased triglyceride levels and coronary heart disease risk is not clear; other blood lipid measurements provide a better assessment of risk.

An inverse relationship exists between HDL cholesterol levels and coronary heart disease risk: the lower the HDL concentration, the greater the risk for coronary heart disease. This significant inverse relationship between HDL cholesterol levels and the incidence of myocardial infarction, angina pectoris, and cardiac death in people 50 years old or older holds true even when studies control for risk factors such as age, other cholesterol components, cigarette smoking, high blood pressure, weight gain, and diabetes mellitus.[3, 16]

Simplistically, elevations of any of the lipoprotein fractions, except HDL, are associated with an increased risk of coronary heart disease.[16-19] Elevated HDL levels, the fraction thought to be involved with clearing cholesterol from tissues and its subsequent metabolism and excretion, is associated with decreased coronary heart disease risk.[16, 17, 19]

Atherosclerosis and coronary heart disease share a common multifactorial origin. At any level of serum total cholesterol, risk will vary over a wide range depending on other associated risk factors. Reductions in any lipoprotein fraction other than HDL are assumed to prevent or reduce atheromatous plaque formation and prolong the lives of high-risk patients.[19]

Initial observations on estrogens and coronary heart disease risk

A definite rise in population total cholesterol and LDL cholesterol levels occurs across the menopause in women.[20] Postmenopausal status is accompanied by a gradual and progressive increase in the incidence of

coronary heart disease and its associated morbidity and death.[20] Coronary heart disease is the leading cause of death in older women, with an incidence that comes close to approximating that in men of comparable age. A common factor that may be responsible for the marked rise in this risk among postmenopausal women in general would appear to be the decline in estrogen levels and the resulting rise in LDL cholesterol levels.

Mortality rates due to coronary heart disease began to decline in the 1960s, and by 1976 had decreased by more than 30% in women and 20% in men.[21] This decline has been widely attributed to hygienic alterations in life-style. For instance, the decrease in mortality rates was accompanied by decreases in the proportion of male (by 26%) and female (by 8%) cigarette smokers between 1964 and 1976. During this same period, the percentage of men and women aged 55 to 64 years with serum cholesterol values greater than 260 mg/dl decreased by 14% and 29%, respectively.[21] Since the early 1960s, postmenopausal estrogen use has been widespread in the United States. Although not yet demonstrated in systematic population studies, some of the decline in coronary heart disease deaths in women since 1964 may be attributable to postmenopausal hormone replacement therapy. Other factors may include the decline in cigarette smoking, earlier detection and treatment of hypertension, decline in consumption of animal fats, other secular trends toward a more hygienic life-style shared in common with men, and the more effective treatment of this disease.

The possible protective role of exogenous estrogens has been controversial for decades. The early negative association between estrogens and atherosclerosis was based on the observation that men under 55 years of age had five to eight times the risk of coronary artery disease as did women of similar age. Researchers therefore suggested that estrogen might protect against progression of atherosclerosis. This association was further supported by the apparent increase in coronary artery disease among climacteric women. However, in the 1960s (the Coronary Drug Project), men with a previous history of myocardial infarction who received a high dose (5 mg/day) of conjugated estrogens had a risk of nonfatal myocardial infarction (6.2%) greater than that in the placebo group (3.2%).[22] In a subsequent evaluation, men given 2.5 mg/day of conjugated estrogens demonstrated a mortality rate of 19.9% compared with 18.8% for the placebo group.[23] As a result, both estrogen treatment arms were terminated early, and estrogen fell from favor as a possible form of secondary coronary disease prevention.

In contrast, other reports have suggested that estrogen use protects against the development of cardiovascular disease. Evidence from animal and autopsy studies suggests that exogenous estrogen may inhibit the development of atherosclerotic lesions.[24-26] Epidemiologic data from case-control and prospective cohort studies have suggested that postmenopausal estrogen use may confer a substantial degree of protection from cardiovascular disease.[24, 26-32]

Resolution of this paradox requires considering the pathophysiology of atherogenesis and the relative contributions of different phenomena at different stages in the natural history of atherogenesis. Women are physiologically protected by long-standing endogenous estrogen secretion; thus the process of atherosclerosis is retarded and superimposed thrombosis is unlikely. In such women, the net effect of estrogen is to prevent coronary disease.

In contrast, middle-aged or elderly men have had years of testosterone secretion with its adverse effects on lipoprotein cholesterol levels. Therefore, the effect of estrogen in men may be to enhance thrombosis, possibly resulting in coronary or cerebral artery occlusion. The effect of estrogen in increasing coagulation diathesis is well known: Estrogen not only increases platelet adhesiveness but also decreases the levels of factors that inhibit thrombosis, such as antithrombin III. Thus what is good for the goose may not be good for the gander!

Evaluating hormone replacement therapy relative to coronary heart disease risk, particularly in view of the small, but definite, risk of endometrial carcinoma associated with this form of therapy, is important. Of current concern is the effect of hormone replacement therapy on coronary heart disease risk factors such as blood pressure levels and lipoprotein profiles, and whether postmenopausal estrogens affect the risk for this disease.

Hormone replacement therapy and blood pressure

Possible evidence of an association between estrogen administration and hypertension was first published in 1967.[33, 34] Initially investigators assumed that hormone replacement therapy could either induce or aggravate hypertension. However, most reports published in the late 1970s and early 1980s failed to demonstrate a consistent, significant association between hormone replacement therapy and elevated blood pressure.[20, 24, 27, 33-35] Mashchak and Lobo[33] have reviewed epidemiologic case-control and prospective, double-blind clinical studies that clearly indicate that hormone replacement therapy does not increase the incidence of hypertension or aggravate preexisting hypertension:

Case-control studies

Davis et al.[36] (1961) reported the absence of an association between hormone replacement therapy and hypertension.

Stern et al.[37] (1976) demonstrated no relationship between current estrogen use and blood pressure alterations in a study that adjusted for age and weight.

Pallas et al.[38] (1977) found no significant increase in mean blood pressure (with or without controlling for age and weight) in women using conjugated estrogens alone. Plasma renin activity, plasma renin substrate, and renin reactivity, but not plasma renin concentration, were elevated.

Pfeffer[39] (1978) found a significant increase in the incidence of hypertension in nondiabetic women (58 to 79 years) taking hormone replacement therapy in a study controlled for age, diabetes mellitus, and stroke but not for weight. Mashchak and Lobo[33] (1979) found no change in blood pressure in either estrogen users or age-matched women who did not use estrogen followed for 5 months.

Barrett-Connor et al.[40] (1979), studying a group controlled for age and weight, found no significant difference between the systolic or diastolic blood pressures of estrogen users and control subjects. Estrogen users 60 to 64 years old had a significantly lower diastolic blood pressure than nonusers.

Persson et al.[41] (1983) showed a significantly higher prevalence of estrogen use in women with hypertension (17% versus 14%); however, 89% of the women were hypertensive before the start of hormone replacement therapy.

Prospective, randomized clinical trials

Lind et al.[42] (1979) observed a small, but statistically significant, fall in mean systolic and diastolic blood pressures in women of similar age (49 to 54 years) who were receiving conjugated estrogen therapy between 6 and 48 months after menopause. Both systolic and diastolic blood pressures returned to pretreatment levels by 3 months after the end of therapy.

Wren and Routledge[34] (1981), in a trial comparing conjugated equine estrogens and piperazine estrone sulfate, reported that 9% and 25% of subjects taking piperazine estrone sulfate and conjugated estrogens, respectively, had an increase in blood pressure, and 25% and 14%, respectively, had a decrease in blood pressure. A second study[35] (1983) demonstrated a slight, but statistically significant, fall in blood pressure when piperazine estrone sulfate was administered. This effect was not seen in women given conjugated estrogens for the same length of time. In fact, 15% of these patients had an increase in blood pressure of at least 15 mm Hg.

Lindsay and Herrington[43] (1983) followed postmenopausal women taking hormone replacement therapy for 3 years and suggested that hypertension in postmenopausal women was related more to obesity than to this therapy. Blood pressure tended to fall in women of normal weight, whereas diastolic and systolic blood pressures tended to rise in the placebo group. Among obese subjects, the blood pressure rise in the estrogen-treated group was not greater than that in the placebo group.

Luotola[44] (1983), in a crossover study, evaluated a normotensive and a hypertensive group's response to estradiol; blood pressure fell significantly in each 4-week treatment cycle for both study groups.

The rare occurrence of estrogen-induced hypertension cannot be disputed. However, these hypertensive episodes represent idiosyncratic reactions to hormone replacement therapy. The most carefully designed studies of blood pressure response to this therapy strongly suggest that blood pressure (both systolic and diastolic) is consistently, although minimally, lowered by estrogen administration.

Hormone replacement therapy, lipids, and lipoproteins

Both natural and surgical menopause are accompanied by adverse changes in serum lipids and lipoproteins that are associated with an increased risk of coronary heart disease.[45] As explained above, the adverse changes are related to cessation of ovarian estrogen production. We have long realized that hepatic protein synthesis and lipid metabolism are sensitive to the effects of exogenous estrogens and can be modified by the type of estrogen, dose, duration, and route of administration.[46-62] Estrogen-induced effects on liver protein synthesis vary depending on which protein is assessed; postmenopausal women's responses to hormone replacement therapy vary between and within organ systems.[46, 47, 63]

Overall, postmenopausal estrogens lower the serum concentration of LDL cholesterol* and increase the serum concentration of HDL cholesterol,† HDL_2,[26, 59, 62] apoprotein AI,[26, 59, 62] and apoprotein AII.[59] In most of the above-cited studies there was no change or a decrease in total cholesterol,[62] an increase in total triglycerides,[25, 57, 62] and no change in HDL_3[59, 62] after estrogen use. Hormone replacement therapy thus beneficially alters the LDL/HDL ratio in both the numerator and the denominator. The overall total cholesterol value may not change because decreases in LDL may be balanced, at least partially, by increases in HDL. An inverse relationship between the plasma concentration of HDL and apoprotein AI and the development of atherosclerotic cardiovascular disease and myocardial infarction has been reported.[59, 62] Therefore, the effect of postmenopausal hormone replacement therapy on lipid metabolism may be to diminish the risk of coronary heart disease in estrogen users.[63]

Hormone replacement therapy and coronary heart disease risk: Results of studies

In a 10-year prospective, double-blind study, Nachtigall et al.[64] compared the effects of high-dose (2.5 mg)

conjugated equine estrogen and medroxyprogesterone acetate (10 mg) with placebo in 84 pairs of randomly chosen postmenopausal inpatients matched for age and diagnosis. Those in the treated group who began the study with elevated LDL/HDL ratios experienced a reduction in that ratio over the course of the study. In the control group, LDL/HDL ratios were either maintained or increased. The treatment group's response occurred within the first 6 months of the study, and lipoprotein levels changed little over the succeeding 0.5 years of follow-up. The treatment group's overall survival rate was higher, although not significantly so, than the placebo group's rate.

The Lipid Research Clinics Program Follow-up Study[25] is the most authoritative study of cardiovascular disease risk in postmenopausal women using estrogens. This study reported that the age-adjusted relative risk for death from cardiovascular disease among estrogen users compared with nonusers was 0.34 (95% confidence limits, range 0.12 to 0.81). Multivariate analysis for age, blood pressure, and cigarette smoking estimated the relative risk for atherosclerotic cardiovascular disease in estrogen users to be 0.37 (95% confidence limits, range 0.16 to 0.88), again a highly significant reduction. When investigators analyzed the role of alterations in HDL and LDL concentrations, they found that more than half of the beneficial effect on cardiovascular disease risk could be attributed to the statistically significant LDL and HDL alterations. In particular, alterations in the HDL concentrations were individually and significantly associated with reduced cardiovascular disease and all-cause mortality rates in this cohort. These data are comparable to those of other studies linking high plasma HDL levels to low coronary death rates[16-19] and suggest an important postmenopausal benefit for hormone replacement therapy.

These data appear to conflict with an earlier report from The Framingham Study[65] that indicated a 50% elevated risk of cardiovascular disease morbidity ($p < 0.01$) in postmenopausal estrogen users. This report also noted a twofold risk for cerebrovascular disease in estrogen users compared with nonusers. An increased incidence of myocardial infarction was observed, particularly among estrogen users who smoked cigarettes. Nonsmoking estrogen users experienced only an increased risk of stroke. However, the postmenopausal estrogen user group included all women who had ever used postmenopausal estrogens in the 8 years before the twelfth biennial examination (1970 to 1972), and the overall user rate was low (24.4%). The Framingham Study data further suggested that estrogen use at baseline was less than 15%.

A separate analysis of the data,[66] excluding angina pectoris as an end point, demonstrated a significant protective effect for estrogen use in women 50 to 59 years old. This analysis suggests that age at menopause should be considered a covariate and is inversely associated with cardiovascular disease risk at a marginally significant level ($p = 0.04$). In this age group there was no increase in all-cause mortality rates, and cardiovascular disease risk decreased in estrogen users. No association was found between estrogen use and cardiovascular disease risk in older nonsmoking women. The original analysis adjusted for HDL level and thus possibly underestimated the benefits of postmenopausal estrogen use.[67]

Lipid, lipoprotein, and blood pressure responses to hormone replacement therapy predict a reduction in

coronary heart disease risk for women receiving this therapy. To date, no randomized trials have been conducted to determine the risk for atherosclerotic cardiovascular disease in women taking estrogens. Therefore, support for the benefits of hormone replacement therapy has come from epidemiologic surveys of case-control, cross-sectional, and prospective cohort design. Most studies[24-32, 64] show that hormone replacement therapy reduces the risk of cardiovascular disease and all-cause mortality rates in postmenopausal women (Tables I and II). Postmenopausal estrogen users fare better for each case-specific end point and significantly better for all-cause mortality rates compared with nonusers.

If cardiovascular disease risk is influenced by postmenopausal estrogen use, as the epidemiologic data suggest, then the associated influence on death will be a primary factor in balancing the risks against the benefits of hormone replacement therapy. For example, even minor relative changes in the risk of fatal heart disease after estrogen use would have a major impact on the overall risk-benefit equation, because the age-adjusted mortality rate due to ischemic heart disease among women in the United States is approximately four times the combined mortality rate due to endometrial and breast cancers.[29,30] In one study that set the relative risk of cardiovascular disease at 1.0, when the risk was reduced by as little as 20% (relative risk = 0.8), there was a net fall in mortality rates of 10% for high-dose (1.25 mg conjugated equine estrogens) therapy and of nearly 18% for moderate-dose (0.625 mg conjugated equine estrogens) therapy.[79] If risk were reduced by 50% (relative risk = 0.5), the net decrease in mortality rate would be in excess of 33% and 41% with high- and moderate-dose therapy, respectively.[28] These estimations underline the importance for determining with certainty any dose-response relationship between estrogen use and coronary heart disease.

Clinicians must consider the possible effects of estrogen therapy on the entire risk-benefit equation. Furthermore, epidemiologists must continue to refine these calculations through additional research. Future research needs must address the following issues before any firm conclusions regarding the effect of hormone replacement therapy on cardiovascular disease are established:

- Further defining the effect of hormone replacement therapy on lipoprotein subfractions, apoproteins, and systolic and diastolic blood pressures
- Determining dose-response relationships between estrogen administration and serum lipids, lipoprotein levels, and blood pressure changes, with a better definition of the effects of different estrogen preparations, routes of administration, dose, and duration of action on these parameters
- Improving definition of the effects of adding progestational agents to hormone replacement therapy regimen relative to lipoprotein and blood pressure response
- Describing the effects of estrogen/progesterone in patients with hyperlipoproteinemia and hypertension
- Undertaking prospective studies of the effect of hormone replacement therapy on cardiovascular and total mortality rates
- Clarifying the interactions between hormone replacement therapy and known risk predictors of coronary heart disease

Summary

Studies have revealed no clear evidence for adverse estrogen-induced effects on blood pressure levels. Post-

menopausal women's blood pressure, both systolic and diastolic, is consistently lowered by estrogen administration, although the decrease is small. Hormone replacement therapy does not aggravate preexisting hypertension. Oral hormone replacement therapy reverses the negative postmenopausal trends in lipoprotein profiles by decreasing LDL cholesterol and increasing HDL cholesterol levels. The significant improvement in lipoprotein profiles, particularly increases in HDL concentrations, implies cardioprotection and should predict a reduced risk of atherosclerotic cardiovascular disease. Epidemiologic data demonstrate that deaths due to myocardial infarction are significantly reduced in postmenopausal estrogen users. Because of its effects on lipoprotein profiles and blood pressure, hormone replacement therapy has been associated with lower overall morbidity and mortality rates due to coronary and total mortality. The available data clearly support using hormone replacement therapy in postmenopausal women.

Compliance considerations with estrogen replacement: Withdrawal bleeding and other factors

Ricardo G. Hahn, MD
Memphis, Tennessee

Withdrawal bleeding and other side effects such as edema, bloating, premenstrual irritability, lower abdominal cramps, dysmenorrhea, and breast tenderness limit compliance with hormonal replacement therapy. Although many of these troublesome side effects can be managed by adjusting the dose or changing the source of the estrogen or progestin components, postmenopausal women view withdrawal bleeding as the most negative factor influencing their decision to use hormonal replacement therapy. Additionally, the potential link between postmenopausal estrogen use and subsequent endometrial hyperplasia and cancer concerns potential users. Cyclic progestins protect the endometrium from hyperplastic changes but may not prevent withdrawal bleeding. Both patient and physician education, including the nature of menopause and the protective role of estrogens in osteoporosis and cardiovascular disease, are critical to improving compliance with hormonal replacement therapy. (Am J Obstet Gynecol 1989;161:1854-8.)

Key words: Estrogen, withdrawal bleeding, compliance

American women currently have life spans of some 80 years. With menopause occurring at a mean age of 51 years, women can expect to live one third of their lives in the postmenopausal state.[1, 2]

A significant number of undesirable physiologic changes in the postmenopausal years result from decreased levels of circulating estrogen. The use of hormonal replacement therapy for relieving vasomotor symptoms and slowing vaginal atrophy is well established. Estrogen also has a role in protecting against osteoporosis.[3-8] Additionally, recent studies have reported cardiovascular benefits from hormonal replacement therapy.[9, 10]

Despite the positive benefit/risk ratio of hormonal replacement therapy, compliance is a problem because of side effects (especially withdrawal bleeding) and other factors, including fear of cancer. This article will discuss these factors and provide suggestions for improving compliance with hormonal replacement.

How side effects can limit compliance

Many investigators have proposed that withdrawal bleeding and other side effects from hormonal replacement therapy limit compliance.[1, 11-13] For example, the rate of compliance with this therapy was only 30% in one study of 301 postmenopausal women.[11] In another investigation, 15 of 18 women receiving combination therapy dropped out of the study.[12]

In addition to withdrawal bleeding, side effects include edema, bloating, premenstrual irritability, lower abdominal cramps, dysmenorrhea, and breast tenderness. Although troublesome, these effects, which occur in 5% to 10% of patients taking combination therapy, may be managed by adjusting the dosage or changing the source of estrogen or progestin components.[14, 15] Edema, bloating, and irritability can be managed by reducing the estrogen dose, although adding a diuretic is occasionally necessary.[14] Changing progestins may alleviate the symptoms of lower abdominal cramps and dysmenorrhea, but a prostaglandin-inhibiting analgesic may be needed.[14, 15]

Withdrawal bleeding may be the most significant factor in the patient's decision to begin, continue, or discontinue hormonal replacement therapy.[1, 12] As stated above, in a comparison of two groups of postmenopausal women,[12] 15 of 18 women with intact uteri who were receiving combination therapy dropped out of the study because of withdrawal bleeding. These women, who were receiving the combination of 0.625 mg conjugated equine estrogens for 21 days with 2.5 mg norethindrone added from day 12 through day 21, had been informed that bleeding was to be expected during days 21 to 30 of the treatment cycle. None of 22 women hysterectomized for nonmalignant pathologic conditions who were receiving only 0.625 mg of CEE for 21 days of each month discontinued therapy. In a survey by Ferguson et al.,[1] women using hormonal replace-

Rating scale: 1 = Very positive to 5 = very negative.

Table II. Patterns of vaginal bleeding with normal and hyperplastic endometrium during unopposed cyclic estrogen therapy

Type of therapy	*Patients with withdrawal bleeding*		*Patients with breakthrough bleeding*		*Patient with no vaginal bleeding*	
	No.	*%*	*No.*	*%*	*No.*	*%*
Cyclic high dose						
Normal endometrium	14	64	11	69	22	71
Endometrial hyperplasia	8	36	5	31	9	29
Cyclic low dose						
Normal endometrium	3		5	56	23	96
Endometrial hyperplasia	1		4	44	1	4

Reprinted with permission from Whitehead MI. Maturitas 1978;1:87-98.

Cyclic high dose = conjugated equine estrogens 1.25 mg/day, piperazine estrone sulfate 3.0 mg/day, estradiol valerate 2.0 mg/day; cyclic low dose = half the high dose, daily.

ment therapy rated withdrawal bleeding as the most negative of a list of factors influencing their decision to use this therapy (Table I).

The atrophic postmenopausal endometrium responds to exogenous hormones by developing proliferative, secretory, and bleeding phases almost identical to those that occur during the normal ovulatory cycle. The so-called withdrawal bleeding can be heavy and painful in some patients.[12, 15]

Unopposed estrogen in some premenopausal and postmenopausal women can result in endometrium hyperplasia, an abnormal increase in the amount of proliferative endometrium. Possible causes include disordered estrogen metabolism, decreased levels of binding protein that allow greater estrogen access into cells, and increased sensitivity of the endometrium to estrogenic stimulation.[16] Two distinct forms of hyperplasia, cystic and adenomatous, exhibit different cytologic findings and premalignant potentials. Cystic hyperplasia converts to adenocarcinoma only at a 1% rate; 12% of adenomatous hyperplasias become carcinomas after 18 months and 30% undergo malignant changes within 10 years.[16]

American and European data have established a link between unopposed estrogen use and endometrial cancer. However, data do not necessarily demonstrate a direct link between endometrial status and vaginal bleeding patterns.[16-18] Withdrawal bleeding and breakthrough bleeding are not accurate predictors of endometrial hyperplasia (Table II).[17]

Maximum antiestrogenic effects appear to be achieved by adding progestins for 10 to 13 days of the monthly cycle.[14] In one series in which the incidence of hyperplasia was 18% to 32% with unopposed cyclic estrogen, the incidence was lowered to 3% to 4% when progestins were added for 7 days, and to zero when progestins were added for 12 to 13 days of the cycle.[19, 20] In another study, 5 to 10 days of progestin therapy reduced the frequency of hyperplasia to 2%; with 13 days of progestin therapy no hyperplasia was found.[21] Other studies confirm this effect.[17, 22, 23]

Although cyclic progestins may protect the endo-

Table III. Attitudes toward menopause

Attitude	Postmenopausal		Premenopausal
	Currently taking hormonal replacement therapy (n = 37)	*Have never taken hormonal replacement therapy* (n = 125)	
Menopause is a medical condition	1.9	3.7	3.1
Women with distressing symptoms should be taking hormonal replacement therapy	2.1	3.7	3.5
Women cannot control menopausal changes	3.3	3.7	4.0
Sexual interest and comfort increase after menopause	3.4	2.9	3.6
Psychologic problems are due to life changes, not hormonal changes	3.0	3.7	4.3
Women who have trouble are those who expect it	4.5	3.7	4.3
Risks of estrogen outweight benefits	4.6	3.8	4.4
Natural approaches are better than hormonal replacement therapy	4.6	2.6	3.0
Male partners of menopausal women see them as less sexually desirable	5.4	6.0	5.3
A woman feels like less of a woman after menopause	5.6	6.3	5.1

Scale: 1 = strongly agree to 7 = strongly disagree.

metrium from hyperplastic changes, withdrawal bleeding can nonetheless occur. Epidemiologic and biochemical arguments tend to support a differential effect among different estrogens when used cyclically. Wren et al.[24] suggested a more marked response of conjugated estrogens compared with estrone sulfate on uterine tissue (including endometrial hyperplasia), an increase in blood pressure, and decreased effectiveness in controlling vasomotor instability (hot flashes).

Many researchers have tested continuous combination therapy as a way to produce amenorrhea, alleviate symptoms, reduce the incidence of side effects, and avoid hyperplasia.[13, 15, 25-28] In a study comparing cyclic with continuous therapy, Prough et al.[13] followed two groups of postmenopausal women for 9 months. Group I was given 0.625 mg conjugated equine estrogen and 2.5 mg medroxyprogesterone acetate daily. Group II received 0.625 mg conjugated equine estrogen for days 1 to 25 and 10 mg medroxyprogesterone acetate during days 16 to 25. Vaginal bleeding was eliminated in all but 2 of the 16 women in group I; both had one episode of spotting. In group II, 8 of 10 patients continued to have withdrawal bleeding. After 9 months of therapy, all patients in the first group had an inactive endometrium. In the second group, nine patients had an inactive endometrium; in one patient the endometrium converted from inactive to proliferative.

In a study comparing different continuous regimens in 75 women, Magos et al.[15] used four combinations of daily conjugated equine estrogen (0.625 or 1.25 mg) and norethindrone (0.35 or 1.05 mg). At 3-month intervals, patients who experienced any bleeding were assigned to receive another 0.35 mg dose of norethindrone. At the start of the study, 65.2% of women taking 0.625 mg conjugated equine estrogen combinations and 46.9% of women taking 1.25 mg conjugated equine estrogen combinations became amenorrheic immediately. After dosage adjustments at the 1-year mark, 95.1% of all patients were amenorrheic. The incidence of unscheduled bleeding decreased with increased duration of treatment. Vasomotor symptoms were controlled, and no abnormal histologic findings developed during therapy.

Other factors that limit compliance

In addition to side effects, other factors contribute to noncompliance with hormonal replacement therapy. These include factors attributable to both patients and physicians.

In an ongoing field study of 2500 postmenopausal women, Ravnikar[29] found that women used hormonal therapy sporadically. The major reported reason for stopping therapy was the patient's fear of cancer. Among patients receiving first-time hormonal prescriptions, 20% stopped therapy within 9 months, 10% took the medication sporadically, and 20% to 30% never had their prescriptions filled.

Ferguson et al.[1] surveyed 289 women by question-

naire. Respondents were divided into three groups: postmenopausal women who currently use hormonal replacement therapy, postmenopausal women who have never used hormonal replacement therapy, and premenopausal women. (Women who had discontinued hormonal replacement therapy were excluded because the subgroups of those who stopped on their own or stopped due to physician suggestion were too small for valid analysis.) Table I summarizes the factors that influenced or would influence the decision to use hormonal replacement therapy. The most negative factor for all three groups of women was the fact that therapy would cause them to have periods. The most positive factors included physician recommendation, "would stop hot flashes," and "would not cause cancer."

Ferguson et al.[1] also examined these women's attitudes toward menopause (Table III). Women using hormonal replacement therapy were more likely to agree that menopause is a medical condition and that symptoms can be treated with this therapy. Most women disagreed or were neutral regarding the relative risks and benefits of estrogen therapy. Although 89% of women currently using hormonal replacement therapy knew that lack of estrogen was a significant factor in the development of osteoporosis, only 27% of postmenopausal women not using hormonal replacement therapy knew this. There was an apparent lack of knowledge of the risk factors for osteoporosis, with women using hormonal replacement therapy being the most knowledgeable.

The role of physicians in patient compliance is important. In the study by Ferguson et al.,[1] the major factor influencing hormonal replacement therapy use was physician recommendation. Another important finding was that of 125 postmenopausal women who had never used hormonal replacement therapy, 64% had never discussed this option with their physicians. Of this group, 75% agreed that a physician recommendation would have a positive effect regarding therapy use. All significant positive predictors of hormonal replacement therapy use ("natural approaches to menopause are less preferable," "women experiencing hot flashes should use hormonal replacement therapy," "menopause is a medical condition," "estrogen can reduce the risk of osteoporosis") can be influenced by physician teaching.

In a survey of 50 primary care providers, Holzman et al.[30] found that most clinicians were more concerned about the risks of endometrial cancer than about possible future fractures and thus did not readily prescribe estrogens.

Weinstein and Schiff[31] have developed a model to show that when all the epidemiologic data of risks and benefits are compared, the effectiveness of treatment in terms of longevity and quality of life is apparent.

Thus both patient and physician education are necessary if compliance with hormonal replacement therapy is to be increased. Research suggests that giving patients more information about hormonal therapy could significantly alter utilization patterns. Important factors to discuss include the nature of menopause, emphasizing that it is a medical condition with symptoms that can be alleviated with hormonal therapy. The protective role of estrogens in osteoporosis and cardiovascular disease must be balanced with the risks of cancer.

The physician's role in self-education is as important as his or her role in educating patients. A knowledge of available alternative regimens is essential because symptoms, side effects, and withdrawal bleeding may be managed by adjusting dosages or changing the estrogen and progestin formulations. The physician should also be aware that perimenopausal women with dwindling or intermittent periods may accept withdrawal bleeding more easily than older women. Additionally, recent data on the use of a Pipelle (instead of a Vabra aspirator) may offer patients who need serial endometrial biopsies a less painful alternative.[32, 33]

Physicians are typically familiar with the absolute contraindications (e.g., estrogen-dependent tumors or acute liver disease) and relative contraindications (e.g., a past history of endometriosis) to estrogen therapy. Equally important is an understanding of the large population of women for whom estrogens are indicated. Improving both patient and physician education will help increase compliance with hormonal therapy.

Areas for future research that may influence compliance include (1) improved combination therapy, perhaps prepackaged in dose packs, and (2) drugs that more specifically reduce the incidence of side effects, osteoporosis, and cardiovascular disease without producing end organ stimulation.

The cancer question: An overview of recent epidemiologic and retrospective data

Brian E. Henderson, MD
Los Angeles, California

Unopposed estrogen stimulates mitotic activity in endometrial and breast tissue. Numerous case-control studies have evaluated the relationship between estrogen use and the risk of endometrial and breast cancers. In general, exogenous, unopposed estrogen use increases the risk of endometrial cancer by tenfold and of breast cancer by twofold after long-term use of high doses. Estrogen's positive effects on osteoporosis and coronary heart disease must be considered when evaluating the potential risks associated with its use in postmenopausal women. (Am J Obstet Gynecol 1989;161:1859-64.)

Key words: Estrogen, breast cancer, endometrial cancer

Experimental, clinical, and epidemiologic evidence indicates that hormones play a major role in causing several human cancers. Based on his studies of estrogens and mammary cancer in mice, in 1947 Bittner[1] first proposed the concept that hormones can increase the incidence of neoplasia. This concept has been refined into epidemiologic hypotheses related to cancers of the breast, endometrium, prostate, ovary, and testis.[2, 3] These hypotheses are based on the association between neoplasia and excessive hormonal stimulation of the specific target organ, the normal growth and function of which is controlled by one or more steroid or polypeptide hormones.

This review will focus on our current knowledge of hormonal replacement therapy and its carcinogenic potential on the endometrium and breast.

Endometrial cancer

Unopposed estrogen stimulates endometrial cell biosynthesis, potentially leading to endometrial hyperplasia due to incomplete shedding of the endometrium (Fig. 1).[4] A proliferative endometrium can progress to cystic or adenomatous hyperplasia, which can then progress to atypical adenomatous hyperplasia, reportedly a premalignant stage.[5-7] The likelihood of developing hyperplasia appears to be directly related to the dose of estrogen prescribed.[8]

Case reports of endometrial cancer occurring in women after the use of estrogens have appeared in the medical literature for more than 30 years. Efforts to evaluate this relationship in a controlled fashion began in 1975, with two case-control studies[9, 10] that found estrogen use increased the risk of endometrial cancer. Since then, numerous case-control studies, some of which are summarized in Table I,[9-26] have reported similar conclusions. In general, exogenous, unopposed estrogen therapy (primarily Premarin) was found to increase the risk of developing endometrial cancer 2- to 15-fold compared with the risk in nonusers. In absolute terms, the overall incidence of adenocarcinoma of the endometrium in women aged 50 to 74 years who have never used estrogen is relatively low (estimated at 1/1000 women per year).[18] Therefore, a 10-fold increased relative risk, a representative value for "ever-users," indicates an increase in absolute risk from 1:1000 to 1:100 women per year.

Evidence suggests that adenocarcinoma of the endometrium after estrogen use is generally low stage and low grade and is associated with fewer cases of myometrial invasion.[11, 13, 17, 19, 25, 27] For example, Chu et al.[27] studied 320 women with endometrial cancer; 79% (285 of 363) had used estrogens for more than 1 year. Estrogen users tended to have well-differentiated tumors and no myometrial invasion. In addition, the women who had used estrogen had primarily stage 0 or I cancers, with a very low incidence of stage II or III tumors (2%) compared with those who had never used estrogen (12%; $p = 0.005$).

Not surprisingly, several studies suggest that estrogen users who develop endometrial cancer survive longer than nonusers who develop the same cancer. Elwood and Boyes[28] found that estrogen users had survival rates at 5 years of 89.1%, compared with 73.5% for nonusers. After adjusting the rates for expected deaths of age-matched women, they calculated relative survival rates for users and nonusers of 94.2% and 81.3%, respectively. At another Canadian study site, Collins et al.[29] similarly found that the estrogen users' 5-year survival rates (92% ± 2%) exceeded those of nonusers (68% ± 2%) (Fig. 2). Furthermore, for the women with en-

dometrial cancer, the risk of any death for nonusers was 2.7 times greater than that for estrogen users.

Disease risk is related to both dose and duration of estrogen use.[9, 10, 11, 17] High-dose users (>0.625 mg of conjugated estrogen per day) had a risk of developing endometrial cancer similar to that of low-dose users (<0.625 mg/day) and controls after short courses of therapy (<3.5 years).[19] In contrast, those who took high doses over long periods (≥3.5 years) had a greater risk of developing cancer than did low-dose users.

The findings from the above case-control studies are supported by data from several cohort studies.[6, 30-32] Never-users of estrogen had a risk of endometrial cancer 10 times less than that of long-term users.[30, 32] Estrogen-progesterone users had a relative risk of endometrial cancer of 0.9, a value lower than that observed among those who used estrogen alone (1.4).[33]

The benefit of adding a progestogen to estrogen replacement therapy to reduce estrogen-induced endometrial mitotic activity has been clearly established in clinical practice.[4, 34, 35] However, the possible adverse effects of progestogen on the risks of heart disease and breast cancer indicate that the dose of progestogen should be minimized and that simultaneous oral progestogen dosing is not suitable for all women, particularly those with a prior hysterectomy.[36] Whitehead et al.[37] showed that duration of progestogen therapy is more important than the dose of progestogen given; however, the optimal type, dose, and duration of progestogen therapy have not been established.

Breast cancer

Breast cancer risk is determined primarily by the total cumulative exposure of breast tissue to bioavailable estrogens and the associated cumulative mitotic activity. In contrast, progesterone does not have a growth-mediating effect on breast tissue comparable to its effect on the endometrium.

Most early studies that assessed the possible effects of estrogen on breast cancer risk were uncontrolled follow-up studies. In the most credible of these studies, Hoover et al.[38] reported 25% more cases of breast cancer in their cohort of menopausal estrogen users than what would have been expected based on general population rates (49 observed versus 39 expected). A more substantial increase occurred among women using high estrogen doses over a long period.

Early case-control studies to evaluate the relationship between menopausal estrogens and breast cancer were often limited by small numbers of subjects, insufficient data on dose and duration of use, and the definite possibility of bias. A series of carefully conducted case-control studies using healthy population controls have recently been published (Table II).[39-46] Overall, long-

				High in BSO with family history

BSO, Bilateral salpingo-oophorectomy; *BBD,* benign breast disease; *TMD,* total cumulative dose greater than 1500 mg.

*Risk relative to never-users.

†Ever users are women who have used estrogens for at least 1 year; ever users and long-term users are compared with women with either less than 1 year of use or no estrogen use.

term estrogen use was associated with small to moderate increases in the risk of breast cancer, although some variation existed across studies based on ovarian status (intact ovaries versus ovaries removed) or hysterectomy status (surgical versus natural menopause).

In women with intact ovaries, Ross et al.[45] found that those who had received a total cumulative conjugated estrogen dose in excess of 1500 mg had a 2.5-fold increased risk relative to nonusers. No such increase was observed for oophorectomized women. In the Cancer and Steroid Hormone (CASH) study,[46] risk with long-term use was elevated only for women who re-

ported surgical menopause. Hiatt et al.[40] reported an increased risk with long-term use by women who had undergone bilateral oophorectomy. Finally, Hoover et al.[41] and Brinton et al.[39] reported an elevated risk of breast cancer for women with and without intact ovaries after replacement estrogen therapy. Estrogen users with 15 or more years of exposure had a 50% elevation in risk, amounting to a 2% cumulative absolute excess risk in women aged 65 to 79 years.

Studies using hospital controls as the comparison group generally found no evidence to suggest that breast cancer risk was increased either overall or with long duration of use[42, 44, 47-49] (Table III). Two other studies reported significantly elevated risks associated with estrogen use by women who had natural menopause.[50, 51] Hulka et al.[42] reported comparably low risks with either hospital-based or community-based controls. A possible explanation exists for this lack of effect: controls in hospital-based studies have more contact with the health care system and are therefore more likely to use elective drugs than the population as a whole.

Buring et al.[52] evaluated the risk of breast cancer associated with postmenopausal hormone use among a cohort of nurses who primarily used conjugated estrogens unopposed by progestogens. These women were at no increased risk due to ever having used postmenopausal hormones before the initial survey in 1976; however, long-term use conferred a moderate risk (5 to 9 years of use, relative risk = 1.5; 10+ years of use, relative risk = 0.9).

Based on case-control studies using population controls, it seems sensible to conclude the following: long-term use of estrogen replacement therapy leads to about a 75% increase in breast cancer risk after 15 years. Certain subgroups of women may be relatively more susceptible to the carcinogenic effects of estrogens than others, including postmenopausal women with a positive family history of breast cancer[41, 42, 44, 46] and women with surgically proved benign breast disease,[37, 39, 45] especially if the estrogen use followed the diagnosis of the benign disease.[53]

Estrogen users who develop breast cancer may survive longer than nonusers who develop the same cancer. Bergkvist et al.[54] found that the relative survival rate was significantly higher ($p = 0.02$, by about 10% at 5 and 8 years) in estrogen users 50 years old or older who had discontinued estrogen therapy less than 1 year before the cancer diagnosis.

The value of adding a progestogen to estrogen replacement therapy to minimize breast cancer risk has not been suitably evaluated in substantial, well-conceived studies. However, we have reason to believe that the addition of progestogen will actually increase the risk of breast cancer beyond that associated with estrogen use alone.[55] Results from studies of premenopausal women receiving depot-medroxyprogesterone acetate provide some information on the possible in-

dependent effect of this progesterone on breast cancer risk. In two of three studies, the relative risk was 1.0[56, 57]; the association between this drug and breast cancer was significant in the third study[58] (which was potentially biased). In a recent cohort study, women who took progestogen and estrogen in combination had a higher risk of breast cancer than women who used estrogen alone.[59]

Other considerations

As reviewed by Genant et al., estrogens prevent osteoporosis and its most serious medical consequence, hip fracture. Estrogens also lower the risk of coronary heart disease. Because death rates from coronary heart disease among American women are four times those from endometrial and breast cancers combined, estrogen's benefit in this respect could far outweigh any carcinogenic potential. In fact, we recently calculated that for nonhysterectomized women aged 65 to 74 years, a daily dose of estrogen (equivalent to 0.625 mg conjugated estrogen) for 10 years would result in an annual saving of 302 lives per 100,000 women. For hysterectomized women the estimated saving was even more dramatic (328 lives per 100,000 women).[60]

Estrogen replacement therapy: What the future holds

Charles B. Hammond, MD
Durham, North Carolina

Although hormonal replacement therapy has proved beneficial for many postmenopausal women, several issues remain to be resolved through future research. Improved combination therapy, better delivery systems, and optimal dosing may enhance compliance, which is essential for maximum benefit from therapy. Epidemiologic studies are necessary to clarify the role of estrogen in osteoporosis and cardiovascular disease. Additionally, the contribution of hormonal replacement therapy to the development of breast and endometrial cancers needs to be clarified. (AM J OBSTET GYNECOL 1989;161:1864-8.)

Key words: Hormone replacement therapy, menopause, research

Women in the United States presently have a life expectancy of 81 years, 30 years beyond the usual age of menopause. When ovarian function ceases, a state of relative estrogen deficiency develops. A woman will live one third of her life without the beneficial effects

of her natural estrogens. Common hypoestrogenic-associated conditions such as vasomotor instability, emotional lability, sleep disturbances, genitourinary atrophy, and osteoporosis develop in 75% to 85% of postmenopausal women. Hormonal replacement therapy is effective in treating these conditions; in most cases it is superior to alternative modes of therapy.[1] In addition to its other benefits, hormonal replacement therapy may reduce the increasing risk of atherosclerosis in postmenopausal women.[2] This therapy is associated with few relative risks and side effects. Hormonal replacement therapy should be considered a preventive measure; for effective prophylaxis, early administration and long-term use are required. Concerns over possible risks of breast and endometrial cancer, coronary artery disease, thrombosis, hypertension, and effects on glucose tolerance have been obstacles to using this therapy. This article will discuss the increasing role of hormonal replacement therapy in both postmenopausal women and in women with induced estrogen deprivation. Future uses and research directions will be suggested.

Formulation and route of administration

Free estrogen is the biologically active form of the hormone. More than 90% of circulating estrogen is protein bound, 30% to sex hormone binding globulin and 60% to albumin, leaving, 2% to 3% unbound. The concentration of free hormone is a function of total estrogen concentration, sex hormone binding globulin concentration, and metabolic clearance rate, which is inversely proportional to the extent of protein binding.[3] Free estrogens exert their metabolic effects by binding to high-affinity, specific low-capacity estrogen receptors in the nucleus of the target cell. The potency of a specific estrogen is determined by the length of time it occupies the steroid receptor.[4] There is no uniform estrogen bioassay: multiple factors determine the efficacy of a particular estrogen compound, including the efficiency of absorption and metabolic clearance, dose and route of administration, and the particular system or effect under evaluation.[4] Dose, route, and frequency of administration vary among different estrogen preparations. Currently, potency is generally assessed by changes in the maturation index of the vaginal mucosa, cervical mucous ferning, and endometrial proliferation. Similar biologic effects are achieved with diethylstilbestrol 5 mg, estradiol 5 mg, conjugated equine estrogens 3.75 mg, estrone sulfate 3.75 mg, ethinyl estradiol 0.05 mg, and mestranol 0.08 mg.

Conjugated equine estrogens, obtained from the urine of pregnant mares, are the most commonly prescribed estrogens of hormonal replacement therapy in the United States. Most circulating estrogen is equilin, which is both potent and long-lasting due to its lipophilic properties that allow storage and slow release from adipose tissues.[5] Conjugated estrogens are effectively absorbed after oral or intravaginal administration. A daily dose of 0.625 mg oral conjugated estrogen or 1.25 mg intravaginal conjugated estrogen raises the total circulating estrogen level to approximately 93 pg/ml (the mean serum level of estrogen after menopause is 35 ng/l).[4]

Other available agents for hormonal replacement therapy include estradiol, estrone, or estriol. Because these estrogens are insoluble in water and are rapidly metabolized in the gastrointestinal tract, they must be esterified or sulfated for oral use. Adding an ethinyl group at the 17 position produces 17β-estradiol; this compound is almost completely absorbed after oral administration. Micronization, by which the particles are made small enough to permit gastrointestinal absorption (20×10^6 m or less), is another technique that makes oral therapy possible.[3, 4] Micronized estrogen preparations may be administered orally, intravaginally, or sublingually. Intravaginal administration results in rapid and effective systemic absorption. In a study of postmenopausal women, subjects experienced a decrease in vasomotor and vaginal symptoms after 15 days of treatment; moderate to marked improvement in symptoms related to atrophic vaginitis was noted in 53 of 54 patients.[6]

17β-Estradiol is also available in the United States as a transdermal patch in dosages of 0.05 and 0.1 mg. The transdermal patch raises estrogen levels from 40 to 80 pg/ml, but estrogen levels fluctuate around the physiologic level and achieving a steady state is not easy.[3] The patch is convenient to use and needs to be replaced only every 3 days. A once-a-week oral estrogen agent, quinestrol (the 3-cyclopentylether of ethinyl estradiol), is also available. This preparation is absorbed through the lymphatic system, stored in adipose tissue, and released gradually.[4]

Thus a variety of estrogen preparations and routes of administration are available. The transdermal forms have only recently been shown to have similar beneficial effects on lipids and bone that the oral preparations confer. If relative dose is considered, no one preparation is clinically more likely to cause major side effects.

Progesterone cotherapy

In the 1970s, evidence indicated that using unopposed estrogens was associated with a significant increase in endometrial cancer.[7] Unopposed estrogens may also cause problems such as abnormal vaginal bleeding for which diagnostic evaluations and surgical treatments may be needed. In a retrospective study spanning 17 years, more than one fourth of women using unopposed estrogen required a hysterectomy to treat nonmalignant complications.[8] The ad-

dition of a progestogen to hormonal replacement therapy can usually avoid both the malignant and nonmalignant gynecologic problems associated with unopposed estrogen. Because natural progesterone is poorly absorbed through the gastric mucosa, synthetic forms are used. Available progestogens include 17-acetyloxyprogestin (medroxyprogesterone acetate) and 19-norprogestins (norgestrel, norethindrone, and norethynodrel). Gastrointestinal absorption varies among patients. Like estrogens, these progestogens may be administered orally, vaginally, and parenterally. A micronized form of progesterone that has been used in Europe produces serum levels greater than 10 ng/ml and a secretory endometrium.[3]

Both 17- and 19-progestins reduce calcium creatinine ratios. Some studies have suggested that regimens of estrogen plus a progestin actually have a beneficial effect on bone metabolism, increasing bone mineral mass rather than just stabilizing it.[9, 10] Progestins' effect on lipid metabolism is the reverse of that of estrogens: they elevate low-density lipoprotein cholesterol while lowering high-density lipoprotein cholesterol. The amount of androgenic activity of a specific progestogen correlates with its lipid effects. To date, oral micronized progesterone has not been shown to affect lipid metabolism adversely.[3]

Despite their adverse effects on lipids, progestins seem necessary to protect the endometrium from hyperplasia. Future areas of research might focus on the development of a transdermal progestin preparation and the development of an estrogen-progesterone minipill containing the proper balance of both agents so that adverse effects are minimized and beneficial effects maximized.

Patient selection, dosage, and compliance

When selecting patients for hormonal replacement therapy, one must balance the potential benefits against the risks. Women with symptoms related to estrogen deficiency should be considered candidates for hormonal replacement therapy as should women at risk of developing osteoporosis or those with a strong family history of cardiovascular disease. Considerable data now suggest that estrogen-progestin therapy can significantly reduce death among postmenopausal women.[11] Hormone replacement therapy should be started as soon as ovarian failure occurs (with the cessation of menses) or in the perimenopausal period if significant symptoms of estrogen deficiency begin. Absolute contraindications include a known or suspected estrogen-dependent neoplasia, undiagnosed genital bleeding, active thrombophlebitis or thromboembolic disorder, and active liver disease. Relative contraindications include a past history of estrogen-dependent thrombophlebitis, uterine leiomyomata, unstable hypertension, and poorly controlled glucose intolerance.[3]

The dose of estrogen used should be the minimum required to control symptoms and to provide protection against osteoporosis. No one estrogen or progestin has been found to be superior when equivalent doses are considered. Conjugated equine estrogen and estrone sulfate at doses of 0.625 mg have prevented osteoporosis in most women.[12, 13] Cyclic administration of estrogen and progestins is no longer recommended. Rather, estrogen should be given continuously, 365 days a year, and a progestogen should be given concomitantly for the first 10 to 14 days of the month. This method of administration provides protection against the development of endometrial carcinoma and produces a predictable bleeding pattern that reflects the status of the endometrium.[3] If menstrual bleeding occurs before the tenth day of the month, a proliferative endometrium is likely present. In this case, the dose of progestin may need to be increased and endometrial sampling is necessary. If bleeding begins after day 10 of the month but before day 18, there is full secretory transformation.[14]

Hormone replacement therapy should be continued until the patient is in her eighties or beyond because rapid bone loss occurs after its discontinuation. The appropriate dose of progestin that will protect the endometrium and produce the least effect on lipids is still unknown. However, a dose of 0.35 mg norethindrone or 5 mg medroxyprogesterone acetate administered for 14 days a month appears to provide adequate protection to the endometrium.[3]

Compliance may be a problem due to several effects of this therapy, including initial mastalgia, vaginal discharge, and resumption of menses. Withdrawal bleeding is a primary compliance problem. When hormonal replacement therapy is administered with 10 to 14 days of a progesterone, as described above, 80% to 90% of women will have regular withdrawal bleeding. If both estrogen and progestogen are given every day, it now seems that less numbers of women experience bleeding.[8]

Future research is needed in three primary areas. The optimal dose of progestins needed to optimize protective effects on the endometrium while minimizing detrimental effects on lipid metabolism must be determined through prospective, randomized studies. In women who have undergone hysterectomies, we must yet determine whether adding a progestin is necessary. This controversy exists due to a few studies showing that progestins may protect against the higher risk that exists for breast cancer with high doses of estrogens. The current approach is to individualize therapy based on the patient's risk of developing breast cancer. The frequency and need for endometrial sampling has still not been established. Women receiving estrogen plus progestin probably do not need periodic endometrial sampling. However, some physicians still recommend

that endometrial sampling be done every 1 to 3 years. Finally, withdrawal bleeding remains a compliance problem; different forms of estrogens and progestogens should be developed to address this problem.

Osteoporosis

Osteoporosis becomes a significant problem in the postmenopausal woman. After menopause, bone matrix formation by osteoblast is reduced, leading to reduced bone density, increased rate of bone loss, and increased susceptibility to atraumatic fractures. One in three postmenopausal women in the United States develops some complication of osteoporosis. Postmenopausal women lose 1% or more of their bone mass per year. Therefore, if left untreated, an 80-year-old white woman may have lost 30% to 50% or more of her skeletal mass.[3] Slowing the development of osteoporosis is the most efficient approach to this problem. Reported possible preventive methods include hormonal replacement therapy, dietary calcium supplementation, modification of life-style risk factors such as smoking and alcohol consumption, regular weight-bearing exercise programs, vitamin D and fluoride supplementation, and calcitonin use.

Unequivocal evidence shows that estrogen is of critical importance in maintaining bone density in women.[3, 15] The mechanism by which estrogen acts to prevent bone loss is not known; however, several large studies have demonstrated a causal relationship between estrogen deprivation and accelerated bone loss. In a 10-year, prospective, double-blind, placebo-controlled study, women who received estrogen-progestin therapy within 3 years of menopause demonstrated a dramatic difference in bone mineral density compared with women who received placebo. All patients receiving hormonal replacement therapy showed an improvement or no increase in osteoporosis and experienced significantly fewer fractures.[16] When hormonal replacement therapy is stopped there is a rapid and progressive loss of bone mineral content, at a rate of approximately 2.5% per year. Within 4 years the bone mineral content of women who discontinued therapy is equivalent to that of women who never began it.[3] The dose of estrogen necessary to protect postmenopausal women against osteoporosis is established at 0.625 mg conjugated estrogen or estrone sulfate per day.[3] For the greatest protection, hormonal replacement therapy should start as close as possible to menopause and be maintained for the balance of life.[17]

Areas in which research is needed include estrogen deficiency–related disorders, estrogens' role and the dosage of estrogen necessary in treating established osteoporosis, and the role of calcitonin in postmenopausal osteoporosis, whether estrogen is a primary or secondary treatment modality. Estrogens clearly play an important role in treating and preventing osteoporosis. However, the optimal regimen of hormonal replacement therapy combined with calcium, diet, life-style modifications, and other measures needs to be established.

Cardiovascular disease

Coronary artery disease is a multifactorial problem associated with at least four identifiable risk factors: hypertension, hyperlipidemia, diabetes, and cigarette smoking. Coronary artery disease is responsible for approximately 500,000 deaths among women in the United States each year.[3] Many epidemiologic case-control studies have shown that postmenopausal hormonal replacement therapy lowers the relative risk for coronary artery disease; however, a few studies indicate little or no protection.[17] Until further data from controlled epidemiologic studies are available, this therapy should be considered a possible mode of preventing coronary artery disease. Data show that after menopause the incidence of coronary artery disease rapidly increases. The importance of estrogen is supported by studies showing that women with premature surgical menopause have a 2.2-fold increase in their relative risk of developing coronary artery disease. This increased risk can be reduced to normal by hormonal replacement therapy.[3] One possible mechanism for this protective effect may be estrogen's beneficial effects on the lipid profile. As stated earlier, estrogen lowers levels of total and low-density lipoprotein cholesterol and increases levels of high-density lipoprotein cholesterol. However, the exact mechanism by which estrogen protects against coronary artery disease remains to be established. Studies on estrogen's effect on platelet adhesiveness and its direct effects on the vessels are needed.

Adverse effects of estrogens

Estrogens' role in the development of endometrial cancer has raised significant controversy and concern over the years. Recently, concerns regarding a similar effect on the incidence of breast cancer have been raised. These data are much less convincing of such a relationship. Prolonged stimulation of the endometrium by estrogen in the absence of progesterone is known to cause hyperplasia in both premenopausal and postmenopausal women.[3] Adenocarcinoma more often seems to develop in women who have endometrial hyperplasia. The primary reason for endometrial hyperplasia, and subsequent carcinoma, in women taking unopposed estrogens appears to be the absence of progesterone. Progestational agents have a protective effect on the endometrium because they inhibit the replenishment of estrogen receptors and increase activity of 17β-estradiol dehydrogenase, which converts estradiol to the less potent estrone. Thus a pseudodecidual endometrium is created and endometrial shedding occurs.[18] The addition of cyclic progesterone for

14 days each month reduces the incidence of endometrial hyperplasia to nearly zero. In our current approach to postmenopausal hormonal replacement therapy, which uses a combination of estrogen and progesterone, the risk of endometrial cancer is no greater than in a patient not receiving therapy and actually may be less.[11]

Breast cancer is a multifactorial disease, and the role of estrogen in its generation is not clear. The potential risk is based primarily on data on estrogen's ability to induce mammary tumors in mice. In one case-control study of 1610 women taking estrogen, the relative risk for an increase in the likelihood of developing carcinoma of the breast was zero.[19] Most clinical studies do not show an increased risk, but several studies have generated some concern. The role of hormonal replacement therapy with added progestins remains controversial in this area. Equally controversial is the decision to add (or not add) progestin to estrogen therapy in women whose uterus has been removed. Another important area of investigation is the safety of hormonal replacement therapy in women with a past history of endometrial or breast carcinoma. Clearly, many more epidemiolgic studies are needed to answer these questions.

Summary

Hormone replacement therapy plays an important role in the preventive medical care of postmenopausal women. There are relatively few contraindications to its use. Programs are needed to educate physicians and women on the role of estrogen in overall postmenopausal well-being. Improved compliance is essential if women are to attain maximum benefit from therapy. Improved combination therapy, better delivery systems, and optimal dosing may enhance compliance. Multicenter epidemiologic studies must be performed to clarify the role of estrogen in bone and cardiovascular disease. Studies to determine the role of estrogens in the development of breast and endometrial carcinoma need to be performed. Despite the need for future investigation, it is increasingly clear that in 1989, for maximum benefit, most postmenopausal women except those with absolute contraindications should receive hormonal replacement therapy.
